12 **Abstract**

13 South-Marutea Atoll is located at the south-eastern end of the Tuamotu Archipelago, French
14 Polynesia, central South Pacific. Understanding the modalities of islet building from low-
15 lying atolls over the mid to late Holocene, in relation to sea-level changes and cycles of
16 marine hazard events, is a prerequisite for better anticipate future geomorphic changes to
17 which the islets will likely be faced in the next decades under global climate warming. Herein
18 is presented the depositional history of two selected atoll islets, based on chronostratigraphic
19 analysis of sedimentary, coral-dominated sequences from six excavations. Identified as Motu
20 Aramu and Motu Vainono, these islets are located respectively in north-north-east and due
21 south of the atoll rim. Additional surficial sampling was conducted on modern ocean-facing

22 shingle ridges, respectively on north-north-west (Motu Oire), west (Motu Aranui) and east
23 (Motu Tekava) rim areas, in order to date the latest ridge-emplacement stages. Oire and
24 Aranui sites, located along the leeward atoll sites, are protected from trade winds, Aramu,
25 Vainono and Tekava are located on the windward sides, directly exposed to northeasterly and
26 southeasterly storm swells respectively. A total of 88 coral clasts were collected to be U/Th
27 dated. The excavated sequences range between 2.50 m and 0.90 m in thickness, from the
28 outer islet sides lagoonwards. Five lithofacies, including two subfacies, were recognized
29 based on texture and biological composition: a coral boulder-cobble-dominated, a coral
30 pebble-dominated – pebble-supported and sand-supported subfacies – and a foraminifera-rich,
31 sand-dominated and an organic-rich, pebble to sand facies. These facies tend to be distributed
32 from ocean sides landwards according to a decreasing grain-size gradient. A model of atoll-
33 island accretion emerges in relation with changes in frequency and intensity of marine hazard
34 events. The islet foundations consist of conglomerate platforms, locally up to 1.0 m thick,
35 deposited from about 5,000 to 1,000 yr BP. Islets began to accrete from 5,000 yr BP. While at
36 Motu Vainono, islet building occurred continuously over the last 5,000 years, at Motu Aramu,
37 there is an apparent non-depositional episode, from 4,000 to 2,000 yr BP, interpreted as
38 caused by a marked decreased in ENSO-related cyclone activity. The outer shingle ridges in all
39 studied sites were regularly reshaped during the last millennium. During the last 5,000 years,
40 the major accretion-islet episodes occurred irrespective of the course of sea level, indicating
41 that sea-level change was not a driver of islet accretion. Periodical, marine high-energy events
42 clearly appear to be the key controls of islet shaping. Shifts of cyclone source areas further
43 south and increasing cyclone intensity, but lower frequency, due to enhanced ENSO variability
44 throughout the 21st century, is postulated to expose the Gambier island Group to stronger, but
45 fewer disturbance events when compared to the last millennia.

53 1. Introduction

54 According to the latest IPCC Report (Pörtner et al., 2022), sedimentary coastal systems will
55 be subjected to drastic topographic readjustments prior to the end of the current century in
56 response to ongoing global climate warming. In the Pacific Ocean, low-lying coastal systems
57 are mainly represented by atolls, i.e. shallow-water, annular to elongate, coral-reef rimmed
58 islands, usually overtopped discontinuously by islets, composed of coral-derived rubble
59 and/or skeletal sands (Woodroffe and Biribo, 2011). These islets are known as *motu* by
60 Polynesian natives. Culminating at elevations rarely exceeding +5 m above present mean sea
61 level (pmsl), these have been interpreted as storm-generated, depositional landforms built up
62 during the last millennia in relation with relative changes in sea level (Pirazzoli and
63 Montaggioni, 1986; Dickinson, 2009; Woodroffe et al., 1999; Kench et al., 2005; Barry et al.,
64 2007; Kench et al., 2014a, 2014b).

65 Over an about twenty-year period, in the Indo-Pacific, a great deal of research was dedicated
66 to understanding the morphological evolution of low-lying atoll islets during the last few
67 decades in response to the rise in sea level (Roy and Connell, 1991; Woodroffe, 2008;
68 Dickinson 2009; Webb and Kench, 2010; Rankey, 2011; Ford, 2012; Yates et al., 2013; Ford
69 and Kench, 2015; Storlazzi et al., 2015; Purkis et al., 2016; Duvat, 2019; Duvat et al., 2017a;
70 Shope and Storlazzi, 2019) and to the intensification of storminess (Kench and Brander, 2006;
71 Hoecke et al., 2013; Canavesio, 2014; Smithers and Hoecke, 2014; Costa et al., 2017; Duvat
72 et al., 2020). The relevant findings were used to attempt predicting the morphodynamic
73 behavior of these islets in the face of global warming in the next future decades. By contrast,

74 a limited number of investigations were carried out in order to reconstruct the morphological
75 reconstruction of atoll islets during the last millennia (Kench et al., 2014a, b; Montaggioni et
76 al., 2018, 2019).

77 Atoll islets are usually regarded as potentially vulnerable, liable to experience submersion
78 and/or erosion (Yamano et al., 2007; Woodroffe, 2008; Dickinson, 2009; Ford and Kench,
79 2014; Canavesio, 2014, 2019; Storlazzi et al., 2015; Shope et al., 2016, 2017; Duvat et al.,
80 2017b; Montaggioni et al., 2021; Amores et al., 2022). As a result, the fate of islets together
81 with the related human settlements, remain uncertain (Shope and Storlazzi, 2019; Magnan et
82 al., 2018, 2022) and therefore is still actively debated. Among scientists, there are those who
83 believe that islets could be submerged (Yamano et al., 2007; Dickinson, 2009; Connell, 2013;
84 Hubbard et al., 2014; Woodruff et al., 2013; Storlazzi et al., 2015), and others who thought
85 that they will persist, migrating laterally across atoll-rim surfaces (Webb and Kench, 2010;
86 Rankey, 2011; Biribo and Woodroffe, 2013; Ford, 2012, 2013; Le Cozannet et al., 2014; Pala,
87 2014; Ford and Kench, 2015; McLean and Kench, 2015; Duvat and Pillet, 2017; Duvat et al.,
88 2017b). In any case, active cyclogenesis are known to promote both islet accretion and
89 erosion, generally at different sites of a same atoll (Stoddart, 1971; Stoddart and Steers, 1977;
90 Scoffin 1993; Canavesio, 2014; Montaggioni et al., 2018, 2019, 2021).

91 In French Polynesia, studies were conducted on the dynamics of atoll-islet shorelines in
92 response to change in sea level over the last few decades (Duvat, 2019; Duvat and Pillet,
93 2017; Duvat et al., 2017a, b). Correlatively, Canavesio (2014, 2019) explored the influence of
94 extreme marine hazards on the short-term evolution of motu morphology. In both cases, the
95 investigations focused on a few atoll sites and atolls only. Furthermore, as claimed by Shope
96 and Storlazzi (2019), such works only based on a few decades of observations may not
97 accurately predicate how atoll islets will react in the future when sea level will reach

98 elevations as high as or higher than those reached during the mid-late Holocene islet accretion
99 phases and, in addition, when storminess will become stronger.

100 Estimating the degree of vulnerability of atoll islets to ongoing climate change requires as a
101 prerequisite detailed reconstructions of the mode and timing of atoll islet formation over
102 millennial timescales. Islet sedimentary beds are known to preserve evidence of the passage
103 of intense storms. In French Polynesia, studies devoted to reconstructing the internal
104 architecture of low-lying islets are still limited to Takapoto (Montaggioni et al., 2018, 2019)
105 and Rangiroa (Montaggioni et al., 2022) Atolls. The findings revealed that, at Takapoto, on
106 both leeward and windward sides, motu have formed over the last 2,500 years, as sea level
107 was falling, from depocentres initially located in the middle parts of the atoll rims, then
108 accreting centrifugally seawards and lagoonwards. By contrast, in northern Rangiroa, islet
109 development appears to have started about 6,000 years ago at the time sea level was moving
110 up to its present position, indicating that the main accretionary phase of the motu has occurred
111 during the rising sea-level episode, approximately from 6,000 to 3,000 years BP. As their
112 islets were demonstrated to have formed at different stages of the sea-level course over the
113 last 6,000 years, the question is to what extent the models from Takapoto and Rangiroa, both
114 located in the northern Tuamotu, are representative at the whole archipelago scale.

115 The present study aims to reconstruct the timing and mode of formation of two rim islets from
116 South-Marutea Atoll (Fig. 1), situated at the south-eastern end of the Tuamotu Archipelago, at
117 a distance of 1500 km and 1300 km from Takapoto and Rangiroa Islands. The selected motu
118 are located in the north and south areas of the atoll respectively. The main objectives are to
119 elucidate if there are potentially time offset in islet initiation and differences in accretional
120 processes between atolls situated at the opposite ends of a same reef province, and suspected
121 to be subjected to differential environmental conditions and storm regimes. Assuming that the

122 mid to late Holocene sea-level pattern defined from the north-western Tuamotu (Pirazzoli and
123 Montaggioni, 1988a; Hallmann et al., 2020) is of regional value, also applicable to the south-
124 eastern parts of the archipelago (Pirazzoli and Montaggioni, 1987) may lead to isolate the
125 respective roles of sea-level change and marine natural hazard events in South-Marutea atoll-
126 islet formation.

127 **2. Regional setting**

128 *2.1. Site location and atoll morphology.*

129 Composed of 77 atolls, the Tuamotu Archipelago is located in the central South Pacific,
130 extending along a west-north-west to east-south-east axis, about 1700 km long. Located at
131 1470 km from Tahiti, South-Marutea Atoll, also known as Quiros, Lord Hood, Marutea-I-
132 Runga or Nuku-Nui, lies in the far south-eastern part of the archipelago, between
133 $21^{\circ}28'27.74''$ – $21^{\circ}34'25.12''$ latitude south and $135^{\circ}38'42.57''$ – $135^{\circ}27'12.46''$ longitude
134 west (Fig. 1a). This atoll has to be differentiated from North-Marutea, located at about 650 km
135 east of Tahiti. South-Marutea is resting on a 37.3–30.4 million years old, oceanic crust (Müller
136 et al., 1997). Geodynamically speaking, it belongs to the Tuamotu trail chain, presumably
137 generated from the Easter hotspot (Ito et al., 1995), to be distinguished from the nearby
138 Moruroa-Gambier-Pitcairn island chain generated by the Pitcairn hotspot (Dupuy et al., 1993).
139 The South-Marutea volcano, about 2700 m high, is likely to have started erupting by the lower
140 Miocene. Geographically and administratively speaking, rising at a distance of less than 200
141 km north of Mangareva Island, South-Marutea is part of the Gambier Island Group.

142 First described by Seurat (1904), South-Marutea is of closed type (totally devoid of passes),
143 broadly trapezoid in shape, 20 km long and 8 km wide, with a circumference of 55 km (Fig. 1b).
144 Its main axis, oriented west-north-west to east-south-east, is consistent with that of the Tuamotu

145 island chains. The atoll reef rim ranges between about 350 and 1100 m in width, covering about
146 15 km². The lagoon is 112 km² in area, -40 m in maximum depth and exhibits a blue hole,
147 -72 m deep, close to its eastern border. A 10 km-long, almost continuous motu occupies the
148 north-eastern rim part while the other rim areas have small islets usually separated by *hoa*, i.e.
149 shallow channels allowing water exchanges between the open sea and the lagoon at high tide.
150 The islets are elongated or crescent-shaped.

151 The atoll rim is fringed oceanwards by a coral-reef flat zone, 150 to 230 m wide, less than
152 1 m deep, overlined by an about 0.50 m-high algal crest, at its outermost borders. The living
153 coral cover rate does not exceed 5 % of the total reef-flat surface. The upper forereef zone
154 consists of a gently-dipping spur-and-groove system, followed outwards by a sub-horizontal,
155 about 50 m-wide terrace, usually ending into a drop-off at depths of 10–15 m. The spur-and-
156 groove system and the terrace are colonized by coral communities dominated by pocilloporids
157 and acroporids. Observations from the north-north-west rim tip (Motu Oire), at base of the
158 spurs, living coral coverage averaged 45 % over the past few years (Chancerelle, Y., CRIOBE,
159 pers. com.)

160 2.2. *Climate*

161 In French Polynesia, the climate system is driven by the trade winds and by the El Niño-
162 Southern Oscillation () which regulates both tropical cyclones and extra-tropical storms
163 (Andréfoüet et al., 2012; Lecacheux et al., 2013). In the Gambier Islands, the climate is
164 typically maritime, tropical, humid, but relatively cooler than that from the north-western
165 Tuamotu region. Rainfall remains relatively stable throughout the year, averaging 140 mm in
166 July and 210 mm in November, thus resulting in an average annual rate of 2,000 mm. As in
167 the whole tropical Pacific, the wind regime at South-Marutea, is dominated by trade-winds,

168 blowing mainly from the north to south-east sectors (Fig. 2). During the winter season, the
169 trade winds generate strong, about 2–2.50 m-high wave surges. During the summer season,
170 the trade winds are significantly less active and generate moderate swells, occasionally
171 disturbed by distant-source storms originating from the southern latitudes (Canavesio, 2019)
172 and cyclones. Tides are semi-diurnal and microtidal, averaging 0.70–0.80 m in amplitude at
173 spring tide.

174 French Polynesia has clearly fewer cyclones than the rest of the central South Pacific. The
175 cyclone season occurs generally during the austral summer. The eastward shift of warmer
176 waters during El Niño events triggers the motion of tropical storms further east to the
177 Tuamotu. Most cyclones come from the west through the Cook Islands, usually passing south
178 of the Society Islands, but more regularly passing over the Austral Islands (Larrue and
179 Chiron, 2010). Some cyclones generate from within the Marquesas. Increase in ENSO
180 variability is driven by a change in the magnitude and frequency of extreme El Niño events
181 (Bjerknes, 1969; Kao and Yu, 2009). During active, El Niño phases, intense cyclonic hazards
182 mainly affect the region bounded by the Tuamotu and Austral Islands, while, during la Niña
183 phases, decreasing cyclonic activity seem to operate between the Gambier and the southern
184 Austral areas (Laurent and Varney, 2014). As a response to global warming, there was a
185 significant enhancement of ENSO variability by about 25 % over the last five decades,
186 compared to the preindustrial times (Grothe et al., 2019). The province is also affected by
187 tropical lows that form over oceanic areas with surface temperature of about 26 °C, just
188 poleward of the Inter-Tropical Convergence Zone (ITCZ) where the trade winds of northern
189 and southern hemispheres are converging. These can generate strong winds and swells across
190 the Tuamotu province.

191 In French Polynesia, the history of extreme marine hazard events is poorly documented
192 (Laurent and Varney, 2014; Dupon, 1987). Between 1822 to 2014, about 24 extreme wave
193 events, most interpreted as related to tropical cyclones, would have passed across the region.
194 The last ones were interpreted as triggered by ‘Super-ENSO’ events (Hameed et al., 2018),
195 presumably in relation to global climate warming. These last events were anomalous since,
196 over periods of several centuries, the number of strong storms and cyclones in the province
197 was expected to probably range between 2–3 per century (Canavesio, pers.comm.) to a
198 maximum of 4–10 (Dupon, 1987). Cyclone events typified by a 50-year return interval would
199 generate wave exceeding 12 m high (Canavesio, 2014).

200 Storm wave surges hitting South-Marutea are generated by tropical cyclones, depressions, and
201 southern, distant-source wave surges. For the 1831 to 1968 period, there were three recorded
202 passages of destructing cyclones in the Gambier region. Initiated close to the Marquesas
203 Archipelago, all these cyclones were described as having followed similarly close trajectories
204 as tracked south-east along the west Mangareva coasts at distances of less than 10 km
205 (Laurent and Varney, 2014). During the 1969–2010 interval, South-Marutea is known to have
206 been impacted by eight cyclones and depressions (Laurent and Varney, 2014) (Fig. 3). In the
207 vicinity of the Gambier Islands, most cyclones tend to become less powerful, grading into
208 tropical depressions, hence unable to displace the largest coral debris. The most recent
209 damaging effects have resulted from the passage of cyclones Nano and William. Nano passed
210 over South-Marutea by 27th January 1983. All atolls located along its trajectory were
211 impacted, especially their north- and east-facing rim sides which were totally submerged.
212 Descriptions from neighbouring atolls of Hao and Tureia reveal that about 15 to 18 m-high
213 waves have flooded over the reef rims, locally resulting in removing portions of islets over
214 lengths of 60 m and widths of 20 m, together with transport of coral-built mega-blocks from
215 the adjacent forereef slopes onto the motu (Laurent and Varney, 2014). The eye of Cyclone

216 William has passed close to the north of South-Marutea by 20th April 1983. At Turea, waves
217 of about 8 to 9 m high were observed. It is noteworthy that, at South-Marutea, while there are
218 several metre-thick, outer shingle ridges, mostly composed of coral boulders and cobbles,
219 deposited along the reef-rim, there is no mega-boulder. Large mega-casts are also missing (B.
220 Salvat, pers. observ.). These are striking features because numerous mega-clasts, a few to tens
221 of cubic metres in volume, are frequently present on reef flats in the majority of atolls in the
222 Tuamotu, locally in the north and central part of the archipelago, usually deposited along the
223 northern and southern faces (Bourrouilh and Talandier, 1985; Etienne et al., 2011; Terry and
224 Etienne, 2011; Lau et al., 2016). This strongly suggests that the studied atoll and most of
225 nearby islands have escaped catastrophic impacts generated by the close passage of cyclones,
226 in contrast to what is seen at Hao and Tureia. South-Marutea, located further south, close to
227 the end of the cyclonic tracks in the south Pacific (Larrue and Chiron, 2010; Laurent and
228 Varney, 2014), is likely to have been hit by cyclones with loss of strength. However, mean
229 tide levels during a cyclonic event can be strongly impacted by both wave setup, i.e. increase
230 of mean water level due to waves breaking on the reef front, and by runup, i.e. maximum
231 elevation reached by waves on the atoll land. For cyclonic wave heights of 8 to 12 m, runup
232 effects could increase the reference ocean water level by more than 4.5–5.0 m along
233 coastlines (Pedreros et al., 2010). It is noteworthy that elevation reached by sea level is
234 sensitive mainly to wave direction. The effects of changing incident waves that deflect into a
235 direction different from the perpendicular to the reef front line could cause increasing risk and
236 disturbances in some areas, especially near passes or *hoa*. Similarly, atoll-islet inundation can
237 occur from waves surges directly generated from lagoonal waters (Damlamian et al., 2013).

238 Distant-source swells originate from high-latitude storms, especially in the south (austral)
239 hemisphere. There is little information about the real influence of distant-source storms in
240 atoll shaping in the Tuamotu, although their return frequency is approximatively annual,

241 probably because these have usually limited effect on human activities. However, these are
242 known to have triggered a rise of up to 2.50 m in atoll lagoon level above low spring tide,
243 resulting in islet submergence and damage (Canavesio, 2019). Lagoon water infilling seems
244 to depend not only upon the magnitude of the storm wave event, but also upon the duration of
245 the event.

246 In addition, little is known about the frequency and effects of tsunamis in French Polynesia
247 and, especially, in the south-eastern Tuamotu end (Sladen et al., 2007). Around fifteen
248 tsunamis were estimated to have hit French Polynesia and the Tuamotu since the fifteenth
249 century (Lau et al., 2016). Earthquake-generated tsunamis from the eastern Pacific subduction
250 zones seem to be potentially not able to impact the Gambier areas (Heinrich et al., 1996;
251 Reymond et al., 2013). According to Sladen et al., (2007), the Tuamotu have been
252 significantly less affected by tsunamis than high volcanic islands in other French Polynesian
253 archipelagoes, although some atoll-rim deposits may be interpreted as resulting from
254 devastating tsunami impacts (Montaggioni et al., 2022). Since the 16th century, less than ten
255 tsunamis were expected to have struck the Tuamotu islands and generated less than 2 m-high
256 waves (Lau et al., 2016).

257 Moreover, as emphasized by Duvat et al. (2020), climate events regarded as moderate
258 compared to tropical cyclones can significantly contribute to atoll-islet shaping. Usually
259 overlooked as sediment providers, low-to medium water energy hazards, with return periods
260 of 2–3 years, compared to those of cyclone (several decades), regularly supply motu with
261 material derived from upper forereef and reef-flat zones and contiguous conglomerate
262 platforms.

263 Rapid, high amplitude mean global sea-level rise is expected for the next centuries (Horton et
264 al., 2020). Highest sea-level positions should be close to those estimated for the last
265 interglacial MIS 5e stage (Rohling et al., 2007; Kopp et al., 2009)..

266 **3. Material and methods**

267 3.1. Field surveys

268 The studied motu sites are the following: north-east (Aramu) (Fig. 1c), due south (Vainono)
269 (Fig. 1d), west (Aranui) (Fig. 1e), north-north-west (Oire) (Fig. 1f) and due east (Tekava)
270 (Fig. 1g).

271 First, detailed levelling along longitudinal profiles across the atoll-reef rim was conducted
272 using a conventional automatic level. Each reference point along the profiles was positioned
273 using DGPS coordinates. Elevations were measured by reference to present-day mean sea
274 level (pmsl), assuming a conservative error of ± 0.10 m. The profiles across the motu reveal
275 similar protruding relief seawards. These relate to shingle ridges bordering the ocean-facing
276 sides of the atoll-reef rim, as observed at Motu Vainono, across its highest tip (Figs. 1d, 4a)
277 and at Motu Oire (Figs. 1f, 4b). The islets rest usually on conglomerate platforms, i.e.
278 lithified, heterometric skeletal sheets, regarded as cemented within vadose and phreatic
279 marine zones during the sea-level lowering over the last 4,000 years (Montaggioni et al.,
280 2021). Conglomerates are less than 1.00 m in apparent thickness, but are thicker locally,
281 particularly in the south-south-west (Motu Aranui) and the west (Motu Oire) areas of the atoll
282 reef-rim (Fig. 5a, b, c). Coral pebbles were collected superficially along the shingle-ridge
283 profiles for radiometric dating submission. Similarly, for comparison, samples were also
284 taken along the ocean-facing shingle ridges on Motu Aranui (Fig. 1e), on the south-south-

285 west coast (21°31'38.6''S, 135°37'48.9''W) and Motu Tekava (Fig. 1g), on the south-south-
286 east atoll-rim end (21°31'51.31''S, 135°27'23.70''W).

287 Additional topographic surveys were conducted in relation to excavated cross-sections
288 through two selected islets, respectively Motu Aramu, exposed to the north-north-east trade
289 winds (21°29'00.2''S, 135°30'48''W) and Motu Vainono, exposed to the south-east
290 (21°34'05.3''S, 135°33'05.9''W). Aramu is 230 m long, while Vainono extends over 720 m.
291 Islet topography are very similar at both studied sites. Along the ocean side, the transition
292 zone between the inner reef-flat zone and the land is occupied by steeply-dipping (up to 20°)
293 sandy, skeletal beaches (Fig. 6). Inland, there are unconsolidated rubble ridges, mainly
294 composed of block-sized (0.30 m on average), individual coral colonies, dominated by
295 pocilloporids and acroporids (Fig. 7). The ocean-facing ridge slopes are steep (up to 30°)
296 while the inner faces are gently-dipping (less than 15°). Ridge heights at the transect sites are
297 2.30 m at Motu Aramu (Fig. 8) and 5.10 m at Motu Vainono (Fig. 9). Behind the ridges, there
298 are gently-dipping (less than 10–15°) to flat-topped benches culminating at elevations of
299 1.60 m to 2.60 m respectively. The benches end into 10° sloping beaches, about 20 to 80 m in
300 width. The inner sides of shingle ridges at Motu Vainono are covered by low-growing plants
301 (*Scaevola taccada*). Conglomerate platforms and beaches from the ocean-facing Aramu areas
302 are colonized by spaced *Pemphis acidula* tufts – *miki-miki* in Polynesian language. The inner,
303 flat-topped surfaces of both islets are occupied by both low-growing plants (*Scaevola*
304 *taccada*, *Microsorium grossum*), shrubs (*Pandanus tectorius*) and trees (*Guettarda speciosa*,
305 *Cocos nucifera*).

306 Second, vertical excavations using backhoe were dug through Motu Aramu (Fig. 8) and Motu
307 Vainono (Fig. 9) from top surface to underlying conglomerate surfaces in order to determine
308 islet subsurface stratigraphy. On both motu, the excavations were dug at three specific

309 locations: just behind the shingle ridge, in the middle part of the motu and on the lagoon-
310 facing margin. From the ocean side inwards, these holes are successively labelled A
311 (21°28'57.1"S, 135°30'45.6"W), B (21°29'00.2"S, 135°30'48.1"W) and C (21°29'02.7"S,
312 135°30'50.3"W) on Motu Aramu, and D (21°34'09.0"S, 135°33'04.2"W), E (21°34'05.3"S,
313 135°33'05.9"W), and F (21°33'57.54"S, 135°33'07.86"W) on Motu Vainono. Field grain-
314 size analysis of coarser detrital material was performed using the Udden-Wentworth
315 classification (Terry and Goff, 2014) as measured along the longest axis from photographed
316 square-metre quadrats. Coral pebbles and gravels were collected for radiometric dating at all
317 excavated sites. Taxonomic identification of dated coral specimens was made at the generic
318 level.

319 3.2. Uranium–thorium dating procedures

320 The reconstruction of atoll islet chronostratigraphy and building history is based on uranium-
321 series dating of the 88 coral gravels to pebbles, labelled M, collected on South-Marutea Atoll,
322 both at the surface of islets and, within excavations, along the walls and at the bottom.

323 Prior to radiometric analysis, millimetric pieces of the coral clasts were cut using a micro saw
324 in order to select the most clean and pristine parts. These pieces were rinsed with mQ water
325 and ultra-sonicated several times. After adding a triple ^{229}Th ^{233}Ue ^{236}U spike in a Teflon
326 beaker, samples (from 150 to 350 mg) were dissolved with diluted HCl. The U–Th separation
327 and purification were performed after coprecipitation with $\text{Fe}(\text{OH})_3$, on 0.6 ml columns filled
328 with U-TEVA and prefilter resins, in nitric media – see Pons-Branchu et al. (2014) for details.

329 The U and Th isotopic compositions were analyzed at the *Laboratoire des sciences du climat*
330 *et de l'environnement* (LSCE, France), on a Multi-Collector inductively coupled plasma source
331 mass spectrometer (MCEICPMS) Thermo Scientific™ Neptune^{plus} fitted with a desolvating
332 introduction system (aridus II), and a jet interface. For mass fractionation correction, we used

333 an exponential mass fractionation law – normalized to natural $^{238}\text{U}/^{235}\text{U}$ isotopic ratio – and
334 standard – sample bracketing. More details on the analytical procedure – chemistry and MC-
335 ICPMS analysis – can be found in Pons- Branchu et al. (2014). After corrections for peak
336 tailing, hydrate interference and chemical blanks, $^{230}\text{Th}/^{234}\text{U}$ ages were calculated (Table 1)
337 from measured atomic ratios through iterative age estimation using the ^{230}Th , ^{234}U , and ^{238}U
338 decay constants of Cheng et al. (2013) and Jaffey et al. (1971). Ages are expressed in calendar
339 years (cal.yr), by reference to 2022, i.e. the year of sample analysis. In order to make age
340 results more easily comparable to previous research, particularly that based on radiocarbon
341 measurements, ages are also given in conventional years BP by reference to 1950 (see Table
342 1, Supplementary Material).

343 *3.3. Significance of coral-clast ages*

344 Radiometric dating of displaced skeletal material (corals, molluscs, foraminifera) for
345 reconstructing depositional histories of atoll islets were discussed by Woodroffe et al. (1999,
346 2007), Kench et al. (2014) and Montaggioni et al. (2018, 2019, 2021, 2022). As an unknown
347 time interval (tens to hundreds of years) is expected to separate the time of death of a given
348 organism from the time of final deposition and stabilisation of its skeletal fragments, islet
349 chronologies have therefore to be interpreted as relative, not absolute. Coral clasts may have
350 experienced successive cycles of displacement, reworking and resedimentation. This is clearly
351 evidenced by a number of age inversions in the stratigraphic sections (Figs. 8, 9). However,
352 islet chronologies is assumed to be consistent, since most of the dated samples occupy a
353 stratigraphic position within the excavations, particularly, within those close to the outer
354 ridges and from the middle parts of both islets, which is in accordance with their age. Samples
355 tend to be younger closer to the surface and older closer to the bottom. In these sites, the
356 youngest ages obtained are regarded to be closer to the time of definitive stabilization of the

357 relevant islet section. Clast stabilization is believed to have taken place within 200–1,000 yr-
358 long intervals, according to clast ages recorded at base of the excavations.

359 **4. Results**

360 *4.1. Expected age of deposition of conglomerate platforms*

361 Ages of coral clasts incorporated into islet-supporting conglomerates, collected from both
362 outcrop surfaces or at the bottom of the excavations vary widely from site to site (Fig. 10). At
363 Motu Aramu, ages range from $3,585 \pm 10$ cal.yr (M1), $3,593 \pm 20$ cal.yr (M4), and
364 $4,108 \pm 10$ cal.yr (M43) to $4,181 \pm 8$ cal.yr (M52). At Motu Vainono, conglomerate clasts
365 yielded ages of $1,109 \pm 4$ cal.yr (M16), $1,204 \pm 8$ cal.yr, (M25), $3,218 \pm 7$ cal.yr (M118), and
366 $3,986 \pm 10$ cal.yr (M88). At Motu Aranui, conglomerate ages are among the oldest recorded:
367 $3,665 \pm 16$ cal.yr (M148) and $4,829 \pm 24$ cal.yr (M149). By contrast, at Tekava, conglomerate
368 deposits are among the youngest ones: $1,011 \pm 32$ cal.yr (M103), $1,339 \pm 6$ cal.yr (M102),
369 and $1,743 \pm 7$ cal.yr (M101).

370 *4.2. Expected age of deposition of ocean-facing shingle ridges and inner sheet surfaces*

371 U/Th dating of coral clasts collected from the shingle-ridge and inner islet surfaces at the
372 different islet settings suggests that the ridges have been supplied in coral detritus between the
373 last few decades to the last millennia (Fig. 10). Clast deposition has taken place decades to
374 century apart depending on exposure to wave surges and local forereef slope physiography of
375 each considered atoll site. The youngest ages are mostly obtained from the outermost, ocean-
376 facing ridge surfaces or tips: Aranui (47 ± 4 cal.yr, M138), Aramu (51 ± 2 cal.yr, M53),
377 Vainono (79 ± 2 cal.yr, M19; 185 ± 3 cal.yr, M18), Oire (304 ± 3 cal.yr, M162;
378 308 ± 5 cal.yr, M164), Tekava (343 ± 4 cal.yr, M107). By contrast, samples from the inner
379 talus, just behind the ridge tips, provide ages significantly older: Tekava (862 ± 5 cal.yr,

380 M100), Oire ($1,255 \pm 11$ cal.yr, M166; $3,565 \pm 13$ cal.yr, M167), Vainono
381 ($2,314 \pm 150$ cal.yr, M21; $2,678 \pm 9$ cal.yr, M24; $2,695 \pm 8$ cal.yr, M22).

382 Ages of samples from the inner sheet surfaces range are the following (Fig. 10):

383 108 ± 3 cal.yr, (M44) and $1,786 \pm 12$ cal.yr (M26) at Aramu, $2,480 \pm 10$ cal.yr (M132),

384 42 ± 2 cal.yr (M65) and $2,885 \pm 8$ cal.yr (M85) at Vainono, $3,846 \pm 15$ cal.yr (M109) at

385 Tekava.

386 *4.3. Internal islet structure and lithostratigraphy*

387 Examination of the excavations dug through both Motu Aramu and Motu Vainono revealed

388 that the relevant unconsolidated deposits are resting on firmly indurated, conglomerate

389 pavements. The conglomerate top surfaces range from 0.40 to 0.70 m (0.50 m on average) in

390 elevation above pmsl. These surfaces are locally overflowed by the ground water table at

391 maximum levels of 0.25 m (excavations C, D and F) (Fig. 11b, c, d). Analysis of the

392 excavation walls reveal that the conglomerate-overlying, loose deposits increase noticeably in

393 thickness and volume from Aramu to Vainono settings (Figs. 8, 9), probably in response to

394 exposure to higher intensity and frequency of islet-building wave surges. The ocean-facing

395 sequences (A and D) located just behind both the outer shingle ridges are 2.00 and 2.50 m

396 thick at Motu Aramu and Motu Vainono respectively. In the middle parts of the islets, the

397 thicknesses of the sedimentary sequences (B and E) are 0.90 and 2.00 m respectively. The

398 sequences from the lagoon sides (C and F) are 1.10 and 2.10 m thick respectively.

399 The sequences consist usually of beds ranging from 0.20 to 0.60 m thick (Figs. 8, 9).

400 However, locally, on Motu Vainono, single bed thickness can reach 1 to 2 m. Sediment grain-

401 size decreases significantly from the ocean-facing shingle ridges (Fig. 11a, c) lagoonwards

402 (Fig. 11b, d). Boulder- to cobble-dominated deposits laterally grade into pebble-dominated,

403 then in sand-dominated facies. Sediment composition and texture are quite similar between
404 Aramu and Vainono sites. Longest axis of coral boulders ranges between 300–350 mm to up
405 to 100 mm with mean values of around 200 mm. Along the islet transects, boulders particles
406 are progressively replaced by cobbles and pebbles. Boulders and cobbles consist
407 predominantly of entire pocilloporid and fragmented acroporid colonies, associated to
408 merulinids and a few poritids (Fig. 7). Pebbly detritus are mainly composed of fragmented
409 pocilloporids, acroporids and merulinids, and low content of molluscan shells and coralline
410 algae. Sand-sized grains are composed of large foraminifera, molluscan, coral and coralline
411 debris. Foraminifera tests are dominated by soritids.

412 On the basis of textural attributes, four sedimentary facies can be recognized.

413 4.3.1. Boulder-cobble-dominated facies

414 This facies tends to be restricted to islet areas close to the ocean sides. It is prevalent at the
415 most exposed site (Excavation D) on Motu Vainono where it represents about 70 % of the
416 volume deposited (Fig. 9). By contrast, on Motu Aramu, within the ocean-facing excavation
417 (A), boulders and cobbles do not exceed 25 % of volume (Fig. 8). Surprisingly, there is a
418 layer composed of the same percentage of cobbles in Excavation C, close to the lagoon side at
419 Motu Aramu.

420 4.3.2. Pebble-dominated facies

421 It is subdivided into two subfacies as differentiated by its clast-supported characteristics:
422 pebble-supported and sand-supported. Pebble detritus (about 50 mm to 5 mm in diameter) are
423 dominantly composed of diverse coral debris, together with a few molluscan shells and
424 coralline algae. Both facies are found throughout both excavated islets (Figs. 8, 9, 11 a, c).
425 However, volumes of pebble-sized material is noticeably higher in Motu Vainono than in

426 Motu Aramu. The pebble-supported subfacies is the main component in the central part of
427 Vainono islet (Excavation E) in which it occupies up to 60 % of the total volume while, in the
428 central part of Aramu islet (Excavation B), it accounts for 20–25 % only. The sand-supported
429 subfacies was encountered in both facing-ocean excavations (A, D) in which it represents
430 20 % and about 60 % of the total volumes respectively.

431 4.3.3. Sand-dominated facies.

432 Sandy material, enriched in low amounts (less than 10 %) of fine pebbles, is deposited
433 predominantly within the inner islet zones, from the central parts towards the lagoonal border,
434 on both Motu Aramu and Motu Vainono (Fig.11b, d). Higher sand amounts were found on
435 Motu Aramu, through Excavations B and C, in which it represents 70 % and 80 % of the total
436 volumes respectively. At Motu Vainono, within Excavations E and F, sand-dominated
437 sediments occupied 25 % and 28 % of the cavity.

438 4.3.4. Organic-rich facies

439 This facies defines the occurrence of brown- to black-coloured, root-bearing horizons at the
440 top part of most excavated sequences, usually at the expense of both pebble- to sand-
441 dominated facies (Fig.11b, d). It is present at all excavation tops, but best developed on
442 Vainono sites. There, its thickness ranges from 0.20 to 0.50 m. At Aramu settings, organic-
443 rich layers are 0.050 to 0.25 m thick.

444 As a summary, it appears that the thicknesses of the different facies and subfacies vary
445 markedly from Motu Aramu to Motu Vainono and from excavation to excavation. As
446 expected, coarser deposits dominate in areas facing the open ocean, while finer ones are rather
447 located near the lagoon sides. No apparent sediment grading was observed in any sequence
448 nor any bed.

449 *4.4. Islet accretion chronology*

450 All ages of the dated coral samples extracted from excavations range approximately within
451 the last 5,000 year-interval – from $5,042 \pm 16$ cal.yr (M61) to 42 ± 2 cal.yr (M65). However,
452 the age distributional patterns differ between the both islets (Fig. 10). On Motu Aramu, two
453 major phases of clast supply occurred (Fig. 12a), the earlier from about 5,000 to 4,000 cal.yr,
454 and the later from 2,000 cal.yr to the modern, separated by a two millennia-long non-
455 depositional episode or at least by a slowdown in clast supply. By contrast, on Motu Vainono,
456 earlier deposition would have initiated between 5,000 and 4,000 cal.yr (Fig. 12a). There, the
457 main accretional episode would have lasted approximately 2,000 years, between 4,000 and
458 2,000 cal.yr. Accretion then progressively decreased in intensity until the modern times.

459 Few sequences have an age-decreasing trend from base to top, consistent with stratigraphy.
460 Despite some age inversions, in Excavations A and B (Aramu, outermost and mid islet sites)
461 and F (Vainono, lagoon-margin site), the older samples tend to be deposited in the lower beds
462 while the younger ones to be found close to the land surface. Within Excavation A, ages range
463 from $4,512 \pm 12$ cal.yr (M63) – $5,042 \pm 16$ cal.yr (M61) at base to 545 ± 4 cal.yr (M55) –
464 51 ± 2 cal.yr (M53) at top. Within Excavation B, ages decrease from $4,363 \pm 13$ cal.yr (M51)
465 to $1,820 \pm 8$ cal.yr (M47) and 108 ± 3 cal.yr (M44). Within Excavation F, ages are
466 $2,278 \pm 9$ cal.yr (M84) at base, around 1,300–900 cal.yr in the medium beds and 42 ± 2 cal.yr
467 (M65) at top. But, in most cases, the samples are found to have been reworked and mixed. As
468 a whole, ages in the sections from Motu Aramu are distributed within a wide range while
469 those from Motu Vainono are distributed narrowly. Excavations A: $5,042 \pm 16$ cal.yr (M61)
470 to 51 ± 2 cal.yr (M53); B: $4,191 \pm 8$ cal. yr (M52) to 108 ± 3 cal.yr (M47); C:
471 $4,644 \pm 25$ cal.yr (M30 bis) to 882 ± 5 cal.yr (M38); D: $4,026 \pm 13$ cal.yr (M89) to
472 $2,885 \pm 8$ cal.yr (M85); E: $3,293 \pm 24$ cal.yr (M134); F: $2,449 \pm 10$ cal.yr (M82). The average

473 age difference between the dated clasts into each excavation can be estimated as follows
474 (Figs. 8, 9, 10): 5,000 years in Excavation A; 4,000 years in B; 4,200 years in C; 1,100 years
475 in D; 1,000 years in E; 1,500 years in F. With a volume at least twice that of Motu Aramu,
476 Motu Vainono is interpreted to have developed continuously and more rapidly throughout the
477 same time interval, from several distinct depositional episodes of 1,000 to 1,500 years in
478 duration.

479 Clasts older than 2,000 to 4,000 years are present within all the sequences, from the outermost
480 as well as from the innermost islet sites, but best stratigraphically organized and mostly
481 concentrated within the outermost excavation (A, D) deposits. This strongly suggests that the
482 earlier depocentres from which the islets have accreted laterally have settled close to the
483 ocean side, just behind the modern coastline. At Aramu, analysis of the age clast distribution
484 within Excavations A and B advocates for an earlier clast deposition at approximately 5,000
485 to 4,500 cal.yr. At Vainono, in the outermost islet sections (Excavations D and E), the
486 reported oldest clast ages range from about 4,000 to 3,000 years, thus supporting the
487 interpretation that initiation of the depocentres may have occurred about 1,000 year later,
488 compared to Aramu sites.

489 Along the lagoon sides, at Motu Aramu, in Excavation C, a number of younger clasts,
490 varying in age from $1,808 \pm 8$ (M26 bis) to 882 ± 5 cal.yr (M38), are mixed with significantly
491 older coral detritus, dated at $4,742 \pm 14$ (M28) to $4,037 \pm 15$ cal.yr (M37). Such an age
492 mixture is regarded as resulting from a severe reworking of about 4,000 yr-old deposits
493 during a later accretional phase of lagoonal islet borders, from about 1,800 cal.yr and
494 probably during the last century. Similarly, on Motu Vainono, in Excavation F (lagoon side),
495 clasts aged 2,500 cal.yr, found at top, and are mixed with some dated 1,600 to 900 cal.yr
496 located downhole. Accordingly, a reworking and resedimentation of the lagoon margins is

497 thought to have occurred presumably during the last century or earlier. Similarly, the ocean-
498 facing shingle ridges from which superficially deposited clasts yield ages ranging from about
499 70 (M19), 300 (M162, M164), 1,200 (M166), 2,500 (M21, M22, M24) to 3,500 (M167)
500 cal.yr, are relatively moving structures, occasionally suffering reshaping.

501 As a summary, Motu Aramu and Motu Vainono are believed to have started developing
502 between 5,000 and 4,500 (Fig. 13) and between 4,000 and 3,000 cal.yr (Fig. 14) respectively,
503 from depocentres settled close to the present coastline. The innermost islet areas, that have
504 probably emplaced about 500 to 1,000 years later, have suffered intense disturbance and
505 reworking, resulting in mixtures between older than 4,000 yr or than 1,500 yr clasts with
506 some younger than 1,800 cal.yr or aged 1,600–900 cal.yr respectively.

507 *4.5. Islet accretion rates*

508 The rate of islet accretion is obviously dependent on the frequency and intensity of wave-
509 surge events, serving as both constructional and erosional agents, which have impacted the
510 atoll over time, but also on the recovery rates of coral communities in the different source
511 zones. For example, the acroporid- and pocilloporid-dominated coral populations along the
512 upper outer-reef zone, i.e. the main source of coral-clasts, are growing at rates of several tens
513 of centimetres per year. Accordingly, these would be able to regenerate after 20 years in high-
514 energy settings (Y. Chancerelle, CRIOBE, pers. com.) at rates significantly higher than the
515 apparent recurrence period of islet building events averaging 50 to 100 years.

516 The accretion rates of atoll-rim islets and adjacent shingle ridges can be estimated based on
517 U/Th dating. Vertical accretion rates at Aramu and Vainonono sites range at around 2–3 to
518 6 cm per century respectively. Lateral accretion rates from the depocentres oceanwards range
519 between less than 1 m per century at Aramu and 2–2.5 m per century at Vainono.

520 Progradation towards the lagoon margins occurred at rates averaging 3–3.5 and 7–9 m per
521 century at Aramu and Vainono respectively. Shingle ridges have prograded to the ocean at
522 rates of 75–60 cm per century at Aramu and 200–250 cm per century at Vainono. These
523 values clearly take into account erosional and reworking phases, given major depositional
524 events are known to have occurred through instantaneous, high-intensity, low-frequency wave
525 surges.

526 **5. Discussion**

527 *5.1. Islet-accretion and sea-level change*

528 In the Tuamotu, the sea-level course during the mid to late Holocene times is relatively well
529 constrained based on dating of exposed coral heads, conglomerates and remnants of reef flats
530 (Pirazzoli and Montaggioni, 1986, 1988a, b) and elevated micro-atolls (Hallmann et al., 2018,
531 2020), especially, in the Gambier islands (Pirazzoli and Montaggioni, 1987) (Fig. 12b). After
532 a rapid postglacial rise (Bard et al., 1996), sea level reached and outpassed its present position
533 by approximately 6,000 cal.yr. Sea level continued to rise up irregularly to heights of about +
534 1m relative to pmsl, from 5,000 to 4,100 cal.yr, then remained stable over a period of about
535 600 years. From about 3,400 yr BP, sea level started to fall progressively (Hallmann et al.,
536 2020). Between 3,000 and 1,500 cal.yr, sea level dropped step by step eaching its modern
537 position during the last millennium (Pirazzoli and Montaggioni, 1987, 1986, 1988a, b;
538 Hallmann et al., 2018, 2020).

539 Throughout the tropics, the initiation and building of atoll-rim islets would have taken place
540 under different eustatic regimes: during a post-highstand sea-level fall (Woodroffe et al.,
541 1999; Dickinson, 2009; Kench et al., 2014a, b; Yasukochi et al., 2014), a rise in sea level
542 (Montaggioni et al., 2022) or stillstands higher than the present (McLean et al., 1978; Stoddart

543 et al., 1978; Woodroffe and Morrison, 2001; Kench et al., 2014a, b, 2020; Yamano et al.,
544 2014). For example, in the north-west Tuamotu, on Takapoto Atoll, motu would have
545 developed during the sea-level drop phase from 2,500 yr BP to present (Montaggioni et al.,
546 2018, 2019). However, there is no evidence that the position of sea level during its course has
547 played a significant role in atoll-islet building.

548 *5.2. Timing and mode of islet-accretion*

549 Radiometric dating of both islet foundations, i.e. conglomerate platforms, and overlying
550 unconsolidated islet deposits, reveal that all these features have deposited over the last 5,000
551 years, from the mid to late Holocene (Figs. 10, 12a). These findings clearly indicate that the
552 emplacement of Motu Aramu and Motu Vainono and their conglomerate foundations has
553 taken place throughout the whole mid-late Holocene sea-level cycle. Atoll-rim nourishment
554 by coral detritus on Aramu sites would have begun from about 5,000 cal.yr as sea-level was
555 rising. Since the top surfaces of conglomerate platforms reach locally elevations of up to
556 1.00 m, it is obvious that their present-day position cannot be related to any higher sea
557 stillstand during the mid-late Holocene (Montaggioni et al., 2021). The timing of deposition
558 of rubble sheets from which conglomerates have formed is consistent with previous data
559 gained from a number of other French Polynesian islands. These revealed that deposition of
560 conglomerates has mostly taken place between 6,000 cal.yr to present, peaking between 4,000
561 and 1,000 cal.yr. It is instructive to recall that both deposition and consolidation of
562 conglomeratic material and accretion of overlying atoll-rim islets were demonstrated to have
563 occurred locally simultaneously. In other words, there have been interplays between
564 deposition of antecedent rubble sheets behind conglomerate pavements and islet building
565 (Montaggioni et al., 2021), as currently observed on Motu Tekava (Fig. 15).

566 The mode of islet development was identical on both Aramu and Vainono sites as illustrated
567 by isochron distribution (Figs. 13, 14). Islet accretion has been initiated from nodal points, i.e.
568 depocentres, as previously observed on Takapoto Atoll, north-west Tuamotu (Montaggioni et
569 al., 2019). However, there is no direct evidence that all islets present around the atoll rim have
570 accreted similarly, from prograding and final coalescence of a series of nearby isolated
571 depocentres, especially, in rim areas on which rest continuous, elongated islets, spreading
572 over several kilometres, as observed in the north-east rim. However, based on the present-day
573 physiography of the south-west rim, typified by alternations of small, isolated motu separated
574 by a series of functioning hoas, the accretional islet model involving prograding depocentres is
575 thought to be realistic (Fig. 16).

576 Starting at around 5,000 cal.yr, the first islet accretional event ended 4,000 yr ago at Aramu
577 sites (Fig. 12a). At the same time, islet deposition was initiated on Vainono reef-rim while sea
578 level peaked at +1m above pmsl (Fig. 12b). At Aramu, the postulated non-depositional
579 episode between 4,000 and 1,800 cal.yr, occurred during the about 600 yr-long high stillstand
580 and lasted up to one millennium. The second and final accretional event took place during the
581 last 1,800 years as sea level dropped to its modern position. Correlatively, over the last 4,000
582 years, at Vainono sites, coral clasts were supplied continuously (Fig. 12a), during both the
583 high sea stand and the following drop (Fig. 12b). Strong discrepancies in accretional histories
584 between two nearby islets from a same atoll clearly support the fact that sea-level dynamics is
585 not the major driver of atoll islet building in French Polynesia, contrary to some previous
586 interpretations in other reef provinces (Perry et al., 2011; Kench et al., 2014b, 2020), even if
587 there is apparently a close correspondence between the course of sea level and islet
588 nourishment by coral detritus on Motu Vainono. In fact, atoll-islet building seems to have
589 been no longer dependent on sea-level dynamics. Fluctuations of some tens of centimetres

590 have not been able to significantly influence the depositional islet patterns in regions
591 periodically subjected to storm wave surges. During the last 6,000 years, the only required
592 control of sea-level was the maintenance of a position close to present throughout the
593 complete cycle of islet accretion, thus facilitating supply of coral detritus from adjacent
594 forereef zones. However, it is noteworthy that initiation of islet accretion can operate even
595 when sea-level was several tens of metres below its present position during the postglacial
596 rising sea-level course, as observed on Rangiroa Atoll, northwestern Tuamotu. In such a case,
597 rubble deposition was interpreted as resulting from occasional tsunamis (Montaggioni et al.,
598 2022).

599 *5.3. Islet accretion: the key role of marine hazard events*

600 Natural hazards, including winter storms, cyclones, distant-source swells, tropical low waves
601 and tsunamis, are known to be drivers of formation and shaping of low-lying reef islands
602 (Woodroffe, 2008; Canavesio, 2019; Montaggioni, 2018, 2019 and references herein; Duvat
603 et al., 2020). Especially, most of them are able to move gravels and large boulders from
604 adjacent reef sources across atoll rims. Unfortunately, it is not possible to identify the
605 respective role of these different islet-building agents in the sedimentary record, especially
606 beyond the historical period due to the lack of record. Only assumptions can be made, based
607 on the frequency of each agent. In the Tuamotu, tropical lows and tsunamis usually produce
608 low intensity impacts, unlikely to be recorded in the sedimentary archives. Only the end-
609 products of tropical cyclones and extreme distant-source events are most likely to be
610 encapsulated into islet-sequences. The end-products are the result of both constructional and
611 erosional processes. The morphological and stratigraphical attributes of these products, i.e.
612 islets and associated shingle ridges and sheets, can provide valuable information on past

613 regional storm dynamics, i.e. frequency and intensity of wave surges impacting islands (Nott,
614 2011; Montaggioni, 2018, 2019).

615 At reef settings and, particularly, in French Polynesia, coral clasts and finer skeletal grains
616 deposited onto reef rims are known to have originated dominantly from the adjacent upper
617 forereef zones, mostly extracted from coral communities living at depths less than 25 m
618 (Laboute, 1985; Harmelin-Vivien and Laboute, 1986; Harmelin-Vivien, 1994) and partly
619 from coral communities living in outer reef-flat and lagoonal environments (Adjas, 1988), as
620 shown from taxonomic analysis of coral clasts and composition of groove sand pockets and
621 lagoonal deposits.

622 In the tropical Pacific, biogeochemical records and climate modelling indicated that mid
623 Holocene was a time of reduced ENSO variability (Clement et al., 2000; Koutavas et al., 2006;
624 Zhang et al., 2014; Emile-Geay et al., 2016; Lawman et al., 2020). Decreased ENSO frequency
625 took place at times in the last few thousand years (Emile-Geay et al., 2015). Cyclone-related
626 rainfall intensity increases after 4,200 yr BP, as well as at 3,200 and 2,000 yr BP in South
627 America (Conroy et al., 2008; Emile-Geay et al., 2015). In the Tuamotu, occurrences of
628 extreme marine wave hazards prior to the mid-nineteenth century are poorly documented
629 (Laurent and Varney, 2014). A comprehensive survey of extreme hydrodynamic events, based
630 on radiometric dating of mega-boulders was published by Lau et al., (2016), focusing only on
631 the central Tuamotu region. Boulder age suggested that 5–9 extreme marine events occurred
632 between 1200 and 1900 AD, with 3–5 events over the seventeenth and nineteenth centuries.
633 In the absence of mega-boulders on South-Marutea, using the U/Th clast-age database
634 provided herein can contribute to define the number of significant wave-surge events that
635 have struck the south-eastern Tuamotu end over the last 5,000 years. A total of 86 are
636 identified during this time span (Fig. 17), taking into account possible age overlapping

637 between samples as recognized from U/Th error range. The number of events recorded per
638 century ranges from zero to 5. It is evident that a database including a relatively limited
639 number of dated specimens cannot provide a comprehensive record of past hazard events.
640 Sedimentary sequences are well known to be truncated records of the depositional history of a
641 given environment (Sadler, 1999). Especially, traces of marine hydrodynamic events are
642 frequently poorly or incompletely preserved in atoll-rim ridge and beach stratigraphies. In
643 addition, defining the number of storm events recorded by any islet sequence may be biased
644 by sampling procedures including incomplete age determination (Nott, 2011). However,
645 assuming that an average of 1 to 5 cyclonic events per century with a mean recurrence time of
646 50 years is consistent with previous historical estimates (Dupon, 1987; Laurent and Varney,
647 2014; Lau et al., 2016), our data is thought to preserve a reliable picture of marine wave-surge
648 event history in the remote south-eastern Tuamotu at a centennial to millennial-scale
649 frequency over the last five millennia (Fig. 17). The historical period, i.e. the last two
650 centuries, includes 6 hazard events, respectively occurring in around 1817, 1914, 1949, 1971,
651 1975, and 1980. The last two younger samples (M138, M65) were probably projected onto
652 the atoll rim during the passage of cyclone Frances (February 1976) and cyclone Nano
653 (January 1983). Related to the year 1971 (M53), there is no direct record of a marine hazard
654 event within the Gambier region; the only record is that of a moderate tropical depression
655 (Vivienne) passed close through the Austral Archipelago, far from the Gambier. Similarly,
656 there is no evidence of a noticeable cyclone activity from 1914 (M44) to 1949 (M19) within
657 the entire Tuamotu region. As for the nineteenth century, only one sample (M18: 1817 ± 3
658 AD) accounts for a storm event at South-Marutea, but not validated in the historical registry.
659 It is noteworthy, as shown by Duvat et al. (2020), projection of coral clasts from outer reef
660 slopes to adjacent atoll rims can occur during tropical lows, under moderate hydrodynamical
661 conditions, without the involvement of any extreme hazard event. Such relatively low-wave

662 energy events do not get enough attention to be listed as part of significantly human-
663 impacting climate phenomena.

664 Throughout pre-European historical times, from the beginning of the Common Era to the
665 eighteenth century, clast dating allows a total of 35 hazard events distributed into three main
666 periods of active storminess to be identified (Fig. 17): from the 18th to 15th, from the 12th to
667 the 7th and from the 3rd to the 2nd centuries, apparently separated by two quiescent intervals
668 between the 12th–15th and the 7th–3rd centuries respectively. Each active interval appears to
669 have been separated from the next by a non-deposition interlude longer than 200 years,
670 although this last event may also have incorporated islet-damaging phases.

671 The regional pattern successively shows a continuous, higher storm activity from about the
672 7th to the 12th centuries, broadly encompassing the Medieval Warm Period, followed by a
673 brief decrease in storminess prior to the 15th century, and finally by a recovery of storm
674 activity over a period (15th–19th centuries) apparently coinciding with the Little Ice Age.
675 This pattern is regarded as consistent with reconstructed variability of past cyclone dynamics
676 across the central south Pacific, controlled by a large shift of the Pacific Walker circulation
677 (Bramante et al., 2020). Similarly, weakening of storminess over earlier, brief intervals within
678 the Common Era could be caused by repeated migrations of the Walker circulation, thus
679 mitigating the activity of ENSO events.

680 Throughout the three millennia-long period preceding the Common Era, 51 hazard
681 occurrences are recorded, with a frequency of one to five per century (Fig. 17) as numerous as
682 those observed during the 2,000 yr-long Common Era. However, the most striking feature is
683 the absence of coral clast samples aged less than 4,000 cal.yr and more than 2,000 years old,
684 collected at Aramu sites, while present in large numbers (17 counted samples) on Motu

685 Vainono (Fig. 12a). Several alternative explanations could be put forward. The absence of the
686 relevant samples could be due to an artefact of collection or to suppression of the 4,000–
687 2,000 yr time-specific coral-clast stocks due to intensive marine erosional phase. Another
688 explanation could be found in the location of Motu Aramu, north of the atoll rim, likely to be
689 less exposed to some extreme marine hazard events, such as distant-source wave surges, that
690 come from the deep South Pacific, when compared to Vainono sites. Interestingly, the non-
691 depositional episode at Aramu sites coincides with intervals of a relatively low-baseline
692 cyclogenesis activity (Fig. 12c, d) and more sustained south-east trade winds in connection
693 with an attenuation of ENSO amplitude by about 20 % to up to 60 % within the 5,000- to
694 2,000-yr band. This decrease in ENSO activity was documented by a number of sedimentary
695 data collected from the central and eastern Pacific: foraminiferal records in the eastern Pacific
696 basinal sediments (Koutouvas et al., 2006), coral archives from Line Islands in the central
697 tropical Pacific (McGregor et al., 2013; Grothe et al., 2019), grain-size analysis of a
698 sedimentary core from Junco Crater Lake in Galapagos (Conroy et al., 2008) and sediment
699 laminae light-intensity in a core from Laguna Pallcacocha in Ecuador (Moy et al., 2002).
700 Assuming that cyclogenesis was at its lowest level during this time span, deposition of high
701 coral-clast volumes at north-facing Aramu sites may be caused by other marine hazards,
702 including trade-wind-generated winter storms. By contrast, at south-facing Vainono sites, islet
703 deposits emplaced during the 5,000–2,000 yr-interval may have been supplied by distant-
704 source, austral swells.

705 As a summary, the age database provided herein seems to reliably reflect the variability of
706 ENSO frequency events at centennial- to millennial scales through the number of recorded
707 wave-surge events in the south-eastern Tuamotu end.

708 *5.4. Conceptual model of atoll-rim islet building*

709 A number of atoll-islet building models have been already described from some cyclone-
710 prone or not-prone reef settings, based on reconstruction of low-lying, reef-rim and lagoon-
711 islet development history, in the Indian and Pacific oceans. (Stoddart et al., 1978; Chivas et
712 al., 1986; Richmond, 1992; McLean and Woodroffe, 1994; Woodroffe et al., 1999; Kench et
713 al., 2005, 2012, 2014a, b, 2020; Barry et al., 2007; Yamano et al., 2014; Montaggioni et al.,
714 2018, 2019; Liang et al., 2022). The initial baseline conditions required for optimal islet
715 building and sustainability were defined as follows: (1) hard antecedent substrates, such as
716 reef flats, conglomerate platforms, are usually prerequisite for islet settlement; (2) substrates
717 have to be close or at sea level at the time of islet initiation; (3) maintenance of growing islets
718 within the range of the sea-level course; (4) availability of sediment producers at close
719 proximity; (5) recurrence of marine, high to low-intensity hazard events.

720 At South-Marutea, on both Motu Aramu and Motu Vainono, islet development occurred over
721 the last 5,000 years while sea level followed a complete trajectory from rising to about +1 m
722 to falling close to its present position (Fig. 12b). Conglomerate platforms, locally as high as
723 +1.10 m relative to pmsl, started to form at around 5,000 cal.yr (Figs. 13, 14) during the rise
724 in sea level. The widespread conglomerate deposits, locally consisting of one single bed,
725 gives evidence of the occurrence of high-intensity, wave-surge events at a starting time of
726 reduced ENSO activity in the central south Pacific. This strongly suggests that non-cyclonic
727 events could occasionally play a dominant role in atoll-islet shaping. Contrary to Takapoto
728 Atoll, northern Tuamotu, on which depocentres were initiated at the middle parts of the atoll-
729 reef rims (Montaggioni et al., 2019), on South-Makatea, incipient depocentres settled over
730 conglomerate pavements close to the outer atoll reef-rim margins, just behind the modern
731 reef-flat zones (Fig. 16). Depocentres as originally preferential sites of clast deposition

732 formed isolated, probably subcircular to elongated features as similar in shape to smaller islets
733 at present found along the south-western atoll rim (Fig. 1b). From 4,000 cal.yr, the
734 depocentres have prograded seawards and lagoonwards at rates of several metres per century.
735 It is noteworthy that conglomerate platforms and islets were continuously being formed until
736 the present. At Aramu, the islet landscape was shaped in two stages, between 5,000 and
737 4,000 cal.yr and 2,000 cal.yr to present. At Vainono, the major shaping phases occurred from
738 4,000 to 3,000 cal.yr during the higher sea stillstand. By contrast, at Motu Aramu, the earlier
739 development episode lasted throughout the rising sea-level phase, but development restarted
740 only at the time while sea level was falling. This means that the position of sea level was not a
741 major determinant of islet building. Islet nourishment took place at sea-level trajectory. In
742 particular, the present findings show that gradual sea-level drop is not a general promoter of
743 islet accretion, as pointed out by Dickinson (2004). The key controls of islet development, at
744 least in the studied sites, appear to be changes in intensity and frequency of marine hazard
745 events rather than sea-level fluctuations over time.

746 The islet accretionary model obtained from South-Marutea Atoll typically refers to the
747 ‘regular lagooward accretion’ model described by Woodroffe et al. (1999) in which accretion
748 begins from depocentres located close to oceanwards shore and then incrementally extends
749 preferentially lagoonwards through time. This model differs markedly from that established at
750 Takapoto, confirming that islet shaping patterns are complex and can vary significantly from
751 site to site.

752 *5.5. Projected future climate regime and its effects in the south-eastern Tuamotu atoll region*

753 In the last decades, warming peak during several ENSO occurrences has moved from the
754 eastern to central Pacific on 100° longitude, accompanied by an increasing amplitude and
755 decadal variability of ENSO events and strengthening of trade winds (Freund et al., 2019;

756 Grothe et al., 2019). Currently, anthropogenic forcings are postulated to affect global climate,
757 especially in the Pacific tropics, altering the geographical distribution, frequency and intensity
758 of storms (Cai et al., 2021) and strengthening trade-winds (Collins et al., 2010). Storminess,
759 including cyclogenesis, would potentially be increased in the central Pacific, with rising sea
760 surface temperatures and weakening of vertical wind shear predicted for the end of the 21st
761 century (Bramante et al., 2020). For the late 20th century, climate observations and
762 reconstructions revealed a significant increase in the central Pacific ENSO activity, at a rate of
763 2.5 to 9 events per 20 years. Similarly, in response to increased intensity of the ENSO regime
764 in the next decades, cyclones are expected to become more frequent (about 20–40 %) during
765 El Niño phases, but significantly less frequent during La Niña episodes (Chand et al., 2017).

766 Cyclones, known as one of the major causes of coral decline around the world (Harmelin-
767 Vivien, 1994; De'ath et al., 2012), are expected to become potentially more destructive with
768 ocean warming (Dixon et al., 2022). Knutson et al. (2020) reviewed knowledge regarding
769 model predictions of global cyclone activity in response to human-induced warming. At 2 °C
770 warmer than the pre-industrial times, global cyclogenesis will become more intense. In the
771 central South Pacific, ENSO events tend to move the mean cyclone genesis loci eastwards,
772 potentially resulting in cyclone influence in French Polynesia (Bramante et al., 2020). South
773 poleward migration 1° latitude (about 100 km) per decade (Kossin et al., 2014; Studholme et
774 al., 2022) may increase cyclone frequency in the remote south-eastern Tuamotu region.

775 However, with the projected expansion of the tropical climate zone, there will have a potential
776 reduction of cyclone activity (Bramante et al., 2020).

777 Large waves generated by storms and cyclones and wave amplification are significant hazards
778 in the tropical Pacific. The largest extreme wave heights are active within the latitudinal 15°–
779 25° south band. Model predictions indicated that the doubling of extreme El Niño frequency

780 in the next decades would have drastic effects on wave climate, particularly when combined
781 with sea-level rise (Stephen and Ramsay, 2014). Median extreme wave heights across the
782 entire south Pacific range from 7 to 11 m (Stephen and Ramsay, 2014) and, more specifically,
783 in French Polynesia (Canavesio, 2014).

784 Unfortunately, there is no available region-specific model projections of the cyclone behavior
785 in French Polynesia for the mid to late 21st century. However, some general trends, in part
786 speculative, emerge, based on climate models from the south-western Pacific (Knutson et al.,
787 2020) that could be applied to French Polynesia. Frequency of severe category 4 and 5 and
788 lower category cyclone as well could decrease by about 15–20 %. Average cyclone intensity
789 is expected to increase 2 %, at medium-to-high confidence levels. The resilience of coral reefs
790 would be more severely threatened by increasing cyclone intensity. However, wave surges,
791 generated by cyclones or other extreme marine hazard events, are known to impact patchily
792 coral reefs (Done, 1992; Harmelin-Vivien, 1994; Cheal et al., 2002, 2017). This may result in
793 preservation of undamaged coral-colonized zones from which abundance of coral
794 communities can recover, usually 10–20 years after impacts (Hamelin-Vivien, 1994; Halford
795 et al., 2004). In a number of locations, coral populations need particularly long periods for
796 recovery after an extreme cyclone damage. In the Tuamotu, recovery of coral communities is
797 estimated to average about 70 years (Cheal et al., 2017).

798 Sea-level rise projections suggest that globally the rise would be around 0.50 m under
799 optimistic scenarios and outpass 1.30 m under pessimistic ones (Horton et al., 2020). These
800 predictions are in line with expectations of sea-level rise in the Tuamotu, where the rise in sea
801 level would be about 0.80 to 1 m higher relative to 2010 at the end of the 21st century
802 (Botella, 2015). Accordingly, sea-level rise will result in higher storm flooding levels, but

803 probably will play a subordinate role compared to marine hazards able to generate swells as
804 high as 12 m (Dalmalian et al., 2014).

805 Other disturbances to which coral reefs are exposed will be amplified (Cheal et al., 2017):
806 loss of coral calcification potential (D’Olivio et al., 2019; Cornwall et al., 2021) due to
807 increasing ocean acidification in relation to higher atmospheric CO₂ content; increasing sea
808 surface temperatures; especially long duration (several months) of marine heat waves
809 (Holbrook et al., 2019), some resulting in more coral bleaching and mortality episodes as
810 those recorded during 1982–1983 (Hoegh-Gulberg and Salvat 1995), 1997–1998 (Mumby et
811 al., 2001), and 2015–2016 in French Polynesia (Hédouin et al., 2020). Interacting effects of
812 various disturbances may exacerbate lethal impacts and will increase the vulnerability of coral
813 reefs to long-term degradation. All these will alter the capacity of coral communities to grow
814 and thus diminish coral cover.

815 As a summary, in the south-eastern Tuamotu end, potential future change in extreme ENSO
816 events may have profound impacts on atoll islet maintenance. Projected global increases in
817 ENSO strength, cyclone intensity, sea level, combined with pH drop and decrease in coral
818 recovery rate, will act to further enhance the impacts of future storm wave surge risk. Based
819 on the review by Knutson et al. (2020), it appears obvious that the combined effects of rapid
820 sea-level rise and increased cyclone activity will result in higher average storm inundation
821 levels, assuming all other factors equal. Cyclone-generated inundation events would be less
822 frequent, about a maximum of 1–2 per century, maybe less, but more destructive. Regarding
823 the other marine hazard events, there is no specific available information about their
824 behaviour over the next decades. Global warming will lead to strengthening of trade winds in
825 the Pacific (Li et al., 2019) and of austral, distant-source swells. Under pessimistic sea-level
826 rise scenarios, the inundated areas by distant swell surges would increase by up to 90 % by

827 2100, as modelled in Fiji (Wandress et al., 2020). Given different locations will likely respond
828 differentially, according to exposure to the arrival direction of marine hazards (Damlamian et
829 al., 2013), there is a need for assessment of site-specific impacts. On South-Marutea Atoll, the
830 present findings show that the north-eastern and south-eastern reef-rim sectors may be most
831 susceptible to be impacted and to suffer damage than the other areas. However, it is difficult
832 to assess the carbonate budget of atoll islets, increase or decrease, in response to climate
833 change.

834 *5.6. Lessons from the past.*

835 How may reconstructing the accretional mode of atoll-islets aid to illuminate their future
836 behaviour in the face of changing climate? First, the atoll-islet development at South-Marutea
837 occurred over the past 5,000 years, irrespective of sea-level position, as sea level rose about 1
838 m from 5,000 to 3,500 cal.yr then dropped close to its present position from 3,500 cal.yr to
839 the last centuries. This suggests that sea level was neutral, did not and will not play a
840 significant role in restricting or promoting islet accretion. If correct, if sea level will rise to up
841 to 1 m at the end of the 21st century, the position of sea level will not contribute to the
842 maintenance or destruction of atoll islets in the region considered. Second, according to
843 observations over the past millennia and historical records, future ENSO variability will
844 promote increasing cyclone activity, with stronger category cyclones, but their frequency will
845 be similar to the recent past, not exceeding 1 to 5 per century. Similarly, as emphasized by
846 Lau et al. (2016), if sea surface temperatures will increase through the current century as
847 projected by IPCC, higher temperatures will be favourable to increasing cyclogenesis and
848 storminess in the central South Pacific. However, the way in which atoll islets will respond in
849 the future is difficult to be clearly appreciated to uncertainties in the effects of cyclone impact.
850 A same cyclone is known to both contribute to building and destruction of low-lying reef

851 islets from a same atoll according to changing trajectories (Scoffin, 1993; Etienne, 2012).
852 Probably, such as during the last millennia, the final budget will be accretional even if
853 flooding episodes will be more frequent in response to increasing cyclone activity. The actual
854 unknown comes from how reefal coral communities as sources of coral clasts will react to
855 increases in water temperatures and ocean acidification. Any drop in coral cover and any shift
856 to non-constructive communities will disturb or preclude coral-clast inputs to islets. As
857 previously suggested (Montaggioni et al., 2021), it is noteworthy that conglomerate platforms,
858 particularly in areas where these exceed 1 m in elevation, may contribute to the persistence of
859 low-lying islets.

860 **6. Conclusions**

861 Several points arise from the chronostratigraphical analysis of rim islets from South-Marutea
862 Atoll.

863 Islet lithostratigraphy is characterized by alternations of unorganized, mixed coral boulder to
864 pebble and skeletal sand beds. Coarser-grained deposits consist dominantly of individual
865 acroporid and pocilloporid colonies, together with subordinate merulinid and poritid detritus
866 as known to house the adjacent forereef zones. Sand-grained sediments are mixtures of
867 various reef-dwelling carbonate producers, especially, larger soritid foraminifera. As
868 supported by substantial clast age inversion and local interbedding of cobbles and pebbles,
869 substantial sediment reworking and redeposition took place at lagoonside settings, hence
870 expressing occasional intense wave agitation of lagoonal waters.

871 Contrary to Takapoto atoll islets in the north-western Tuamotu, emplaced during the last
872 2,500 years as sea level was falling (Montaggioni et al., 2019), islet initiation at South-
873 Makatea sites occurred from about 5,000 cal.yr. Islet development apparently occurred

874 independently of the mid to late Holocene sea-level course. In northern sectors, islet accretion
875 slowed down significantly from 4,000 to 2,000 cal.yr, likely in response to weakening El
876 Niño activity. By contrast, in reef-rim areas oriented to due south, islet building acted
877 continuously and even peaked in the 4,000–2,000 cal.yr interval, may be in response to
878 increasing storminess from the deep south regions. Between 5,000 and 3,000 cal.yr, islet
879 accretion responded contrastingly at the local scales, very active on the southern atoll-rim and
880 ineffective in the northern areas. Availability rate of coral-dominated sediment stocks and
881 frequency and intensity of marine hazard events are regarded as the key factors for islet
882 building.

883 The clast-age distributional pattern suggests that, over the last 5,000 years, high-energy wave
884 events occurred at frequency of one to five per century, in accordance with the historical
885 records in French Polynesia, occasionally interrupted by 200 to 300 yr-long quiescence times.
886 The outer shingle ridges may have been reshaped during the last millennium, at least ten
887 times, based on clast dating.

888 The evolution of atoll-rim islets on South-Marutea in the future is difficult to predict, mainly,
889 because model climate projections are missing in the considered region. In the next few
890 decades, based on non-deposition of mega-boulders on the atoll over the last centuries, it is
891 unlikely that extreme marine hazard events will impact the atoll. Later, as the zone of cyclone
892 influence is moving polewards and cyclone intensity is increasing, but frequency decreasing,
893 South-Marutea and the nearby Gambier Island Group could possibly be impacted by stronger,
894 but fewer cyclones prior to the end of the 21st century. Of course, actual damaging effects on
895 islets would depend upon the arrival direction and heights of generated wave surges and, as
896 recently, the southern rim sectors would risk to be most disturbed than other. A future sea
897 level at about +1m relative to present would not increase the disturbing effects of storms

898 predicted to generate waves of up to 10 m high. Assuming a return time of 50 to 100 years for
899 stronger storm events and a predicted coral recovery time averaging 70 years, the potential
900 detritus stocks used to rebuild islets may be reduced drastically over a few centuries. Up to 1
901 m high, conglomerate platforms could serve as natural flood defense and thus contribute to
902 islet durability.

903 **Acknowledgements**

904 This work was partly supported by the POLYCONE (Integrated and Sustainable Regulation of
905 Cones in Eastern Polynesia) research project. Field work was conducted from 20th November
906 to 26th November 2021, by BS, GP and JMZ. BS conceived the original project, through
907 discussions and exchanges with LFM. U/Th datations were performed by EPB. LFM, the
908 corresponding author, was in charge of interpreting all the collected data and of writing the
909 manuscript. He leads the manuscript development, in collaboration with all co-authors. BS
910 and GP provided field pictures. Figures were conceived by LFM and BM-G and drawn by
911 BM-G.

912 The authors warmly thank the following colleagues for their contribution, particularly,
913 Tamatoa Bambridge, coordinator of POLYCONE at the French Polynesian level. Field work has
914 benefited from logistical and financial support and help by Robert Wan, the owner of South-
915 Marutea Atoll, Johnny-John R. Atger-Wan, his atoll manager. The atoll team members, Mike
916 Tahai and Claudio Temauri, are acknowledged for effective engineering of the excavations in
917 Aramu and Vainono atoll sites. Many thanks to the anonymous reviewers whose comments
918 have significantly helped improving an early version of the manuscript. The three anonymous
919 reviewers and Editor-in-Chief Xinyu Wang are warmly thanked for their helpful criticism and
920 suggestions for improvement.

921 **Declaration of competing interest**

922 The authors declare to have no competing interest.

1239 **Figure captions**

1240 Fig. 1. (a) Location map of South-Marutea Atoll in the Gambier Island Group, south-eastern
 1241 Tuamotu Archipelago, French Polynesia, central south Pacific; (b) Google Earth map of
 1242 South-Marutea Atoll showing the location of the studied site areas (boxes): Motu Aramu (see
 1243 Fig. 1c), with location of excavations (star symbols); Motu Vainono (see Fig. 1d), with
 1244 location of excavations (star symbols), and ocean-facing shingle-ridge profile (Fig. 4a); Motu
 1245 Aranui (see Fig. 1e) with location of dated coral-clast samples (open circle symbols); Motu
 1246 Oire (see Fig. 1f) with location of outer shingle-ridge profile (Fig. 4b); Motu Tekava (see Fig.
 1247 1g) with location of dated coral-clast samples (open-circle symbols).

1248 Fig. 2. Wind rose for Mangareva site – altitude: +91 m; 23°07'48" S, 134°57'55" W –,
 1249 Gambier island, south-eastern Tuamotu, showing the dominant wind directions from the north
 1250 and north-east sectors. Based on records from Météo-France and reprinted with the
 1251 permission of Météo-France. Data duplication and redistribution are prohibited except with
 1252 the prior agreement of Météo-France.

1253 Fig. 3. Tracks of some tropical cyclones within the south-eastern Tuamotu region since the
 1254 beginning of the twentieth century. Modified from Laurent and Varney (2014).

1255 Fig. 4. Transverse topographic profiles across outer shingle ridges of the reef- rim and islet,
 1256 South-Marutea Atoll, showing the different geomorphic components. (a) south-east of Motu

1257 Vainono – see fig. 1 d for location –; (b) west of Motu Oire – see fig. 1f for location. The
1258 location of the dated coral-clast samples is indicated. Ages are given in years before present
1259 (before 2022). See Table 1 for dating parameters.

1260 Fig. 5. Conglomerate platforms from the reef rim, South-Marutea Atoll; (a) overview of the
1261 two-layer, 1.10 m thick conglomerate pavement, hoa side, south of Motu Oire; (b) close-up
1262 picture of the 1.20 m thick conglomerate bed, reef-flat side, west of Motu Oire – see fig. 1f
1263 for location –; (c) close-up picture of the two-layer, 1.20 m thick conglomerate pavement,
1264 west of Motu Aranui – see fig. 1b and 1e for location. The location of the dated coral-clast
1265 samples is indicated. Ages are given in years before 2022. See Table 1 for details on dating
1266 parameters.

1267 Fig. 6. Aerial view of the south-south-east side of Motu Vainono, southern reef-rim area of
1268 South-Marutea Atoll, showing, from the ocean landwards, the reef-flat zone, about 200 m
1269 wide, the conglomerate-platform front line (brown colour), the outer beach (white colour), the
1270 successive shingle ridges (grey colour) and the vegetation-covered islet bench. See fig. 1d for
1271 location and fig. 4a for geomorphic profile.

1272 Fig. 7. Close-up picture of the upper part of the ocean-facing shingle ridge, composed of
1273 blocky, pocilloporid and acroporid coral clasts, south-east of Motu Vainono, southern reef-
1274 rim area, South-Marutea Atoll.

1275 Fig. 8. Transverse topographic profile across Motu Aramu, north-north-eastern reef-rim area,
1276 South-Marutea Atoll, showing the location and lithostratigraphy of excavations A, B and C,
1277 with location and radiometric ages of the dated coral-clast samples. See figure 1b, c for
1278 location of excavations and Table 1 for dating parameters. Ages are given in calendar years

1279 – relative to 2022, the year of analysis. See Table 1 (Supplementary material) for details on
1280 dating parameters. WL: water-table level.

1281 Fig. 9. Transverse topographic profile across Motu Vainono, south-south-western rim area,
1282 South-Marutea Atoll, showing the location and lithostratigraphy of excavations D, E and F,
1283 with location and radiometric ages of the dated coral-clast samples. See fig. 1b, d for location
1284 of excavations and Table 1 for dating parameters. Ages are given in calendar years (relative to
1285 2022, the year of analysis). See Table 1 (Supplementary material) for details on dating
1286 parameters. WL: water-table level.

1287 Fig. 10. Plot of the U/Th dated coral-clast samples *versus* their respective topographic or
1288 stratigraphic location across or within the studied motu sites – see figs. 1b to 1g, 4a, 4b, 8 and
1289 9 for location. Ages are given in calendar years (relative to 2022, the year of analysis).
1290 Vainono excavations: note the decreasing age trend from the ocean-facing islet side
1291 lagoonwards. Aramu excavations: note a similar, but less continuous age decreasing trend,
1292 due to both younger clast deposits at the ocean-facing islet site and hiatus in clast supply
1293 between 4,000 and 2,000 calendar yr.

1294 Fig. 11. Views of the internal structure and lithostratigraphy of the sedimentary piles, from
1295 excavations through Motu Aramu and Motu Vainono, respectively; (a) Excavation A, ocean-
1296 facing islet margin, showing the upper 1 m section, composed of pebble-dominated, sand
1297 supported material; (b) Excavation C, lagoon-facing islet margin, showing the whole section,
1298 composed of sand-dominated, pebble-rich sediments, overtopped by a dark, organic bed. The
1299 level of the water table is about 0.20 m above the excavation bottom; (c) excavation D, ocean-
1300 facing islet margin, showing the lower section composed of cobble-to pebble-dominated, sand
1301 to pebble-supported detritus. The level of the water table is about 0.10 m above the

1302 excavation bottom; (d) excavation F, lagoon-facing margin, showing the whole section,
1303 composed of sand-dominated, pebble-rich material. The top section exhibits an about 0.50 m
1304 thick organic deposit. The level of the water table is about 0.25 m above the excavation
1305 bottom.

1306 Fig. 12. Relationships between the main islet accretional phases on South-Marutea Atoll,
1307 regional changes in sea level and in ENSO-controlled cyclogenesis over the past 5,000 years;
1308 (a) accretional phases at Aramu and Vainono sites, based on the number of dated coral-clast
1309 samples; (b) regional sea level curve, modified from Pirazzoli and Montaggioni (1987), and
1310 Hallmann et al. (2020); (c) record of ENSO activity based on measurement of sand percentage
1311 in Juna Crater Lake, Galapagos, modified from Conroy et al., 2008; (d) record of ENSO
1312 activity based on sediment laminae light-intensity from a core extracted from Laguna
1313 Pallcacocha, Ecuador, modified from Moy et al., 2002.

1314 Fig. 13. Cross-section through Motu Aramu, north-eastern rim area, South-Marutea Atoll,
1315 showing the successive phases of islet accretion. The dashed lines refer to accretion
1316 isochrons, given in years before present and are defined from time intervals between the dated
1317 coral-clast samples. Are indicated the location of the excavation and of the dated coral
1318 samples extracted from conglomerates.

1319 Fig. 14. Cross-section through Motu Vainono, southern rim area, South-Marutea Atoll,
1320 showing the successive phases of islet accretion. The dashed lines refer to accretion
1321 isochrons, given in years before present and are defined from time intervals between the dated
1322 coral-clast samples. The location of the excavation and of the dated coral samples extracted
1323 from conglomerates are indicated.

1324 Fig. 15. View of the south-east-facing, outer shingle ridge, Motu Tekava, east-south-eastern
 1325 rim area, South-Marutea Atoll, clearly showing that coral-clast deposits are in process of
 1326 rapid cementation, probably under the control of percolating vadose fresh waters.

1327 Fig. 16. Planimetric reconstruction of Motu Aramu (north-eastern rim area) and Motu
 1328 Vainono (southern rim area), South-Marutea Atoll, showing the expected successive phases
 1329 of islet accretion over the last 5,000 years. Isochrons delineate the expected surface areas of
 1330 initial depocentres and incipient islets through time. Interrogation points relate to the younger
 1331 accretional sections from which there are insufficient age records. From 5,000 to about 3,000
 1332 calendar yr at Aramu and from 5,000 to about 1,500 calendar yr at Vainono, spaces between
 1333 adjacent depocentres and incipient islets are interpreted to have acted as hoas prior to have
 1334 been sealed.

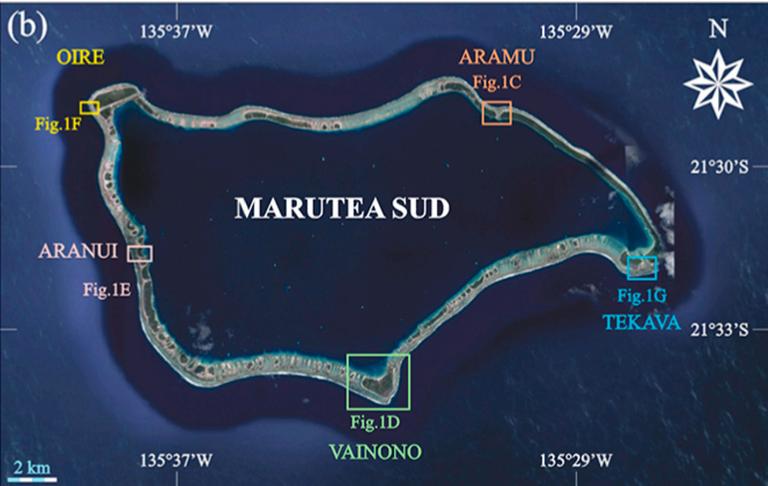

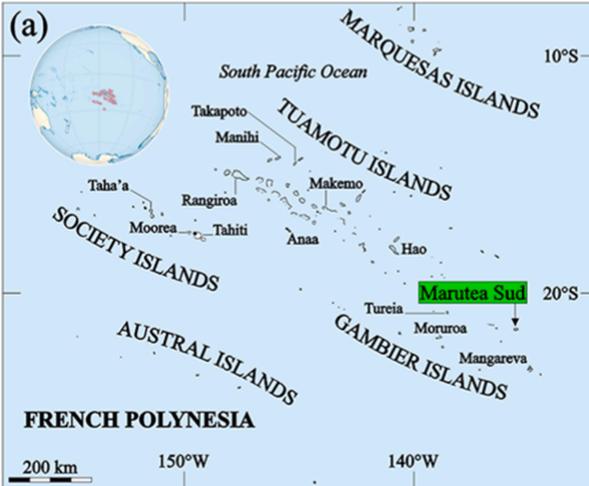

1335 Fig. 17. Age distribution of identified wave-surge events over the last 5,000 years, based on
 1336 U/Th dating of coral-clast samples extracted from conglomerate platforms, islet excavations
 1337 and surficial deposits. The last 2,000 years, i.e. the Common Era, is also expressed in a
 1338 centurial scale to facilitate comparison between the historical record of marine hazard events
 1339 and the wave-surge events recorded in the present study.

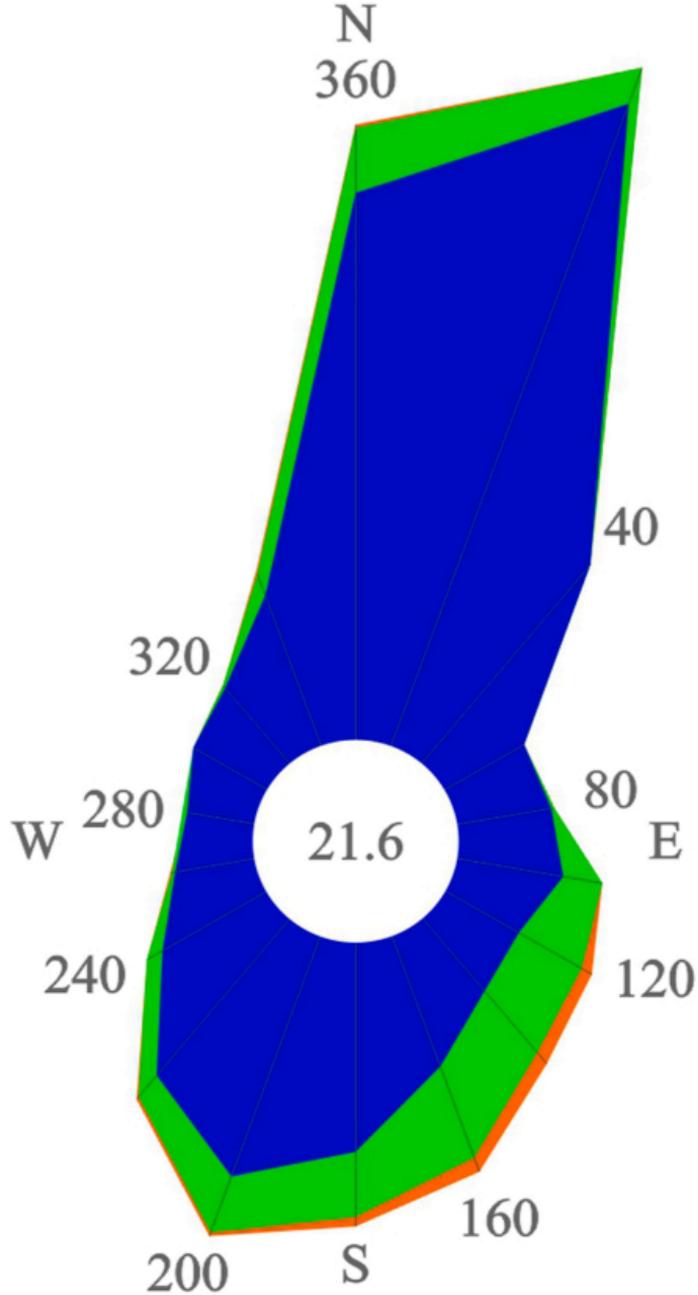

1340 **Table 1 (Supplementary material)**

1341 Uranium–Thorium data of coral samples from South-Marutea Atoll. Are given successively
 1342 laboratory sample codes, field sample (SAT) numbers, uranium and thorium contents,
 1343 isotopic composition with statistical errors – two standard deviations of the mean – and ages.
 1344 Uranium and thorium contents and isotopic ratios. $\delta^{234}\text{U}_M = \{[(^{234}\text{U}/^{238}\text{U})_{\text{sample}}/(^{234}\text{U}/^{238}\text{U})_{\text{eq}}] -$
 1345 $1\} \times 1000$, where $(^{234}\text{U}/^{238}\text{U})_{\text{sample}}$ is the measured atomic ratio and $(^{234}\text{U}/^{238}\text{U})_{\text{eq}}$ is the atomic
 1346 ratio at secular equilibrium. $\delta^{234}\text{U}_{(T)}$ is the initial value and is calculated by the equation:

1347 $\delta^{234}\text{U}_{(0)} = \delta^{234}\text{U}_{\text{meas}} \exp(\lambda_{234}t)$, where t is the age in years and λ_{234} is the decay constant for
1348 ^{234}U . Ages were corrected for authigenic ^{230}Th using $^{230}\text{Th}/^{232}\text{Th}$ of the detrital fraction = 10
1349 ± 5 . Note that, for Samples M103, M123 and M129, uranium content is significantly lower
1350 than classical values for uranium content within aragonitic corals. M103 is a conglomerate
1351 and not massive coral. Calcite primary deposition could explain the low U content value for
1352 this sample. For Samples M123 and M129, the very low U content could be a clue of
1353 diagenetic alteration (with U loss during the well-known aragonite to calcite transformation).
1354 These two ages could be considered with caution, because a hypothetical U loss could have
1355 biased the relevant age (with an apparent age being too old). Ages are expressed in both
1356 calendar years, relative to the year of sample analysis (2022) corrected for detrital content
1357 using a $^{230}\text{Th}/^{232}\text{Th}$ isotopic ratio = $7 \pm 50\%$ and conventional ages BP (Before Present,
1358 relative to 1950).

HIGHLIGHTS

- North of Rangiroa Atoll, due to a former uplift, the top of the Miocene carbonate basement peaks at depths of less than 10 m beneath the modern reef-rim surface.
- Unusual, extreme marine hazard events were essential drivers of early atoll rim-island accretion.
- Island accretion started by about 6,000 calendar years, 3,500 years before it did in nearby subsiding atolls.
