Abstract	<p>The kinetochore is the multi-protein complex that drives chromosome segregation in eukaryotes. It assembles onto centromeric DNA and mediates attachment to spindle microtubules. Kinetochore research over the last several decades has been focused on a few animal and fungal model organisms, which revealed a detailed understanding of the composition and organization of their kinetochores. Yet, these traditional model organisms represent only a small fraction of all eukaryotes. To gain insights into the actual degree of kinetochore diversity, it is critical to extend these studies to nontraditional model organisms from evolutionarily distant lineages. In this chapter, we review the current knowledge of kinetochores across diverse eukaryotes with an emphasis on variations that arose in nontraditional model organisms. In addition, we also review the literature on species, in which the subcellular localization of kinetochores has changed from the nucleoplasm to the nuclear membrane. Finally, we speculate on the organization of the chromosome segregation machinery in an early eukaryotic ancestor to gain insights into fundamental principles of the chromosome segregation machinery, which are common to all eukaryotes.</p>	

Evolutionary Lessons from Species with Unique Kinetochores

Ines A. Drinnenberg and Bungo Akiyoshi

Abstract The kinetochore is the multi-protein complex that drives chromosome segregation in eukaryotes. It assembles onto centromeric DNA and mediates attachment to spindle microtubules. Kinetochore research over the last several decades has been focused on a few animal and fungal model organisms, which revealed a detailed understanding of the composition and organization of their kinetochores. Yet, these traditional model organisms represent only a small fraction of all eukaryotes. To gain insights into the actual degree of kinetochore diversity, it is critical to extend these studies to nontraditional model organisms from evolutionarily distant lineages. In this chapter, we review the current knowledge of kinetochores across diverse eukaryotes with an emphasis on variations that arose in nontraditional model organisms. In addition, we also review the literature on species, in which the subcellular localization of kinetochores has changed from the nucleoplasm to the nuclear membrane. Finally, we speculate on the organization of the chromosome segregation machinery in an early eukaryotic ancestor to gain insights into fundamental principles of the chromosome segregation machinery, which are common to all eukaryotes.

1 Introduction

Mitosis is the process that partitions newly replicated chromosomes from the mother cell into the two emerging daughter cells (McIntosh 2016). Fundamental to this process is the kinetochore, the macromolecular protein complex that assembles onto specialized chromosomal regions called centromeres to mediate the attachment of sister chromatids to spindle microtubules (Cheeseman and Desai 2008;

e-mail: bungo.akiyoshi@bioch.ox.ac.uk

Santaguida and Musacchio 2009). Kinetochores also promote recruitment of cohesin complexes around centromeres to hold duplicated sister chromatids together until anaphase (Nasmyth and Haering 2009). At their DNA-binding interface, kinetochores need to ensure stable attachment to tolerate the pulling forces exerted by kinetochore microtubules (Allshire and Karpen 2008; Fukagawa and Earnshaw 2014; Westhorpe and Straight 2015; McKinley and Cheeseman 2016). In contrast to this more static attachment, the attachment to spindle microtubules must be dynamically regulated (Foley and Kapoor 2013; Cheerambathur and Desai 2014; London and Biggins 2014; Etemad and Kops 2016). Faithful chromosome segregation requires that sister kinetochores form bioriented attachments to spindle microtubules emanating from opposite poles (Nicklas Nicklas 1997). Biorientation is necessary for the accurate distribution of sister chromatids into daughter cells during anaphase.

Research on kinetochores has mainly been performed on a few model organisms, such as fungi, worms, flies, and vertebrates. Their studies have been instrumental in informing us about the basic composition and organization of kinetochores among these species. However, these “traditional” model organisms only represent a small fraction of the entire eukaryotic biodiversity. In fact, both animals and fungi are members of the Opisthokonta, that is, only one out of six major supergroups of eukaryotes (Fig. 1) (Walker et al. 2011; Adl et al. 2012). While extensive analyses have not been performed on kinetochores in non-opisthokonts, glances into kinetochores from additional species scattered across the eukaryotic phylogenetic tree have revealed extraordinary levels of variations in kinetochore composition and subcellular location. This stands in sharp contrast to many other cell cycle machines that are highly conserved among diverse eukaryotes (e.g., Cyclin/CDK, cohesin, condensin, the anaphase promoting complex, and proteasomes). In this chapter, we will first discuss the extent of similarity and variation in kinetochore composition among animals and fungi. We will then review kinetochores in select organisms from different supergroups, as well as unique kinetochores that evolved in kinetoplastids. Following up on that, we will highlight membrane-bound kinetochores found in some unicellular organisms. Finally, we will speculate on the organization of the chromosome segregation machinery in early eukaryotes.

2 The Kinetochore Complex in Animals and Fungi

Genetic and biochemical analyses in fungi and vertebrates have led to the identification of more than 80 proteins that are part of the kinetochore (Biggins 2013; Cheeseman 2014). The structural core of the kinetochore consists of an inner and an outer complex. The inner kinetochore complex binds centromeric chromatin. It serves as a platform for the recruitment of the outer kinetochore complex that binds microtubules during mitosis and meiosis. Both complexes are characterized by a

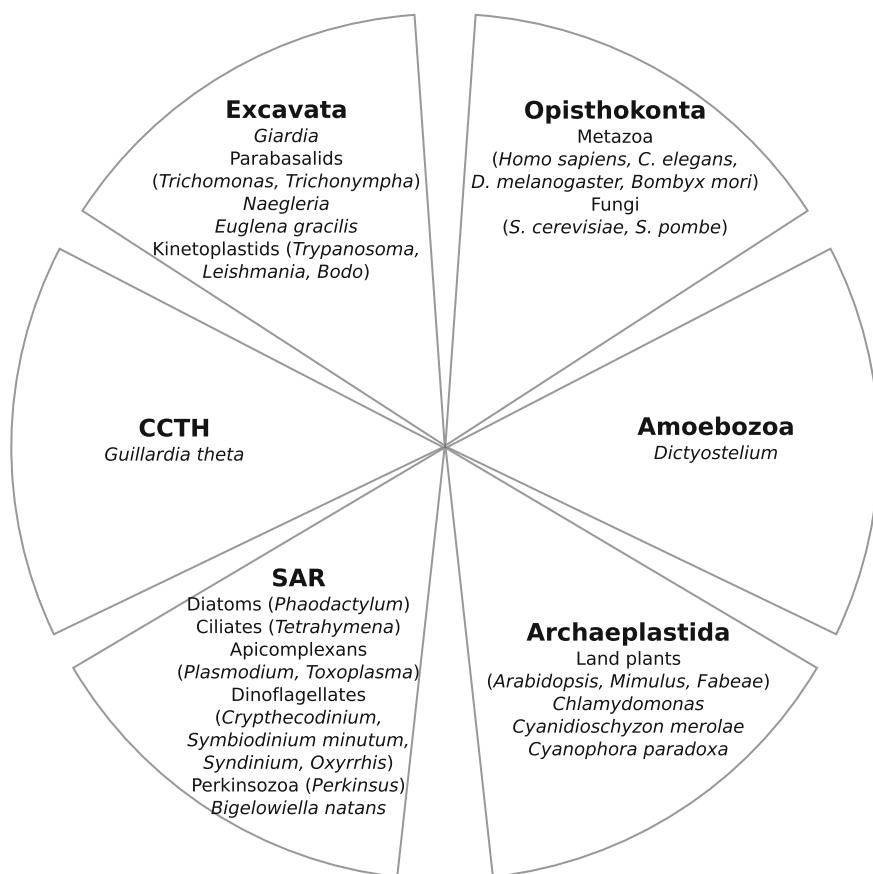

Fig. 1 Six eukaryotic supergroups. Representative organisms from each supergroup are shown as examples

network of several protein complexes that work in concert to regulate the proper attachment of kinetochore microtubules to centromeric DNA.

2.1 Similarities and Variations of the Inner Kinetochore in Animals and Fungi

In fungi and vertebrates, the inner kinetochore consists of ~16 members that are commonly referred to as the Constitutive Centromere Associated Network or CCAN (Cheeseman and Desai 2008; Westermann and Schleiffer 2013; Westhorpe and Straight 2013; Fukagawa and Earnshaw 2014) (Table 1). It is generally agreed that the recruitment of all CCAN members in these species depends on a specialized

76 centromeric histone H3 variant, CENP-A (also known as CenH3—see the Note on
77 nomenclature at the end of this chapter) (Black and Cleveland 2011; Müller and
78 Almouzni 2014; Earnshaw 2015) and its direct DNA-binding partner CENP-C
79 (Carroll et al. 2010; Basilico et al. 2014). In addition to CENP-A and CENP-C,
80 other CCAN components also make DNA contacts, including the histone-fold
81 proteins CENP-T and CENP-W as well as CENP-U^{Ame1} and CENP-Q^{Okp1} in
82 budding yeast (Hori et al. 2008; Hornung et al. 2014).

83 Given their central role in kinetochore function, it is surprising that several inner
84 kinetochore components undergo rapid evolution at the amino acid level, which
85 complicates homology-based predictions even in well-sequenced species (Henikoff
86 et al. 2001; Talbert et al. 2009; Malik and Henikoff 2009). While sequence simi-
87 larity of several CCAN components between vertebrates and budding yeast was
88 revealed early on (Meraldi et al. 2006), the identification of phylogenetic rela-
89 tionship for other CCAN components often required advanced bioinformatics tools
90 due to limited sequence similarities (Schleiffer et al. 2012; Westermann and
91 Schleiffer 2013). For example, the budding yeast CENP-T^{Cnn1} was only identified
92 using a combination of proteomic approaches and remote homology predictions
93 (Schleiffer et al. 2012). Thus, experimental approaches as well as advanced
94 bioinformatics are required to obtain a comprehensive picture of kinetochores.

95 While most CCAN components are conserved between vertebrates and fungi,
96 CCAN proteins appear to be absent in *Caenorhabditis elegans* and *Drosophila*
97 *melanogaster* except for CENP-C (Table 1). While it is formally possible that these
98 species have highly divergent CCAN members, the wealth of extensive genetic
99 screens for chromosome segregation defects and biochemical purifications of
100 kinetochore components makes this unlikely (Cheeseman et al. 2004; Goshima
101 et al. 2007; Przewloka et al. 2007, 2011). Therefore, it appears that nematodes and
102 Diptera have “simpler” inner kinetochore complexes that just consist of CENP-C,
103 which connects the CENP-A-containing chromatin to outer kinetochore proteins.
104 The reason for this potential reduction in kinetochore complexity remains unknown.
105 In contrast to *D. melanogaster*, homologous CCAN members have been identified
106 in other insects (see below), showing that the near-complete loss of CCAN is not
107 common to all insects and instead occurred in a dipteran ancestor around 250 Mya
108 (Hedges et al. 2006).

109 While CENP-A was thought to be essential for kinetochore assembly in all
110 animals and fungi, recent studies showed that a number of insects have recurrently
111 lost CENP-A (Drinnenberg et al. 2014). Intriguingly, all CENP-A-deficient insects
112 analyzed are derived from independent transitions from monocentric chromosomes
113 (where microtubules attach to a single chromosomal region) to holocentric chro-
114 mosomes (where microtubules attach along the entire length of the chromosome)
115 (Melters et al. 2012; Drinnenberg et al. 2014). This strong correlation between the
116 change in centromeric architecture and the loss of CENP-A supports a causal
117 relationship between the two events in that the transition to holocentromeres
118 facilitated the loss of CENP-A or vice versa. While CENP-A and its binding partner
119 CENP-C are lost, several of the CCAN components continue to be present even in
120 CENP-A-deficient insects (e.g., the silkworm *Bombyx mori* (Table 1)). These

The composition of the outer kinetochore, not inner kinetochore, is widely conserved. In those cases where multiple homologous proteins are identified, only one is listed unless otherwise specified. Note that kinetochore localization has yet to be established for many of the proteins listed here. CENP-S and CENP-X have independent roles in DNA repair and may not be involved in CCAN function in some organisms. KNL1 homologs were predicted in Tromer et al. (2015)

126 findings suggest that the assembly of the inner kinetochore has been altered in
127 CENP-A-deficient insects, allowing CENP-A-independent kinetochore formation.
128 Whether or not new kinetochore components have evolved to compensate for the
129 loss of CENP-A is an open question. It is important to note that other holocentric
130 organisms including nematodes (e.g., *C. elegans*) have retained CENP-A^{HCP-3}.
131 Thus, despite the usage of the generic term “holocentromere”, the basic architecture
132 and regulation of holocentromeres is likely to be diverse among different species.

133 **2.2 *The Composition of the Outer Kinetochore Is Highly***
134 ***Conserved in Animals and Fungi***

135 The outer kinetochore complex is recruited to centromeres upon the onset of mitosis
136 to connect to spindle microtubules. This interaction is accomplished by
137 the ~10-subunit KMN network that consists of the Knl1, Mis12, and Ndc80
138 complexes (Cheeseman et al. 2006; Petrovic et al. 2014). In contrast to the inner
139 kinetochore, the composition of the outer kinetochore is widely conserved across
140 animals and fungi (Meraldi et al. 2006; Tromer et al. 2015). Even
141 CENP-A-deficient insects encode the same repertoire of outer kinetochore com-
142 ponents, implying similar means of attaching to microtubules while utilizing
143 alternate inner kinetochore assembly pathways (Drinnenberg et al. 2016). A notable
144 exception to the otherwise conserved composition of the KMN network is found in
145 Diptera. *D. melanogaster* has lost Dsn1, a subunit of the Mis12 complex
146 (Przewloka and Glover 2009). In addition, the Nnf1 subunit of the Mis12 complex
147 underwent a duplication event giving rise to two paralogs, Nnf1a and Nnf1b, that
148 are part of two distinct Mis12 complexes with similar biochemical behaviors
149 (Przewloka et al. 2007; Schittenhelm et al. 2007; Liu et al. 2016; Richter et al.
150 2016; Blattner et al. 2016). The loss of Dsn1 could have been compensated by the
151 C-terminal part of the *Drosophila* Knl1 homolog (Przewloka et al. 2009). Indeed,
152 the overall organization of this complex appears to resemble the human and yeast
153 counterparts (Hornung et al. 2011; Przewloka et al. 2011; Scropanti et al. 2011).
154 Whether these changes have any functional consequences on the *Drosophila* KMN
155 complex is currently unclear.

156 **3 Glimpses into Kinetochore Compositions in Diverse**
157 **Eukaryotes**

158 While research on kinetochores in fungi and animals has revealed a paradigm for
159 the basic organization of kinetochores, it remains unclear whether other eukaryotes
160 have similar kinetochores. Comparative studies in additional eukaryotic lineages are
161 a key to revealing the degree of conservation and divergence of kinetochores among

162 eukaryotes. Although bioinformatics analyses have identified some homologous
163 kinetochore proteins in diverse eukaryotes (Table 1), very few studies have char-
164 acterized the function of individual kinetochore proteins. Furthermore, extensive
165 proteomic screens have not been carried out in most organisms, leaving open the
166 possibility of lineage-specific evolution of additional kinetochore proteins. Below
167 we summarize the current knowledge of kinetochores in select eukaryotes from
168 different supergroups to highlight their peculiarities.

169 3.1 Supergroup Amoebozoa

170 The only kinetochore protein that has been characterized in the supergroup
171 Amoebozoa is the centromere-specific histone H3 variant in *Dictyostelium discoideum* (Dubin et al. 2010). In contrast to nearly all other characterized CENP-A
172 proteins that have at least one extra amino acid in the loop 1 region within the
173 histone fold compared to histone H3 (Malik and Henikoff 2003), *D. discoideum*
174 CENP-A^{CenH3} does not have a longer loop 1. While alterations or shortening of
175 residues in loop 1 in other species can impair centromere targeting (Vermaak et al.
176 2002), cytological studies of *D. discoideum* CENP-A^{CenH3} revealed incorporation
177 into centromeric DNA (Dubin et al. 2010). Therefore, the insertion of extra amino
178 acids in loop 1 is not an obligatory feature of CENP-A.
179

180 3.2 Supergroup Archaeplastida

181 Several kinetochore proteins have been characterized in land plants (e.g.,
182 *Arabidopsis*, maize, and barley) (Dawe et al. 1999; ten Hoopen et al. 2000; Sato
183 et al. 2005). For example, homologous kinetochore proteins (such as CENP-C and
184 Mis12) identified by bioinformatics searches were analyzed by means of cytological
185 and mutational studies, confirming their importance for chromosome segregation in
186 mitosis and meiosis. Although most eukaryotes have a single CENP-A protein,
187 multiple CENP-A^{CENH3} variants are found in *Arabidopsis halleri*, *A. lyrata*
188 (Kawabe et al. 2006), *Brassica* sp. (Wang et al. 2011), *Mimulus* monkeyflowers
189 (Finseth et al. 2015), barley (Ishii et al. 2015), and *Fabaceae* sp. (Neumann et al.
190 2012; Neumann et al. 2015). While it is currently unclear whether the individual
191 CENP-A^{CENH3} variants are functionally distinct, it has been hypothesized that
192 CENP-A^{CENH3} duplications occurred to counteract the evolutionary force from
193 centromere drive (Finseth et al. 2015) (centromere drive is discussed in the chapter
194 by Lampson and Black).

195 Compared to land plants, much less is known about kinetochores in other
196 Archaeplastida species. *Cyanidioschyzon merolae* is a thermoacidophilic red alga
197 that is thought to be one of the most primitive photosynthetic eukaryotes. Its simple
198 cellular architecture and reduced genome make it an attractive organism for cell

199 biological study (Matsuzaki et al. 2004). Among several homologous kinetochore
200 proteins identified (Table 1), only CENP-A^{CENH3} has been experimentally char-
201 acterized to date (Maruyama et al. 2007; Kanesaki et al. 2015). Given its hot and
202 acidic living habitats, it will be interesting to test for potential adaptations of
203 kinetochore components that evolved to cope with such extreme environments.

204 3.3 Supergroup SAR

205 The supergroup SAR (Stramenopiles, Alveolates, and Rhizaria: also referred to as
206 Harosa) includes diatoms, ciliates, apicomplexans, and dinoflagellates (discussed
207 later). Ciliates have a somatic macronucleus with highly amplified genes for RNA
208 synthesis as well as several germline micronuclei for genome maintenance. The
209 number of chromosomes in the somatic macronucleus can be as high as 16,000 in
210 some species (Swart et al. 2013). While the germline micronucleus has
211 CENP-A^{CNA1} and segregates its chromosomes accurately, the somatic macronu-
212 cleus does not have CENP-A^{CNA1} and segregates its chromosomes randomly
213 (Cervantes et al. 2006; Cui and Gorovsky 2006).

214 Apicomplexans include a number of important human pathogens, including
215 *Plasmodium* and *Toxoplasma* (Francia and Striepen 2014). Several kinetochore
216 proteins have been identified and functionally characterized in *Plasmodium falciparum*
217 and *Toxoplasma gondii* including CENP-A^{CENH3}, CENP-C, and members of
218 the Ndc80 complex (Brooks et al. 2011; Verma and Surolia 2013; Farrell and
219 Gubbels 2014). While the domain architecture appears to be conserved, the *T.*
220 *gondii* Nuf2 homolog contains a conserved amino acid motif that appears specific
221 to apicomplexan (Farrell and Gubbels 2014). The functional relevance of this motif,
222 however, remains unclear.

223 3.4 Supergroup CCTH

224 Very little is known about kinetochores in the supergroup CCTH (Cryptophytes,
225 Centrohelids, Telonemids, and Haptophytes: also called Hacrobia). Cryptophyte
226 algae are thought to have evolved by engulfing a red alga that contained a primary
227 plastid (Tanifuji and Archibald 2014). In cryptomonad *Guillardia theta*, the sec-
228 ondary plastid has retained the red algal-derived relict nucleus (called nucleomorph)
229 (Curtis et al. 2012). How the nucleomorph genome is maintained during cell
230 division remains unknown. While the nucleomorph genome encodes for a putative
231 CENP-A homolog (Douglas et al. 2001) (Table 1), this protein lacks the hallmark
232 of an extended loop 1 region. It will therefore be necessary to experimentally
233 confirm whether it indeed functions as the centromeric histone variant for the
234 segregation of the nucleomorph genome.

235

3.5 Supergroup Excavata

236 Excavata is a group of predominantly flagellated species (Walker et al. 2011; Adl
237 et al. 2012). It is divided into Metamonads and Discoba. A number of human
238 parasites belong to this supergroup, such as *Giardia*, *Trichomonas vaginalis*,
239 *Naegleria fowleri*, and *Trypanosoma brucei*.

240 *Giardia intestinalis* (Metamonads) has two histone H3-like molecules that have
241 a longer loop 1. Cytological studies have revealed that only one H3 variant
242 incorporates into centromeres, while the other variant localizes to pericentric
243 heterochromatin (Dawson et al. 2007), underlining the need for experimental
244 approaches to corroborate the identity of the centromeric histone H3 variant. As in
245 *Dictyostelium* (see above), another metamonad *Trichomonas vaginalis* has a
246 CENP-A^{CenH3} protein that does not have a longer loop 1, but its localization pattern
247 is suggestive of centromeric incorporation (Zubáková et al. 2012).

248 Discoba (also called JEH for Jakobids, Euglenozoa, Heterolobosea) includes
249 *Naegleria*, *Euglena*, and kinetoplastids. Although canonical kinetochore proteins
250 have been identified in *Naegleria gruberi* and *Euglena gracilis* (Table 1), none has
251 been identified in the genome of kinetoplastids.

252

4 Unconventional Kinetoplastid Kinetochores

253 Identification of at least a fraction of canonical kinetochore proteins (especially
254 CENP-A and the Ndc80 complex) in diverse eukaryotes led to a notion that all
255 eukaryotes may build the structural core of the kinetochore using a conserved set of
256 kinetochore proteins (Meraldi et al. 2006). However, none of canonical kinetochore
257 proteins were identified in the genome of kinetoplastids (Lowell and Cross 2004;
258 Berriman et al. 2005), a group of unicellular eukaryotes defined by the presence of
259 kinetoplast (a large structure in the mitochondrion that contains mitochondrial
260 DNA) (Vickerman 1962). They belong to the supergroup Excavata, Discoba group,
261 Euglenozoa. Euglenozoa is a diverse group of flagellates that include euglenids,
262 diplomonads, symbiontids, and kinetoplastids (Walker et al. 2011; Cavalier-Smith
263 2016).

264 To uncover the repertoire of kinetoplastid kinetochores, recent studies utilized
265 proteomic and functional approaches and identified 20 kinetochore proteins in
266 *Trypanosoma brucei*, named KKT1–20 (Akiyoshi and Gull 2014; Nerusheva and
267 Akiyoshi 2016). The majority of these proteins are conserved among kinetoplastids,
268 including free-living *Bodo saltans*. However, obvious orthologs of KKT proteins
269 were not found even in euglenids, which instead have canonical kinetochore pro-
270 teins (Akiyoshi 2016). The unique KKT-based kinetochores are therefore not
271 conserved across Euglenozoa but are apparently restricted to kinetoplastids. It
272 remains unclear why kinetoplastids possess a unique set of kinetochore proteins
273 (discussed below).

274 4.1 Domain Architectures of Kinetoplastid Kinetochore 275 Proteins

276 Sequence analyses of kinetoplastid kinetochore proteins have revealed the fol-
277 lowing conserved domains: a BRCT (BRCA1 C terminus) domain in KKT4, FHA
278 (Forkhead-associated) domain in KKT13, WD40-like domain in KKT15, divergent
279 polo boxes (DPB) in KKT2, KKT3 and KKT20, unique protein kinase domain in
280 KKT2 and KKT3, and CLK (cdc2-like kinase) kinase domain in KKT10 and
281 KKT19. While orthologs of any of the KKT proteins have not been identified in
282 non-kinetoplastid species, the domain architecture and sequence similarity of
283 KKT2, KKT3, and KKT20 suggest that these proteins may share common ancestry
284 with a Polo-like kinase (PLK) (Nerusheva and Akiyoshi 2016). Consistent with this
285 possibility, although the kinase domain of KKT2/3 is apparently unique (Parsons
286 et al. 2005), the next closest kinase domain is that of PLK (Akiyoshi 2016).
287 Furthermore, putative DNA-binding motifs are present in KKT2 and KKT3, sug-
288 gesting that these proteins likely bind DNA and play a critical role in establishing
289 unique kinetochores in kinetoplastids. Although PLK localizes at the kinetochore in
290 some species, it is not considered to be a structural kinetochore protein in any
291 eukaryote. Substrates of these KKT kinases have yet to be identified.

292 BRCT, FHA, or CLK-like kinase domains are not present in canonical kineto-
293 chore proteins. Domains found in canonical kinetochore proteins such as CH
294 (calponin homology) and RWD (RING finger, WD repeat, DEAD-like helicases)
295 domains have not been identified in KKT proteins. Although KKT proteins do not
296 have similarity to canonical kinetochore proteins at the primary sequence level,
297 high-resolution structural data are necessary to reveal if there is any similarity at the
298 tertiary level.

299 4.2 Common Features

300 Although components of the core kinetoplastid kinetochore appear distinct from
301 canonical kinetochore proteins present in other eukaryotes, various regulatory
302 proteins that are known to be important in chromosome segregation are conserved,
303 including Aurora B, Cyclin/CDK, cohesin, condensin, separase, and the anaphase
304 promoting complex (Berriman et al. 2005; Akiyoshi and Gull 2013). Aurora B
305 apparently localizes at the kinetochore during prometaphase and metaphase in
306 *Trypanosoma brucei* (Li et al. 2008), suggesting that its kinetochore regulatory
307 function may be conserved. It is known that the kinase–phosphatase balance is
308 important for regulating kinetochore functions in other eukaryotes. For example, the
309 KNL1 outer kinetochore protein recruits the PP1 phosphatase (Liu et al. 2010;
310 Rosenberg et al. 2011; Meadows et al. 2011; Espeut et al. 2012). Interestingly, a
311 conserved PP1-binding motif is present in KKT7, suggesting that PP1 may regulate
312 kinetochore functions in kinetoplastids. It is therefore possible that kinetoplastid

313 kinetochores, while being structurally distinct, may still utilize a conserved
314 mechanism for the regulation of kinetochore functions.

315 **4.3 Implications from Kinetoplastid Kinetochores**

316 The discovery of KKT-based kinetochores in kinetoplastids challenged a widely
317 held assumption that the core of the kinetochore would be composed of proteins
318 conserved throughout eukaryotes (e.g., CENP-A and Ndc80). A corollary is that
319 eukaryotic chromosome segregation can be achieved using proteins distinct from
320 CENP-A or Ndc80. Understanding how KKT proteins carry out the conserved
321 kinetochore functions will likely provide important insights into fundamental
322 principles of the kinetochore. It also raised a possibility that there might be as yet
323 different types of kinetochores to be discovered in eukaryotes.

324 **5 Membrane-Embedded Kinetochores**

325 In addition to compositional variations, the subcellular location of kinetochores has
326 also been altered in some lineages. In all eukaryotes, chromosomes are enclosed
327 inside the nuclear envelope during most of the cell cycle. This keeps
328 chromosome-based activities physically separated from the cytoplasm where pro-
329 tein synthesis and metabolic processes take place (Martin and Koonin 2006;
330 Koumandou et al. 2013). This separation necessitates proper nuclear remodeling to
331 be coordinated with the chromosome segregation apparatus. There are mainly three
332 types of mitoses depending on the extent of nuclear envelope breakdown: open,
333 semi-open, and closed (Sazer et al. 2014; Makarova and Olierenko 2016). In open
334 mitosis, the nuclear envelope breaks down completely during mitosis, facilitating
335 access for cytoplasmic spindle microtubules to chromosomes. Semi-open mitosis
336 involves a partial breakdown of the nuclear envelope, allowing transport of material
337 while keeping chromosomes inside the nucleus. In this case, the spindle assembles
338 either inside or outside of the nucleus. In the latter case, spindle microtubules
339 appear to penetrate through the nuclear envelope and capture chromosomes that are
340 located inside the nucleus. Finally, in closed mitosis, the nuclear envelope does not
341 break down. To enable capturing of sister chromatids, most eukaryotes with closed
342 mitosis assemble an intranuclear spindle. Some eukaryotes, however, assemble an
343 extranuclear spindle where spindle microtubules are located outside of the nucleus.
344 This type of mitosis, though not very common, is found in some Alveolata
345 (dinoflagellates and Perkinsozoa) and Parabasalids (Trichomonads and
346 Hypermastigia), suggesting that it arose independently. To enable attachments
347 between spindle microtubules and kinetochores, these organisms embed their
348 kinetochores in the nuclear envelope. Below we will summarize the current

349 literature on these organisms as well as their sister species and then discuss potential
350 adaptations and implications from such kinetochores.

351 **5.1 Dinoflagellates**

352 Dinoflagellates are a highly diverse group of flagellates, including photosynthetic
353 free-living and parasitic species (Taylor et al. 2007). They belong to the supergroup
354 SAR, Alveolata group, and their sister groups include Perkinsozoa and
355 Apicomplexa (Saldaña et al. 2004) (Fig. 2). Dinoflagellates are characterized by
356 large genome sizes in the range of 1,500 Mbp to 185,000 Mbp (Wisecaver and
357 Hackett 2011). Despite having all core histone genes, histones are not involved in
358 packaging the majority of nuclear DNA (Hackett et al. 2005; Marinov and Lynch
359 2015). In addition, other basic nuclear proteins including Dinoflagellates/Viral
360 NucleoProteins (DVNP) and HU-like proteins might substitute major histone
361 functions in some of these organisms (Sala-Rovira et al. 1991; Chan and Wong
362 2007; Gornik et al. 2012; Talbert and Henikoff 2012; Bachvaroff et al. 2014). Their
363 chromosomes are permanently condensed, showing a characteristic liquid crys-
364 talline state even in interphase. Interestingly, some, but not all, dinoflagellates have
365 kinetochores embedded in the nuclear envelope with an extranuclear spindle
366 (Leadbeater and Dodge 1967; Kubai and Ris 1969; Spector and Triemer 1981).

367 Dinoflagellates are divided into core dinoflagellates, Syndiniales, and early
368 diverging Oxyrrhinales (Fig. 2) (Wisecaver and Hackett 2011). Electron micro-
369 scopy revealed that kinetochores are embedded in the nuclear envelope in core
370 dinoflagellates [e.g., *Amphidinium* (Oakley and Dodge 1974) and *Cryptocodonium*
371 *cohnii* (Bhada et al. 2000) (Fig. 3)] as well as in Syndiniales (e.g., *Syndinium*
372 sp. (Ris and Kubai 1974)). Due to their large genome sizes, genome sequence data
373 are limited in dinoflagellates. In fact, the only dinoflagellate genome sequence
374 available to date is for *Symbiodinium minutum* (Shoguchi et al. 2013), which
375 revealed putative CENP-A and outer kinetochore components (Table 1) as well as a
376 spindle assembly checkpoint protein (Mad3/BubR1: symbB.v1.2.026514.t1). These
377 findings suggest that this organism still utilizes canonical kinetochore components
378 and the spindle checkpoint. Indeed, a microtubule inhibitor nocodazole delayed
379 mitotic exit in *Cryptocodonium cohnii*, showing that the spindle checkpoint is
380 functional in core dinoflagellates (Yeung et al. 2000).

381 In contrast, a member of the early diverging Oxyrrhinales, *Oxyrrhis marina*, has
382 an intranuclear spindle, and its chromosomes are not attached to the nuclear
383 envelope (Triemer 1982; Gao and Li 1986; Kato et al. 2000). These studies show
384 that the extranuclear spindle is not a ubiquitous feature of dinoflagellates.

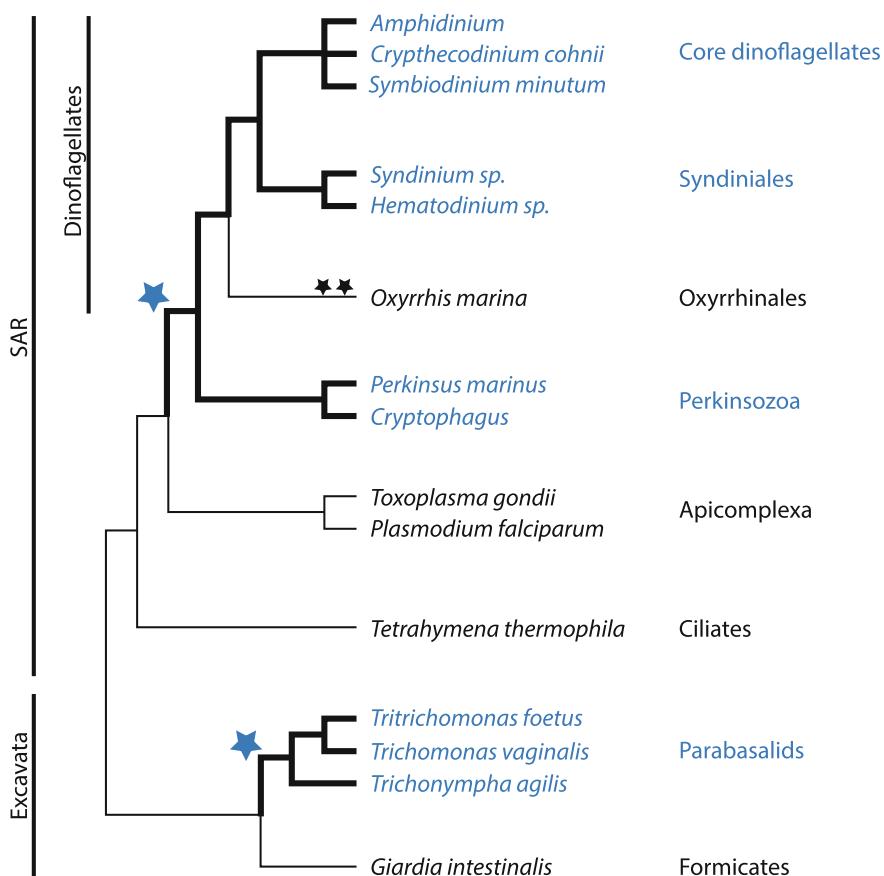

Fig. 2 Membrane-bound kinetochores have independently evolved at least twice. The diagram shows the evolutionary transition to membrane-bound kinetochores in Perkinszoa and Parabasalids indicated by the blue star and thick branches. Two black stars indicate the reversion to non-membrane-bound kinetochores

385

5.2 Perkinszoa

386

Perkinszoa is one of the closest relatives of dinoflagellates (Fig. 2). Like core dinoflagellates and Syndiniales, Perkinszoa undergoes a closed mitosis with an extranuclear spindle, suggesting that its kinetochores are embedded in the nuclear envelope (e.g., *Perkinsus marinus* (Perkins 1996) and *Cryptophagus* (Brugerolle 2002)). Unlike dinoflagellates, however, Perkinszoa has a smaller genome size that is packaged into nucleosomes (58 Mbp in *Perkinsus marinus* (Gornik et al. 2012)), and its chromosomes are not permanently condensed. Taken together, the observations in Perkinszoa suggest that extranuclear spindles and

387

388

389

390

Note that the kinetochore-like structure embedded in the nuclear membrane makes contact with extranuclear spindle microtubules (arrows). Bars 0.8 μm (left), 0.3 μm (right). Reproduced from Baud et al. (2000) with permission from the Company of Biologists Limited. *Bottom* Simplified schematic of top images

394 membrane-embedded kinetochores are not necessarily the consequence of expanded genome or diminution of packaging histones.
395

396 In contrast to Perkinszoa, its sister group Apicomplexa (e.g., *Plasmodium* and
397 *Toxoplasma gondii*) undergoes a closed mitosis with an intranuclear spindle as is
398 the case for many other species in the SAR supergroup (Francia and Striepen 2014).
399 These observations suggest that the nuclear envelop-embedded kinetochores and
400 the extranuclear spindle appeared at or before the emergence of Perkinszoa
401 (Cavalier-Smith and Chao 2004) (Fig. 2). Therefore, the intranuclear spindle in
402 *Oxyrrhis* is most likely a derived feature, i.e., back to a more canonical state. The
403 driving forces underlying the switch to the extranuclear spindle or back, however,
404 remain unclear.

Note that some extranuclear spindle microtubules terminate outside the nuclear membrane. Bars 560 and 320 nm (*inset*). Reproduced from Ribeiro et al. (2002) with permission from John Wiley and Sons. *Right* Simplified schematic of the *left*

405 5.3 Parabasalids

406 Membrane-bound kinetochores have also evolved in Parabasalids that belong to the
407 supergroup Excavata, Metamonads group. They are characterized by a unique
408 parabasal apparatus (Honigberg 1963). Electron microscopy studies showed that
409 Trichomonads (*Tritrichomonas foetus*) and *Trichomonas vaginalis*) and
410 Hypermastigia (*Trichonympha agilis*) undergo a closed mitosis with an extranuclear
411 spindle, and have kinetochores embedded in the nuclear envelope (Kubai 1973;
412 Ribeiro et al. 2002) (Fig. 4). As in dinoflagellates and Perkinszoa, canonical
413 kinetochore proteins are found in the genome of *Trichomonas vaginalis* (Carlton
414 et al. 2007; Zubáková et al. 2012) (Table 1). Because other members of meta-
415 monads such as *Giardia* have intranuclear spindles (Sagolla et al. 2006),
416 membrane-embedded kinetochores and extranuclear spindles in Parabasalids appear
417 to be a derived feature that independently evolved in this lineage.

418 5.4 Implications from Membrane-Bound Kinetochores

419 The findings of nuclear envelope-embedded kinetochores raise several questions.

420 It is likely that the change in the location required adaptations of the kinetochore
421 due to the change in biophysical environment. What modifications are necessary to
422 allow kinetochores to be embedded in the nuclear envelope and what are possible
423 consequences? Although the exact position of kinetochores/centromeres within the
424 lipid bilayer of nuclear membranes remains unclear, electron microscopy data
425 indicate that microtubules likely interact with kinetochores in the cytoplasm rather

than in the nuclear envelope. This implies that the microtubule-binding domain of the Ndc80 complex is located outside of the nuclear envelope. Other kinetochore proteins that bridge between the Ndc80 complex and CENP-A-containing centromeric chromatin within the nucleus must therefore be embedded within the nuclear envelope. Transmembrane domains have so far not been identified in any of *Symbiodinium minutum* and *Trichomonas vaginalis* kinetochore proteins. It is possible that their kinetochores insert into the lipid bilayer by interacting with other nuclear envelope-embedded components such as the nuclear pore complex as previously suggested (Kubai 1973; Ris and Kubai 1974; Cachon and Cachon 1977; Drechsler and McAinsh 2012).

Another question is how membrane-embedded kinetochores form biorientation and regulate cell cycle progression. Can kinetochores move freely in the nuclear envelope or do they require new membrane synthesis? And once biorientation is achieved, how do nuclear and cytoplasmic environments communicate to promote the transition to anaphase, activating the anaphase promoting complex to disrupt cohesion (in the nucleus) and Cyclin B (in the nucleus or cytoplasm), while coordinating the elongation of spindle microtubules (in the cytoplasm)? Finally, what was the evolutionary driving force that underlies the assembly of kinetochores within the nuclear envelope? To address these unknowns, new tools and model systems need to be developed. Importantly, genetic manipulations have already been established in some dinoflagellates (Te and Lohuis 1998; Radakovits et al. 2010) and *Trichomonas vaginalis* (Delgadillo et al. 1997). Studies on these membrane-embedded kinetochores will likely shed new light onto the diverse mechanism of kinetochore assembly and chromosome segregation in eukaryotes.

450 6 Speculation of Kinetochores in Early Eukaryotes

451 Chromosome segregation in the last eukaryotic common ancestor (LECA) was
452 likely driven by tubulin-based polymers because microtubules are a universal
453 feature of the chromosome segregation machinery in all known eukaryotes
454 (McIntosh et al. 2010; Yutin and Koonin 2012; Findeisen et al. 2014). In addition,
455 the LECA likely used condensins to compact chromosomes and cohesins to connect
456 duplicated sister chromatids until anaphase (Nasmyth and Haering 2009; Hirano
457 2016). Furthermore, the presumed presence of cyclin-dependent kinases and the
458 anaphase promoting complex suggests that chromosome segregation was probably
459 already regulated in the cell cycle dependent manner (Nasmyth 1995;
460 Cavalier-Smith 2010a; Garg and Martin 2016).

461 In contrast to these components, no obvious ortholog for any of the kinetochore
462 proteins has been identified in prokaryotes, including Lokiarchaeota that is con-
463 sidered to be the closest sister group to eukaryotes (Spang et al. 2015). Therefore, it
464 is unclear whether the LECA utilized canonical kinetochore components, such as
465 CENP-A and Ndc80 that are found in nearly all extant species. It is formally
466 possible that the LECA utilized a KKT-based complex that has later been replaced

467 by canonical kinetochore components in most eukaryotic lineages. This model is
468 consistent with the controversial hypothesis that kinetoplastids might represent the
469 earliest branching eukaryotes (Cavalier-Smith 2010b; Cavalier-Smith 2013;
470 Akiyoshi and Gull 2014). Alternatively, the KKT-based kinetochore may be a
471 derived feature that replaced early eukaryotic kinetochores at some point during the
472 kinetoplastid evolution. A third possibility is that either canonical kinetochores or
473 the KKT-based kinetochores had not yet evolved in the LECA. In this case,
474 chromosome segregation in early eukaryotes might have been similar to the
475 plasmid-partitioning systems found in Bacteria (Gerdes et al. 2010; Reyes-Lamothe
476 et al. 2012) and Archaea (Barillà 2016) where specific DNA elements are recog-
477 nized by DNA-binding proteins that connect to filament-forming proteins to drive
478 segregation. In such a system, chromosome movement and DNA attachment in the
479 LECA could have been mediated by kinesin or dynein motor proteins. In fact,
480 motor proteins that transport cargo along microtubules and chromokinesins that are
481 capable of connecting chromosomes to microtubules were likely already present in
482 the LECA (Wickstead and Gull 2007; Wickstead et al. 2010).

483 Kinetochores in all extant eukaryotes are highly complex and consist of many
484 components. Gene duplication likely played an important role in increasing the
485 structural complexity in both canonical and kinetoplastid kinetochores, as evident
486 by the presence of multiple kinetochore proteins that apparently share common
487 ancestry (Schmitzberger and Harrison 2012; Nerusheva and Akiyoshi 2016;
488 Dimitrova et al. 2016; Petrovic et al. 2016). To ensure proper assembly and bior-
489 entiation of kinetochores, the invention of the Aurora kinase could have been a key
490 evolutionary step that likely had occurred before the emergence of the LECA
491 (Lampson and Cheeseman 2011; Carmena et al. 2012; Hochegger et al. 2013).
492 Error correction by Aurora and direct stabilization of kinetochore-microtubule
493 attachment by tension likely increased the fidelity of chromosome segregation
494 (Akiyoshi et al. 2010; Miller et al. 2016).

495 7 Conclusions

496 Most cell biological research over the last several decades has focused on a limited
497 number of model organisms that were selected largely based on historical, not
498 necessarily biological, reasons. Although these studies revealed insights into basic
499 principles of kinetochore organization, a number of differences have been noted
500 even among traditional animal and fungal model organisms. In addition, the
501 unconventional kinetochore in kinetoplastids, the absence of CENP-A in holo-
502 centric insects, and nuclear envelope-embedded kinetochores in some eukaryotic
503 lineages all suggest that kinetochores are more plastic than previously thought. The
504 advance of sequencing and genome editing techniques combined with experimental
505 approaches should enable researchers to characterize kinetochores in nontraditional

506 model organisms in relatively short space of time (Warren 2015; Kobayashi et al.
507 2015; Gladfelter 2015; Goldstein and King 2016). Insights into kinetochores from
508 diverse species outside of our current catalog of model organisms have a potential
509 to reveal fundamental design and working principles of the eukaryotic segregation
510 machines.

AQ1

511 Note to Nomenclature

512 In different organisms, the centromeric histone H3 variant is referred to with dif-
513 ferent names (Earnshaw et al. 2013; Talbert and Henikoff 2013). To be consistent
514 with other chapters, we generally refer to the centromeric histone as CENP-A
515 across species. To account for the differences in nomenclature in specific organ-
516 isms, we donate the superscript of the original name wherever appropriate (for
517 example, CENP-A^{HCP-3} for *C. elegans*).

518 **Acknowledgements** We thank Paul Talbert, Kim Nasmyth, Geert Kops, and members of the
519 Akiyoshi and Drinnenberg groups for comments on the manuscript. I.A.D. was supported by funds
520 from the CNRS (Atip Avenir) and Institut Curie. B.A. was supported by a Sir Henry Dale
521 Fellowship jointly supported by the Wellcome Trust and the Royal Society (grant number
522 098403/Z/12/Z), as well as a Wellcome-Beit Prize Fellowship (grant number 098403/Z/12/A).

Author Query Form

Book ID : **426837_1_En**
Chapter No : **5**

Springer

the language of science

Please ensure you fill out your response to the queries raised below and return this form along with your corrections

Dear Author

During the process of typesetting your chapter, the following queries have arisen. Please check your typeset proof carefully against the queries listed below and mark the necessary changes either directly on the proof/online grid or in the ‘Author’s response’ area provided below

Query Refs.	Details Required	Author’s Response
AQ1	Please check and confirm the placement of ‘Note to Nomenclature’ is correct. Amend if necessary.	

MARKED PROOF

Please correct and return this set

Please use the proof correction marks shown below for all alterations and corrections. If you wish to return your proof by fax you should ensure that all amendments are written clearly in dark ink and are made well within the page margins.

Instruction to printer	Textual mark	Marginal mark
Leave unchanged	... under matter to remain	✓
Insert in text the matter indicated in the margin	↪	New matter followed by ↪ or ↪ ^②
Delete	/ through single character, rule or underline ———— through all characters to be deleted	⊖ or ⊖ ^②
Substitute character or substitute part of one or more word(s)	/ through letter or ———— through characters	new character / or new characters /
Change to italics	— under matter to be changed	←
Change to capitals	≡ under matter to be changed	≡
Change to small capitals	= under matter to be changed	=
Change to bold type	~ under matter to be changed	~
Change to bold italic	~~ under matter to be changed	~~
Change to lower case	Encircle matter to be changed	≠
Change italic to upright type	(As above)	+
Change bold to non-bold type	(As above)	—
Insert 'superior' character	/ through character or ↪ where required	Y or X under character e.g. ³ or ³
Insert 'inferior' character	(As above)	↪ over character e.g. ²
Insert full stop	(As above)	◎
Insert comma	(As above)	,
Insert single quotation marks	(As above)	Y or X and/or Y or X
Insert double quotation marks	(As above)	“ or ” and/or “ or ”
Insert hyphen	(As above)	—
Start new paragraph	—	—
No new paragraph	≈	≈
Transpose	□	□
Close up	linking () characters	()
Insert or substitute space between characters or words	/ through character or ↪ where required	Y
Reduce space between characters or words	between characters or words affected	T
