19 Abstract

20 On 30 October 2020 a large $M_w = 7.0$ earthquake occurred north of the island of Samos, Greece. Here we present the characteristics of the seismic fault (location, geometry, 21 22 geodetic moment) as inferred from the processing of geodetic data (InSAR and GNSS). We use the InSAR displacement data from Sentinel-1 interferograms (ascending orbit 29 and 23 24 descending 36) and the GNSS offsets from fourteen (14) stations in Greece and Turkey to 25 invert for the fault parameters. Our inversion modeling indicates the activation of a normal 26 fault offshore Samos with a length of 40 km, width of 15 km, average slip of 1.7 m, a 27 moderate dip-angle (37°) and with a dip-direction towards North. The inferred fault is 28 located immediately north of, and adjacent to Samos, with the top of the slip ~ 0.6 km 29 below surface, and ~1 km off-shore at its closest to the island. Near the fault the earthquake 30 caused the permanent uplift of the island up to 10 cm with the exception of a coastal strip along the NE part of the northern shore that subsided 2-6 cm. The co-seismic horizontal 31 32 motion of GNSS station SAMO was 35.6 cm towards south and 3 cm towards west. A postseismic signal (22-33% of the co-seismic on the vertical component) was observed at 33 34 GNSS stations SAMO and SAMU, with a time constant of 30 days. The effects of the earthquake included liquefaction, rock falls, rock slides, road cracks and deep-seated 35

landslides, all due to the strong ground motion and associated down-slope mobilization ofsoil cover and loose sediments.

41 **1.** Introduction - Tectonic Setting

42 The Samos island is located in the eastern Aegean Sea, a well-known extensional terrain, 43 as it is found on the back-arc area behind the Hellenic subduction (Fig. 1; McKenzie, 1978; Angelier, 1979; Taymaz et al. 1991; Ganas and Parsons, 2009; Meng et al. 2021). The plate 44 45 kinematics are determined by the ongoing northward subduction of the African slab under the Aegean continental lithosphere and the synchronous, westwards motion of the 46 47 Anatolian microplate. The GPS velocity field, with respect to Eurasia (fixed reference), is characterised by a counter-clockwise rotation of the continental plate, with increasing GPS 48 49 velocities from eastern Anatolia towards the Hellenic trench (McClusky et al. 2000; 50 Reilinger et al. 2010; Briole et al. 2021). Within this setting the central Aegean block 51 (including Samos) moves almost uniformly southwest (S24°W) at an average velocity of ~30 mm/yr (w.r.t to Europe; Briole et al. 2021; revising the 33 mm/yr value of Ganas and 52 53 Parsons, 2009; Vernant et al. 2014). This velocity plateau marks the end of the significant increase in N-S extension of the whole Aegean as observed from North to South (Briole et 54 55 al. 2021, their Fig. S29; see also McClusky et al. 2000; D'Agostino et al. 2020). Crustal 56 extension is accommodated by seismic slip along normal-slip and strike-slip active faults, 57 that are scattered throughout the north and central Aegean and western Anatolia (Mascle 58 and Martin, 1990; Taymaz et al. 1991; Ganas et al. 2005; Chatzipetros et al. 2013; Tan et al. 59 2014; Yolsal-Çevikbilen et al. 2014; Melis et al. 2020). The last seismic activity in the broader 60 Samos area was the October 2005 seismic sequence in Seferihisar – Sigacik (Benetatos et 61 al. 2006; Fig. 1) in the Turkish coastal area (North of Samos), involving strike-slip ruptures 62 with moment magnitudes in the range 5.4-5.8.

63 The geology of Samos comprises metamorphic and carbonate rocks of Mesozoic and early Cenozoic age that bound two Neogene sedimentary basins (mostly composed of marls and 64 sandstone formations; Theodoropoulos, 1979). The metamorphic complex of Samos is 65 composed mainly of marbles and phyllites, serpentinites, blueschists and greenschists 66 (Okrusch et al. 1984). The active tectonics is dominated by extensional kinematics along 67 numerous faults (Boronkay and Doutsos, 1994; Ring et al. 1999) with fault-slip data 68 indicating nearly N-S extension (Boronkay and Doutsos, 1994). A major, north-dipping 69 normal fault occurs just north of the island (Fig. 1) and it tilted Samos Island to the south 70 71 (Ring et al. 1999; Chatzipetros et al. 2013; Nomikou et al. 2021). Geological evidence (marine biogenic notches now found above mean sea level) suggests that a large part of 72

the northwestern coastline has been uplifted due to a combination of regional
 geodynamics and earthquake activity (Stiros et al. 2000; Evelpidou et al. 2021).

75 As the 30 October 2020 epicentre is located offshore Samos (Fig. 1) we investigated the 76 bathymetric features (submarine scarps, ridges etc.) and other geophysical evidence for 77 active faulting. The grids publicly available (gmrt https://www.gmrt.org/; emodnet 78 https://emodnet.eu) show that overall depths of the basin north of Samos mark a 79 deepening from ~500 m to 1000 m towards the west. Early seismic profiles in this area of the Aegean are limited to the Ikaria area, and reveal a half-graben offshore structure 80 81 (Mascle and Martin, 1990). Immediately following the Samos earthquake, a bathymetry 82 survey of the area north of Samos and around the earthquake epicentre revealed ~E-W 83 seafloor structures consistent with the surface expression of a normal fault scarp, showing seafloor slopes of 30-50°, and bounding the Samos Basin that is interpreted as a half-graben 84 85 (Nomikou et al., 2021). These data are consistent with a normal faulting event nucleating in the prolongation towards the north of this fault's trace (Nomikou et al., 2021), and also 86 87 reveal numerous mass wasting scarps and deposits throughout, that may be linked to the 88 long-term activity of this fault system. Around Samos – Kuşadası (Fig. 1) Tan et al (2014) 89 showed that the seismicity is heterogeneously distributed including an activity offshore 90 Samos in the vicinity of the epicentre of the 2020 Samos earthquake, and that there is 91 microseismic activity onshore Samos as well as onshore activity in the Kuşadası area.

In terms of finite strain, the amount of crustal extension between Samos and the Menderes region of western Anatolia (including the broader Izmir area) ranges from 5.3-7.4 mm/yr according to Vernant et al. (2014; with 0.8-1.0 mm/yr uncertainty) based on GNSS data modeling. New GNSS data provide an extension rate of 6.2 ± 0.7 mm/yr between eastern Samos and Izmir (Fig. 1; Briole et al. 2021). A component of left-lateral slip was also proposed by Vernant et al. (2014; 4.8-5.0 mm/yr) along with their proposed WNW-ESE crustal boundary offshore Samos.

99 Previous seismicity around Samos includes a cluster of poorly-located M=6.0+ events in 100 1904 (Ambraseys, 2001; Fig. 1). A M_s=6.1 (surface magnitude) event occurred on 11 August 101 1904 (this event is reported as M=6.8 in the online catalog of AUTH's seismological 102 laboratory) south of Samos, followed by a M_s=6.0 event on 18 August 1904; a third event 103 with M_s=6.0 occurred on 10 October 1904. All those events caused severe damage to 104 Samos and settlements along the Turkish coast. Eight (8) M≥6.0 size events are reported by Tan et al. (2014) to have affected Samos during the 19th century. A M=7.0 event occurred 105 106 in 1955 to the southeast of Samos, probably on the normal fault bounding the northern 107 side of the Büyük Menderes graben (Fig. 1). During October 2005 three moderate events 108 (5.4≤M≤5.8) occurred west of Seferihisar, Turkey (Fig. 1) about 40 km north of Samos 109 (Benetatos et al. 2006; Papadopoulos et al. 2006).

In this paper we use geodetic observations (GNSS and InSAR) to model the seismic fault(sections 3, 4 and 5). The fringes in the interferograms onshore Samos show a pattern that

supports more the north-dipping fault plane. Even if the InSAR data cover only a portion of 112 the deformation field, it allows us to distinguish between the two patterns (north-dip vs. 113 114 south dip) in terms of gradient, density, curvature and the concentration patches of the fringes. We also present field observations (section 6) including liquefaction phenomena 115 116 and InSAR data suggesting massive gravitational movements and discuss our findings in 117 terms of footwall deformation patterns (section 7). We show that both InSAR and GNSS 118 data provided evidence for co-seismic and postseismic deformation (uplift) of northern 119 Samos. We finally discuss the significance of our findings for the active tectonics and strain 120 in this part of the Aegean.

Fig. 1. Shaded relief map of the 30 October 2020 Samos M_w=7.0 earthquake area showing 123 location of the seismic fault determined in this study (black rectangle). Solid stars indicate 124 mainshock epicentres from the National Observatory of Athens (NOA), Kandilli Observatory 125 and Earthquake Institute (KOERI) and the European-Mediterranean Seismological Center 126 (EMSC). Blue dots indicate the first 24-hrs aftershocks from the EMSC catalogue (N=484). 127 128 Initials A-A' denote the end points of the cross section in Fig. 17. Inset box at upper right 129 shows study area within Greece. Red lines are active faults from the NOAFAULTs database http://doi.org/10.5281/zenodo.3483136 130

132 2. The Samos 30 October 2020 earthquake

On 30 October 2020 11:51 UTC a strong and shallow earthquake rocked the eastern Aegean 133 134 Sea (ITSAK, 2020; Kalogeras et al. 2020; Ganas et al. 2020a; Lekkas et al. 2020; Foumelis et al. 2021; Mavroulis et al. 2021). The epicentre was determined offshore the Greek island 135 136 of Samos, about 260 km to the East of Athens (Fig. 1). The local magnitude (Richter scale) 137 was measured by NOA as M_L=6.7, while the moment magnitude was calculated by various agencies in the range $6.9 \le Mw \le 7.0$ (see Table 1; Papadimitriou et al. 2020; Kalogeras et 138 al. 2020; Ganas et al. 2020a). The Peak ground acceleration at Vathy, Samos (Fig. 1) reached 139 0.17 g (Kalogeras et al. 2020). The earthquake triggered a tsunami that caused minor 140 damage at the surrounding islands (Samos, Chios, Ikaria; Fig. 1) and especially in the coastal 141 towns of Vathy (Samos) and Sigacik (Turkey; Kalogeras et al. 2020; Triantafyllou et al. 2021). 142 Immediately after the earthquake field surveys showed coastal uplift at several locations 143 144 of Samos (Lekkas et al. 2020; Evelpidou et al. 2021; Mavroulis et al. 2021), however, in this study we provide GNSS and InSAR evidence that there was no uplift along the south coast. 145 146 The focal mechanisms reported by various agencies for the mainshock are listed in Table 1.

150

151	The effects of the earthquake were devastating in Greece and Turkey (Vadaloukas et al.
152	2020; Cetin et al. 2020). In Greece, two young children lost their lives from a wall collapse
153	in the town of Vathy, eastern Samos (https://edition.cnn.com/europe/live-news/aegean-
154	sea-earthquake-dle-intl/h 9d313a45fc3463479a6ff1ec4da29755). In Turkey more than
155	100 people died from multiple building collapses in the city of Izmir, ~60-km to the north
156	of the epicentre (Fig. 1; <u>https://en.wikipedia.org/wiki/2020 Aegean Sea earthquake</u>).
157	The Samos earthquake ranged in magnitude $6.6 \le M_w \le 7.2$ (see Table 1 for estimates;

excluding AFAD-ERD it becomes $6.9 \le M_w \le 7.2$) and it occurred along a normal fault oriented

E-W as indicated by the moment tensor solutions of both regional and teleseismic data. 159 160 Until 20 November 2020 06:21 UTC more than 1445 aftershocks (with 2.0≤M_L≤5.2) were 161 recorded by the European-Mediterranean Seismological Centre (EMSC; Fig. 2). The 162 mainshock was followed by one moderate-size aftershock, on 30 October 2020 15:14 UTC 163 and with magnitude M_w=5.2. The moment tensor solutions of the mainshock indicate E-W 164 to ESE-WNW normal faulting in agreement with the regional, extensional tectonics (Table 165 1; Ring et al. 1999; Chatzipetros et al. 2013). The aftershock sequence extends over a E-W distance of ~70-km with most of events occurring east of the mainshock and within a depth 166 167 range 2-15 km (Fig. 2; see Fig. S1 for a map view). The EMSC aftershock data show an incipient decay the day after the mainshock (Fig. 2a) while the longitude location vs time 168 169 plot (in days from main shock) shows that the sequence is spatially constrained between 170 26.4°E – 27.2°E (Fig. 2b); this plot also shows that the sequence is unevenly distributed along strike. Indeed, the data show a peak in seismicity between 26.8° and 27.1°E, a 171 secondary peak immediately to the west and centered at 26.7°E, and a third peak centered 172 173 at 26.45°E with a clear seismic gap ~26.55°E (Fig. 2c). This uneven and segmented 174 distribution of the aftershocks is established immediately at the start of the aftershock 175 sequence (see aftershock distribution in Fig. 1), and persists over time, even during the 176 most recent periods of lower seismic activity (Fig. 2d; a similar feature is reported by Papadimitriou et al. 2020). This seismicity gap may be due to the complete rupture of the 177 178 main asperity along the fault plane and subsequent aftershock activity triggering around the co-seismic slip patches (e.g., Atzori et al. 2008; Chiaraluce et l. 2011; Ganas et al. 2019; 179 180 Melgar et al. 2017, 2020). The E-W extent of the early (24-hr) aftershocks (Fig. 1) is about 55 km, or 1.4 times the size of the modelled fault in this paper (40 km), close to the mean 181 182 value for the aftershock zone ratio in California (Neo et al. 2020).

Fig. 2. Spatiotemporal evolution of the Samos aftershock sequence (source of data: EMSC, data until 20 November 2020 N=1445) a) histogram of aftershock frequency of occurrence vs time (6h bins) to show the decay over time b) Daily frequency of occurrence with respect to longitude (east-west) and depth (circle colours correspond to depth, and size to the magnitude) c) histogram of aftershocks in frequency per day along strike (east-west; 1 km bins) d) Magnitude distribution with time and depth. Triangles (yellow with blue outline) in b and c indicate the location of the mainshock for reference.

191

192 **3. InSAR data processing**

193 We used Synthetic Aperture Radar (SAR) C-band images acquired over the Samos area by 194 the Copernicus European satellites Sentinel-1 from the ascending tracks 29 and 131 and 195 the descending track 36. The first co-seismic, differential interferograms spanning the 196 dates 24-30 October 2020, and 18-30 October, 2020 with images of track 131 (Fig. S2) were 197 calculated on the Geohazards Exploitation Platform (<u>https://geohazards-tep.eu</u>) using the 198 SNAP v5.0 software and were presented in Ganas et al (2020a). The acquisition time of the 199 postseismic image was at 30 October 2020, 16:07 UTC, thus 4 hours & 16 minutes after the 200 mainshock. Then, we produced 17, 15, 17 co-seismic and 10, 6, 6 post-seismic 201 interferograms for each of tracks 131 (ascending), 29 (ascending) and 36 (descending) 202 respectively, using the Automatic Interferometric Processing Station (AIPS; http://aips-203 p.space.noa.gr/Samos) at NOA. More information on AIPS can be found in text S2. The east, 204 north and up unit vectors, from the ground to the satellites, at the range direction (in the 205 centre or Samos island), are [-0.680 -0.157 0.716] for track 29, [0.629 -0.145 0.764] for track 206 36 and [-0.540 -0.125 0.832] for track 131. The interferograms captured the ground motion 207 along the line of sight (ILOS; see Look arrows in Fig. S2). These LOS measurements of were 208 used in the inversion model to retrieve the parameters of the seismic fault.

209 After reviewing all the co-seismic interferograms we decided not to use the track 131 in this paper, because of the better quality of track 29, which is ascending, too. In Fig. 3 we 210 211 present the best co-seismic interferogram belonging to track 29 and spanning the period 212 23 October – 10 November 2020. Moreover, we selected the four (4) best interferograms 213 (marked in bold and framed in Table S1) in terms of low tropospheric noise and high 214 coherence of each of the track 29 and 36 (Fig. 4a, 4d). We then unwrapped the 215 interferograms, removing the bias by setting each one of them to a zero mean value. Then, 216 for both the ascending and descending tracks, we averaged the LOS displacement grids these two averaged grids were used for the inversion modelling in section 5. All the 217 following interferograms for which their extent is limited only to the Samos island, are at 218 219 the notion of post-event minus pre-event, thus phase increasing towards satellite. Fig. S3 220 demonstrates the increase of signal to noise ratio obtained when using the average interferogram over the best interferogram of track 36 (D), both wrapped and unwrapped. 221

224

225 Fig. 3: The best co-seismic differential interferogram calculated with images acquired from 226 ascending track 29 and spanning the period 23 October 2020 - 10 November 2020 227 (produced by AIPS; grey colour indicates no data). The formation of the interferograms is 228 at the notion of post-event minus pre-event image, thus phase decreasing towards 229 satellite. The fringes in the interferogram onshore Samos show a pattern that supports 230 more the north-dipping fault plane as such concentration requires the vicinity of a fault 231 edge to them. The InSAR data show that most of Samos moved roughly upwards with the 232 exception of a coastal strip (from Agios Konstantinos to Kokkari; see Fig. 9) that moved 233 roughly downwards. Thin white line on Samos indicates location of profile shown in Fig. S9.

235

238

239 The interferograms of Fig. 3, Fig. 4, & Fig. S2 show several fringes corresponding to ground 240 deformation onshore Samos. The pattern of deformation shows two main features: an area 241 along the north coast with three fringes oriented ENE-WSW indicating motion away from 242 the satellite (region between Agios Konstantinos and Kokkari; see Fig. 9 for exact locations) 243 and another, larger region mostly in the central and west part of the island with a motion 244 towards the satellite. The absolute value of the interferometric fringes is estimated by 245 anchoring to the LOS the offsets measured at GNSS station SAMU in Vathy (Fig. 1), that is 246 +33 mm for the track 29 and +23 mm for track 36. Considering that the sense of the 247 deformation is the same in both tracks we can infer that the north-northeastern tip of Samos island shows subsidence and the western part of Samos shows an uplift. 248 249 Accordingly, we proceeded to the extraction of the vertical and east components of the 250 deformation. As InSAR provides only information on two independent LOS measurements 251 (Fig. 4), in order to retrieve the 3-D motion we use as third observation the north 252 component derived from the model that is presented in the next section. The north-south 253 displacements produced by this earthquake are large in the northern Samos, but the weight 254 of the north-south component to the calculation of the LOS displacement is small (between 255 10-15%). Therefore, our model is sufficient to provide a first order estimate that is accurate 256 enough for constituting the third source of displacement. The vertical and east components 257 of the deformation are shown in Fig. 5 (a and d, respectively). The fact that we can retrieve 258 an accurate measurement of the vertical displacements is particularly important for 259 comparison with the field observations along the shoreline (see section 6) and further 260 geological interpretations.

We interpret the deformation of the central and west part of the island as a result of coseismic motion along an offshore normal fault, running E-W and dipping to the North. As the rupture is shallow, and the dip angle (from seismology) is significantly different from 45°, the two conjugate planes produce modelled differential interferograms that are not similar to each other. Therefore, InSAR has the capability to discriminate between the two conjugate planes. Our joint inversion (based on InSAR & GNSS displacement data) approach has resulted in a robust fault model, providing its location, geometry (strike/dip-angle/rake angles and concluding on its dip-direction) and amount of finite slip while assuming a simple and planar fault geometry.

276

277 4. GNSS data processing

278 Dual-frequency data from fourteen (14) permanent (continuously recording) Global 279 Navigation Satellite System (GNSS) stations were processed. We used GPS observations 280 covering approximately 7-10 days before and after the earthquake (23 October 2020 to 10 281 November 2020; Table 2 and Fig. 6) in order to obtain position time series and their offsets 282 due to the earthquake. The sampling interval was 30 s, and the data comprise 24-hr daily 283 files. All station records were complete (rejected epochs 0.00%) thus providing substantial 284 observations for mapping the co-seismic displacement field and were included in our 285 processing. The stations belong to the Ktimatologio SA (HEPOS), HxGN SmartNET and Uranus networks of Greece and the Turkish National Permanent GNSS/RTK Network. The 286 287 azimuthal distribution of the GNSS stations is very good, extending uniformly around the 288 epicentral area (Fig. 6). However, most of the GNSS stations are located more than 50 km 289 away from the epicentre and therefore captured small displacements of the order of a few 290 cm. The daily coordinates are calculated in ITRF14 (epoch 2020.049) and converted to 291 Universal Transverse Mercator UTM (North) zone 35. Their uncertainties were converted 292 onto the local geodetic frame, based on the given Cartesian (ECEF; earth-centered, earth-293 fixed) sigma (95%) ones.

294 The processing was made with the Precise Point Positioning (PPP) strategy by means of the GIPSY/OASIS II software (version 6.4) developed by the Jet Propulsion Laboratory (JPL; 295 296 http://gipsy-oasis.jpl.nasa.gov). We used the JPL final satellite orbits (flinnR) and clocks, 297 absolute antenna calibration, random walk troposphere estimation, and the FES2004 298 ocean loading model. We calculated the static offsets (and their uncertainties) for the 30 299 October 2020 event (Table 2 & Table S2; Fig. 7 and Fig. S4a & S4b). The offsets indicate cm 300 size motion mainly along the N-S direction. Station SAMO (Fig. 6) registered the largest 301 displacements as it moved 35.6 cm towards south and 3 cm towards west. In terms of Up-302 Down (vertical) displacement we obtained clear trends of co-seismic motion for the three 303 stations located onshore Samos (SAMO, 093A & SAMU) with amplitudes +8.2, +2.3 and +2.1 304 cm, respectively.. The vertical displacements at the GNSS stations enhance the robustness 305 of the north-dipping fault model as they allow to discriminate between the two conjugate 306 focal planes (see also synthetic models of Okada-type dislocations; Okada, 1985) in Fig. S5. 307 Regarding the large aftershock on 30 Oct. 2020 15:14 UTC (M=5.2; located 9 km to the N 308 of Samos, NOA solution), we could not find any evidence of this aftershock in the GNSS 309 time series. Furthermore, the GNSS time series of SAMU and SAMO stations show the 310 existence of a small post-seismic motion in the days following the mainshock (Fig. 7). This postseismic motion leads to drifts of LOS values in our interferograms that we can estimate. 311 312 The values of those drifts is low so we can assess that the interferograms presented in Fig. 2, 3 & 4 are not biased by post-seismic motions and represent well the co-seismic signal of 313 314 the earthquake.

315

Table 2. List of co-seismic offsets (in mm) determined by PPP processing. Columns dE, dN, dUp show displacements (East, North, Up) and mE, mN, mU the modelled values, respectively. The uncertainties of E, N, Up displacements are reported in Table S2. The GNSS stations are shown in Fig. 6.

Fig. 6: GNSS co-seismic displacement map showing also topography/bathymetry, the focal mechanism (beachball; compressional quadrants in red) and the epicentre of the Samos October 30, 2019 earthquake. Blue rectangle indicates the surface projection of the seismic fault (thick black line is the upper edge with boxes on the downthrown side). Triangles indicate permanent GNSS station locations. Vectors indicate horizontal displacement of GNSS stations with 67% confidence scaling.

Fig. 7. Position time-series of stations SAMU (Vathy) and SAMO (Karlovasi) (E, N, Up in blue,
 red, black dots, respectively). The time-series have been offset for clarity on the Y-axis. The
 small post-seismic signal is visible mainly in the North-South component. Station locations
 are shown in Fig. 6.

5. Joint inversion of geodetic data – fault model

337 We inverted the geodetic data (InSAR and GNSS) assuming a half-space elastic model with 338 uniform slip along a rectangular fault surface, using the code *inverse6* (Briole, 2017). For 339 the modelling of the InSAR data, the same weight was given to the ascending and 340 descending picks. The ascending and descending observations (fringe pickings), here 64 for 341 the ascending track 29 and 33 for the descending track 36, thus the weight ratio descending 342 over ascending is 5/10. The 99 data points are compared against the model in Table S3 (see 343 Fig. S6 for location of picked fringes). We then used the 14 sets of GNSS offsets (horizontal 344 and vertical; Table 2) weighting 10 times more the horizontal offsets than the vertical ones 345 and the InSAR data. The root mean square (r.m.s) scatter between data and model is 6.4 346 mm for the GPS horizontal data, 9.8 mm for the GPS vertical data and between 23 - 59 mm 347 for the InSAR data (see Table 4 for model performance), respectively. We tuned the model 348 in favor of GNSS horizontal with the ratio 6:1 because of the higher reliability of the 349 horizontal GNSS displacements and their broad coverage, while InSAR is confined inland 350 Samos, which is, in particular, the reason for the weak constraint on the fault length from 351 InSAR only.

352 The geodetic observations presented above imply clearly and unambiguously that the 353 seismic fault plane is the one dipping towards north (Fig. 8). Indeed, there is no solution 354 with the antithetic plane that can fit correctly both GNSS and InSAR at the same time. 355 Moreover, the north-dipping plane is consistent with the submarine geomorphology (e.g. 356 Mascle and Martin, 1990; Nomikou et al. 2021) and the tectonic context of the area.. At a 357 local scale there are two to three fringes showing motion away from the satellite in the 358 coastal area between Agios Konstantinos and Kokkari; (Fig. 4; see Fig. 9 for locations) that 359 cannot be modelled with our simple model of uniform slip on a single fault plane. We 360 suggest that they were formed because of a "local effect" due to the complexity and 361 possibly the non-planarity of the mainshock rupture near its eastern termination. We also 362 considered the case of a "deep-seated" gravitational instability that was induced due to strong ground shaking but the size of the feature (nearly 6-km E-W) and the shape of the 363 364 fringes seem to rule it out. Moreover, there are no clearly defined boundaries of the local deformation visible in the interferograms, and the coastal area covered by this pattern 365 changes in different orbit interferograms, thus hinting at a tectonic source. 366

We started the inversion for the East, North, Up coordinates of the fault-top centre and for the fault length. We did not invert for the dip, and rake angles, assuming 37°, and -90° respectively, i.e., using the GCMT solution which is consistent (±2°) to our geodetic solutions for previous events in the Aegean Sea (i.e. Kos, 2017; Zakynthos, 2018; Durres, 2019; Ganas et al. 2019, 2020b, 2020c). The 37° dip-angle is close to the average (39°) of the teleseismic determinations of the focal mechanism parameters (see Table 1; also, the 37° angle fits the hypocentre determinations from regional networks, see Fig. 17 below). 374 The InSAR data alone do not allow to invert for the fault azimuth because of their 375 insufficient spatial coverage but thanks to the existence of the GNSS data we inverted for 376 the azimuth, too. We have not tried to constrain the rake of the slip vector, as we know 377 that in the modelling of InSAR (and also GNSS), there is a strong trade-off between rake 378 and azimuth angles. Therefore, we considered that it was more rigorous to rely on the 379 angles provided by seismology through the focal mechanisms; rake angle between [-116° / 380 -65°], median -92°, and azimuth [260°/ 294°], median 272°. Considering the fault as pure 381 normal (rake -90°) we inverted only for the azimuth (strike) with small relaxation. In Fig. S7 382 we see that it is inverted to 276°±1°. Indeed, there is a strong agreement between the 383 azimuth of the modelled fault and orientation of the known active structures (see active 384 faults in Fig. 1).

385 Concerning the location of the fault, we obtained robust estimates on the 3D position of 386 the top-fault centre (uncertainty of 0.7 km, 0.5 km and 0.3 km in east, north, vertical, 387 respectively), i.e., the horizontal coordinates are well constrained by InSAR displacement 388 data and the vertical coordinates are also well constrained by the gradient of the InSAR 389 fringes. The best-fitting length was 40±3 km (Fig. S7). Like for azimuth and rake, there is 390 also a trade-off between the amount of slip and the fault width. The best-fitting depth to 391 top-fault was 0.6±0.3 km and the fault width 15±3 km. Non-planar fault solutions were not 392 tested as the GNSS and InSAR data do not have sufficient coverage in the near field of this 393 offshore fault.

394 The fault parameters were used to construct a synthetic interferogram which is shown in 395 Fig. 8 (ascending orbit) and Fig. S8 (descending orbit), respectively (also shown are the fault 396 projection to the surface and the measured and modelled horizontal co-seismic GPS 397 vectors). The modelled GNSS displacements agree well with the observed GPS data (Table 398 2, Fig 6, Fig. 8, Fig. S8). We also present the residuals of the InSAR vertical and east 399 components and the north component model In Fig. 5c and Fig. 5e, respectively. As 400 mentioned earlier the negative residuals in Fig. 5e are due to the unmodelled "rupture 401 complexity" effect along part of the northern coastline (Agios Konstandinos to Vourliotes; 402 Fig. 9). We also drew a 21-km long NNW-SSE displacement profile (Fig. S9; the profile 403 location is shown in Fig. 3) over central Samos in order to compare LOS InSAR vs modelled 404 values and we obtained an average difference of 5.5 mm between the two sets (the standard deviation is 8 mm). In terms of earthquake size, the geodetic moment (Mo) is 405 406 calculated to 3.06 10¹⁹ N m assuming a rigidity of the medium of 3.0 10¹⁰ Pa. This value is close to the median of the seismological one which is 3.5 10¹⁹ N m. The fault parameters 407 408 are presented in Table 3 in comparison to the parameters obtained using only ascending 409 orbit data (Ganas et al. 2020a).

The geodetic data does not allow to constrain multiple patches on the fault plane. This is due to the fact that the fault is offshore, thus without geodetic constraints in the near field (on its hangingwall). However, the aftershock distribution along the fault (in an E-W direction, Figs. 2b and c), shows a clear differentiation that may be related to either a) a
fault geometry that is more complex than the simple planar fault that we have adopted
here, and/or b) that the finite displacement is unevenly distributed along strike. Seismicity
data alone, however, do not have the required precision in location to clearly delineate the
geometry of the seismogenic fault (see also seismicity cross-sections in Papadimitriou et al.
2020 and Foumelis et al. 2021).

419

Fig. 8: Map showing a synthetic interferogram (ascending orbit). The black rectangle
indicates the surface projection of the modelled fault (dip-direction is towards north).
Arrows indicate GPS offset vectors (observed vs. predicted; see Table 2). The formation of

424 the synthetic interferogram is at the convention of post-event minus pre-event, thus phase

425 decreasing towards satellite.

426

427 **Table 3.** List of fault parameters after inversion of geodetic data.

	Ganas et al. 2020a	This study
Number of inversions	2267	5610
M _o (N-m) – geodetic	3.5e+19	3.06e+19
Mw	7.0	7.0

Rms InSAR LOS ascending (mm) on whole Samos		50
Rms InSAR LOS descending (mm)		59
rms GPS vertical (mm)		9.8
rms GPS horizontal (mm)		6.4

428

With a fault dip-angle assumed to be 37° , the top-edge of the fault at 0.6 ± 0.3 km, and a

430 width of 15 ± 3 km, the root of the fault is located at a depth of 9.6 ± 2 km, and the geodetic

431 centroid depth is at 5.1 ± 2 km. This depth of the fault root is consistent with the 10-13 km 432 range of hypocentre depths determined by USGS, OCA, KOERI, INGV (see Table 1) and 433 Papadimitriou et al. (2020). For the Kos 2017 M6.6 event with a similar north-dipping 434 geometry we estimated the fault root at 10 km (Ganas et al. 2019).

435

436 6. Earthquake Environmental Effects

437 The environmental effects of the 30 October 2020 include rock falls, rock slides, landslides, 438 road-fill failures, coastal uplift and small-size liquefaction features (see also Lekkas et al. 439 2020; Foumelis et al. 2021; Mavroulis et al. 2021). The data were collected during a field 440 survey that took place on 6-8 November 2020, one week after the occurrence of the 441 earthquake. We were able to timely record the triggered geo-environmental effects 442 (mainly slope failures and liquefaction). The areas affected by these phenomena are mainly 443 found on the northern coastline of the island (Fig. 9) such as a) the villages of Avlakia, 444 Kokkari and the town of Vathy on the east and b) by the coastal zone from Agios 445 Konstantinos to Karlovasi to the west (Fig. 9). Regarding the other parts of the island, the 446 earthquake triggered only sparse and small size rock falls and rock slides on sites very prone 447 to slope failures. In particular, liquefaction phenomena such as sand craters and ejection 448 of fine-grained sand through ground cracks were documented at the coastal site of 449 Malagari beach, on the NW edge of the Vathy bay (Fig. 10a). Additional environmental 450 effects were mapped over Samos island using Copernicus Sentinel-2 & Maxar WorldView 451 optical satellite imagery. A map showing the spatial distribution of earthquake-induced 452 failures is shown in Fig. 9, while the coordinates of the field-documented failures are listed 453 at Table S4.

454 We observed that the dominant geological effects triggered by the earthquake are related 455 to slope failures. In particular, rock falls and slides, and shallow and deep-seated landslides were mapped on the northern and western part of the island and at the Karlovassi 456 457 hinterland area, on both natural and cut slopes. In several cases we observed that the 458 failures are associated with pre-existing tectonic discontinuities (faults, joints) and steep slopes within heavily fractured sedimentary rocks e.g., limestones (as is the case in Avlakia 459 460 where sliding occurred along a steep, northeast-facing slope with northeast-dipping 461 limestone strata; the dip angle was measured by AG between 51 and 53°). Moreover, no 462 primary fault surface ruptures were observed in the field which is consistent with the off-463 shore fault location determined by geodesy (Fig. 8).

The liquefaction site at Malagari beach (Fig. 10a) is a few metres away to a coastal site which subsided as it is evidenced by the partial submergence of a coastal tree line, that was located along the beach (approximately oriented N-S). Part of the beach is now under water with preliminary measurements indicating a maximum subsidence of 53 cm (Fig. 10b, c, d). 468 We suggest that this is due to strong ground shaking that induced lateral spreading of the 469 surface soil horizons.

470 Additional data were provided by the InSAR images that showed extensive decorrelation in 471 the hilly area both east and south of Karlovasi (Fig. 11). The InSAR images indicate chaotic 472 structures that formed inside valleys (Fig. 12). As the structure is clear on all co-seismic pair 473 combinations (including the 30 October 2020 scene) it is evident that it does not represent a tropospheric effect between the SAR acquisitions or an artefact of the DEM used to make 474 475 the interferograms. We mapped a convergent pattern of motion (Fig. 11a) inside the main 476 valley to the east of Neo Karlovassi (Fig. 12) that we interpret as a gravitational feature than 477 a primary (seismic) one.

Fig. 9. Locations of mapped earthquake environmental effects of the October 30
earthquake over Samos island (6-8 November 2020 field survey). Arrow shows location of
Fig. 10. Box shows extent of Fig. 11 & 12. Background geology is a simplified version of the
geological map of Theodoropoulos (1979).

Fig. 10. Field photographs showing earthquake-induced failures at Malagari, Samos (see
Fig. 9 for its location, opposite to the town of Vathy) a) liquefaction b) coastal subsidence
of 53 cm c) submergence of former beach d) submerged tree line.

488

489 Both InSAR and optical satellite data support this interpretation as a set of massive, deep-490 seated gravitational displacements (DSGD; e.g. Moro et al. 2011), distributed along the 491 western and eastern slopes of the Neo Karlovassi valley, that were triggered during the 30 492 October 2020 earthquake. The decomposed unwrapped interferograms (East – West 493 component; Fig. 11b) document the converging motion of the ground surface and show 494 the extent of triggered landslides. The valley also contains huge (1-4 km) paleo-landslide 495 complexes visible in optical satellite images and the digital elevation model, parts of which 496 were activated (Fig. 12). Most clear earthquake-induced landslide cases are the one up-497 stream from Neo Karlovasi (interpreted as a Pliocene limestone cap that slided along ENE-498 dipping beds; Fig. 13), and the area north of village Kontakeika towards the coast, on the 499 other side of the valley (Fig. 12). The deformation and offsets from the main activated 500 landslide complex near Kontakeika are also visible along the coastal road network and they 501 were confirmed by field inspection on November 6, 2020 (Fig. 11 c,d). Due to the small 502 amount of displacement of the triggered DSGDs, field evidence is limited to local tensional 503 fractures perpendicular to the slide movement axis, and ground cracks along its boundaries 504 (Fig. 11d). Co-seismic triggering of large deep-seated landslides is a common occurrence during shallow earthquakes, and are frequently observed through mainly geodesic imaging
due to the small amount of displacement involved (Moro et al. 2011; Lacroix et al. 2014;
Lacroix et al. 2020).

508

509

510

Fig. 11. Maps showing co-seismic landslide activity around Karlovasi, evident in Sentinel-1 511 512 differential interferograms. De-correlated areas and fringe patterns mark the location of 513 DSGDs (black arrows) in descending (a) interferogram. Decomposed unwrapped 514 interferograms (East – West component) show the extent of triggered landslides (b). The 515 E-W displacement raster image was deramped around the landslide area in order to 516 diminish the co-seismic displacement effect and to enhance movement along the eastern 517 and western slopes. c & d) Field photos of ground cracks along the boundaries of activated landslides (see Table S4 for coordinates). 518

Fig. 12. Shaded relief map of the valley to the east of Karlovasi where deep-seated
gravitational displacements (DSGD) were observed both in InSAR images (Fig. 11) and in
the field. The activated slides are delineated by polygons, along both sides of the valley.
Northernmost structure (orange) showed displacement during the early post-seismic
period (30 October – 5 November 2020). Contour interval is 10 m.

23 October – 4 November 2020 (b) and cross-section (c) of earthquake-induced slide to
the SE of Neo Karlovassi, Samos. The sliding surface is located at the base of the Pliocene

531 limestone beds that overlie the Miocene clastic series of western Samos.

532

533 **7. Discussion-Conclusions**

534 **7.1** Postseismic deformation of the footwall and relation of co-seismic to post-seismic535 slip

536

537 One of the important aspects of the Samos earthquake is that it is one of a few cases of 538 normal-slip earthquakes where we can accurately measure postseismic deformation of the 539 footwall block. This is possible because of the magnitude of the mainshock (M_w=7.0) and 540 of the existence of sufficient geodetic data. The two GNSS stations (SAMU & SAMO) that 541 were situated on the footwall close to the fault (Fig. 6) have provided accurate information 542 on ground deformation during both the co-seismic and the post-seismic phases (during the 543 first 10-days; Fig. 14 and Table 4). The earthquake produced a significant amount of post544 seismic displacement in the near field (a few km from the top-fault edge; Fig. 14), detected 545 by the two stations; larger in SAMO with a few cm amplitude, a horizontal motion of -4.4 546 cm (North-South component) and 1.8 cm of uplift; Table 4). In SAMU, located 24 km 547 towards East, the postseismic motion was 1.6 cm and 0.7 cm, respectively. The ratio of the 548 postseismic to co-seismic motion per station is 12-25% (north-south component) and 22-549 33% (on the vertical component). Interestingly we observe that the co-seismic and post-550 seismic vectors are not aligned; the SAMO station shows a motion towards N202°E during 551 the postseismic period as opposed to N185°E during the co-seismic one. The fastest part of 552 the postseismic motion lasted until 10 November 2020, that is 11 days (Fig. 14 inset). Then, the decay was slower until the 1st of December 2020 where we cannot see it anymore 553 554 because of data being comparable to noise (Fig. 14 inset). Thus, the duration of the 555 detectable post-seismic signal is 30 days which is measured on the horizontal component of station SAMO. This value is close to the 21 days we found in the case of the M_w=6.7 556 Zakynthos earthquake (Ganas et al. 2020b). It is reasonable to suggest that the cause of the 557 deformation is shallow afterslip along the rupture plane of the mainshock as it has been 558 559 documented in other similar ruptures (e.g., Cheloni et al. 2014; Pousse-Beltran et al. 2020; Briole et al. 2021). Shallow afterslip near the top-edge of the rupture plane may be 560 561 responsible for the early aftershocks (24-hr) that are aligned along Samos's north coast (Fig. 1). For capturing the full pattern of the fast post-seismic motion that lasts just a few weeks 562 563 it would have been necessary to deploy in the field additional GNSS stations which were not available. This would be also necessary to fully capture the flexure of the footwall away 564 565 from the rupture (e.g., Fernandez-Blanco et al. 2020), as our data (Fig. 15) plot on the flat 566 part of the vertical displacement profile.

567

Table 4. Estimation of seismic displacements at stations SAMU and SAMO and their InSAR equivalents. Ratio is the post-seismic displacement divided by the cos-seismic one. The post-seismic data refer to the first 10-day period following the mainshock.

571

Station	dE (mm)	dN (mm)	dU (mm)	l.o.s (mm) track 29	l.o.s (mm) track 36
SAMU co- seismic	-5	-64	21	33	23
SAMU post- seismic	0	-16	7	8	8
SAMO co- seismic	-30	-356	82	155	82
SAMO post- seismic	-11	-44	18	27	13
SAMU ratio	0	0.25	0.33	0.24	0.35
SAMO ratio	0.36	0.12	0.22	0.17	0.16

572

Fig. 14. Time series of North coordinates of station SAMO (Karlovasi; blue dots) and SAMU (Vathy; red dots). The inset box shows the post-seismic period of SAMO with a break in slope around 11 November 2020, thus signifying the end of the fast term of the post-seismic motion.

580 We also detected postseismic motions in the InSAR data (as did Foumelis et al. 2021), in particular a post-seismic signal is visible on track 131, that was acquired on the same day, 581 ~4h15' after the mainshock. In three out of five postseismic interferograms having as 582 primary image (master) this particular acquisition, one fringe is visible, spread out in the 583 north of the island, with the same direction of motion (LOS) with that of the co-seismic 584 585 ones. To compare with the GPS data (Table 4), the postseismic difference in the LOS of pixels enclosing the two GPS stations of the island, for the ascending pass are 19 mm (5 586 587 mm for the LOS. of the descending pass), and in terms of percentage the postseismic LOS 588 motion is about 15-34 % of the co-seismic one. Our observations support almost one whole 589 fringe on the north coast of the island (ending northern than SAMO), however the same 590 area has been partially subjected to gravitational motions (see Fig. 12 and Fig. 13) so at this 591 stage we didn't proceed further into differentiating those signals. Moreover, the 592 deformation mapped in post-seismic interferograms (secondary images on 11, 17 and 23 593 November 2020), demonstrate the continuation of the post-seismic process, in agreement with the GPS data (Fig. 13). These post-seismic interferograms are stored in the AIPS (see 594 595 text S2 and http://aips-p.space.noa.gr/Samos/products/131/post).

In terms of vertical motions, we also observe a fast postseismic uplift in the data of footwall
 stations SAMO (Fig. S3) and SAMU. The postseismic uplift ranges between 12-28% of the

co-seismic value measured at the GNSS stations (Table 4) that are located about 3.7 km 598 599 south of the top-fault line surface projection (Fig. 15). As already mentioned this 600 deformation is due to fault afterslip, so it will be sustained over months or years (Ergintav 601 et al. 2009; Briole et al. 2021) because of the size of the earthquake (M_w =7.0). We also note 602 that the vertical postseismic motion is on the same direction as the co-seismic motion (Fig. 603 15), i.e., positive thus signifying further uplift of the footwall. We suggest that postseismic 604 uplift is a process that should be included in long-term deformation studies in both fore-605 arc (e.g., Crete; Robertson et al. 2019; Ott et al. 2021) and back settings (e.g., Corinth; 606 Houghton et al. 2003; Fernandez-Blanco et al. 2020).

607

Fig. 15. Cross-section across the seismic fault showing vertical displacement (according to
the model of Table 3; red line). GNSS station SAMO is shown on the footwall. The vertical
displacement (in m) is shown on the left-Y axis. Elevation and bathymetry are shown on the
right-Y axis. Vertical exaggeration is times 6 the horizontal (X-axis).

613

614 **7.2 Asymmetric Elastic response of the crust**

615 Geodetic processing of GNSS observations can supply reliable and unsaturated 616 measurements of ground motion displacement during earthquakes (e.g., Melgar et al. 617 2015; Huang et al. 2017; Ruhl et al. 2019). The displacement data are extremely useful for 618 earthquakes with moment magnitudes larger than M=5.0 and originating from stations at 619 the near-field (equal to or less than one fault length) up to regional distances (200-300 km 620 or even more). The displacements comprise measurements (offsets) of GNSS antenna 621 positions due to tectonic strain of the crust imposed by the passage of seismic waves. The 622 peak ground displacements (PGD) are defined on the horizontal plane (sum of offsets of 623 the North-South and East-West component of GNSS; e.g., Ganas et al. 2018) and/or all 624 three directions of motion (3D; Melgar et al. 2015). The PGDs are related to earthquake 625 magnitude (M_w) and distance to hypocentre R by a relation of the form LOG(PGD) = a + b * 626 Mw + c* LOGR * Mw (Ganas et al. 2018). The Samos event data (Table 2) show that GNSS 627 horizontal displacements increase closer to the epicentre in a systematic way, in agreement 628 with the response of an elastic body to tectonic strain (Fig. 6; Fig. 16). First, we observe that 629 GNSS offset data from "near-field" stations (one fault length) SAMO, SAMU, 093A, (Fig. 6) 630 are in agreement with the PGD scaling relationships where offset data are correlated to 631 earthquake magnitude and distance to hypocentre (Melgar et al. 2015; Ganas et al. 2018b; 632 Ruhl et al. 2019). As with other shallow earthquakes in the Aegean (period of data 1997-633 2017; Ganas et al. 2018) we mapped a linear displacement field (in Log-Log space) as 634 expected from an elastic response of the crust to the permanent strain caused by 635 instantaneous seismic slip along the offshore fault. However, the stations located across 636 strike (blue squares in Fig. 16) align close to the M_w=7.0 regression line (in agreement with seismology estimates) while the stations located along strike (±45°; red squares) are 637 638 aligned close to the M_w=6.5 regression line. We attribute this difference in magnitude 639 scaling with distance to the azimuthal position of the GNSS station with respect to the strike 640 of the rupture plane. The pattern of tectonic strain is asymmetric in elastic earth (see the 641 Okada-type model of Fig. S5) and this is reflected on the co-seismic geodetic data 642 (horizontal GNSS offsets). Moreover, there are two stations onshore Ikaria island (IKAR & 643 IKAU; Fig. 6) that are located to the SW of the rupture at a distance of ~60 km from the hypocentre. Those stations scale with the M_w=7.0 regression line despite their azimuthal 644 645 position (~45° off-strike); we believe that their offsets are impacted by a possible 646 (westward) directivity effect of the rupture. In case of a bilateral rupture, we would 647 anticipate lower PGD at IKAU & IKAR and higher PGD in SAMU, DIDI and ADY1, as the latter 648 three stations are located towards east of the epicentre. The Samos case demonstrates 649 that (when available) GNSS stations across strike of dip-slip ruptures should be considered 650 first in magnitude-scaling estimates. .

651

Fig. 16: (top panel) two-dimensional graph of geodetic data (Y-axis; cm) that uses logarithmic scales to show a linear decrease of PGD (peak ground displacement) with hypocentral distance (X-axis; km) for the Elazig (black rhombs) and Samos (coloured squares) earthquakes2020). Blue squares show the Samos earthquake data from GNSS stations across strike. Red stars indicate the data from GNSS stations along strike. Date format in legend (upper right) is YYYYMMDD. (bottom panel) Graph as above but showing decrease of PGD-S (cm) with hypocentral distance (km). The oblique blue lines are the

predicted scaling values for a particular earthquake magnitude from the relations above
each graph (from Ganas et al. 2018). The Elazig earthquake data (24 Jan. 2020; M_w=6.7) are
from Melgar et al. (2020).

665

666 7.3 Extension across the Samos – Kuşadası Bay

667 In the eastern Aegean crustal extension is accommodated by a combination of normal-slip 668 and strike-slip faulting as demonstrated by geological, seismological and geodetic data (i.e., 669 Boronkay and Doutsos, 1994; Ocakoglou et al. 2004; Benetatos et al. 2006; Ozkaymak and 670 Sozbilir, 2012; Chatzipetros et al. 2013; Tan et al. 2014; Yolsal-Çevikbilen et al. 2014; Ganas 671 et al. 2019), however, in the offshore area of Samos detailed knowledge was lacking. 672 According to our joint-inversion (GNSS & InSAR) model, the main structure is the 40-km 673 long seismic fault (activated by the Samos 2020 earthquake) that dips towards north at an 674 angle of 37° and reaches the depth of 10 – 11 km (Fig. 17). The root of the fault is at the 675 base of the upper crust which comprises about 40-50% of the total crustal thickness (about 676 30-km thick in the area of Samos; Grigoriadis et al. 2016). As such this fault comprises a 677 major Quaternary structure of the Aegean Sea given that fault length is about 3.3 times the 678 seismogenic part of the crust. It seems that fault growth was more efficient along strike of 679 the fault, although this is not reflected in sea-bottom morphology (that deepens towards 680 the western part of the footwall), similarly to the 1949 earthquake offshore Chios (Melis et 681 al. 2020) and the 2019 earthquake offshore Kos (Ganas et al. 2019).

682 The Samos fault throw assuming a) pure normal slip and b) flat pre-rift topography, should 683 exceed 2 km (by summing footwall relief south of Karlovassi and offshore basin depth), thus 684 providing a preliminary estimate for a mean throw rate of 1 mm/yr or about 1.4 mm/yr 685 mean slip rate. This fault accommodates a significant portion of tectonic strain 686 accumulation in the Samos – Kuşadası Gulf (Fig. 17) where a crustal block boundary has been suggested by Vernant et al (2014) and Briole et al. (2021). Both fault size and 687 688 geometry indicate that this is a relatively young structure developed during the Quaternary 689 and represents the main source of seismic hazard in this region. We note that our geodetic 690 data inversion is fit by a planar fault (40 by 15 km), although we are well aware that in 691 nature faults are non-planar.

The surface projection of the fault is found near the northern shore of Samos (Fig. 15; Fig. 17), about 1.5-km offshore the port of Karlovassi, assuming a 37° dip-angle. In addition, the N276°E orientation of the fault is roughly similar to that of the active faults and/or seismogenic sources in this area (Chatzipetros et al. 2013; Caputo and Pavlides, 2013; Ganas et al. 2013). All databases contain an offshore north-dipping normal fault that is described as the main seismic source for the Samos Gulf.

Fig. 17. Tectonic model across the Samos Gulf (See Fig. 1 for location A – A'). Black lines are
 active faults (half arrow indicates downthrown side). The bold black line corresponds to the
 model fault, and dashed lines are inferred normal faults from literature. The yellow colour
 indicates the recent sediment cover. Solid stars indicate mainshock hypocentres, projected
 onto the cross-section. White solid arrows indicate long-term extensional strain within the
 crust.

699

707 Although it is crucial for short-term seismic hazard assessment, we cannot infer the 708 structure towards east, i.e., towards the Kuşadası area where large active normal faults 709 exist (Meng et al. 2021). It is possible that the 2020 rupture plane continues eastwards for 710 another 10-15km or that another, north-dipping fault segment exists towards the east of the 2020 rupture. Preliminary aftershock data (Papadimitriou et al. 2020; Foumelis et al. 711 712 2021) are not conclusive on the geometry of the structure towards east. The eastern cluster of the 2020 aftershocks (offshore NE Samos and onshore eastern Samos; Fig. S1) probably 713 714 reflects triggered seismicity on optimally-oriented faults to N-S extension because of Coulomb stress transfer (Papadmitriou et al. 2020). More offshore data are needed to 715 716 better define the fault zone geometry and size, and shed light on a possible co-planar (to 2020) configuration of seismic sources or not. Towards the west, the recent offshore 717 718 seismic survey data by Nomikou et a; (2021), confirm that the Samos earthquake seismic fault has its surface trace roughly projected near the Samos coast (in Fig. 8) following the 719 720 planar geometry assumed in our inversion. In addition, the main rupture patch extends for 721 ~25-km west of Karlovassi (Fig. 1) as evidenced by the visible E-W gap in the early 722 aftershock (24-hr) distribution. In summary, the proposed fault characteristics (Table 3) as 723 revealed by the 2020 earthquake in terms of location, geometry and seismic potential are 724 robust and they should update the fault databases of active structures of the eastern 725 Aegean Sea (e.g., Papazachos et al., 2001; Ganas et al., 2013; Caputo and Pavlides, 2013; 726 Sakellariou et al., 2013; Emre et al., 2016).

728 8. Conclusions

- Our joint inversion (GNSS and InSAR) modeling indicates that the Samos M7.0
 earthquake occurred along a north-dipping normal fault. The fault is located
 offshore Samos occupying a length of 40 km, width of 17 km, an average coseismic
 slip of 1.7 m, and a moderate dip-angle (37°).
- 733 2. The root mean square (r.m.s) error between geodetic data and model is 6.4 mm for
 734 the GPS horizontal data, 9.8 mm for the GPS vertical data and between 23 59 mm
 735 for the InSAR data (see Table 3 for model performance), respectively.
- The earthquake caused the permanent uplift of the island in the range 1-10 cm with
 the exception of a coastal strip along part of the northern shore (between Agios
 Konstantinos Kokkari) that subsided 2-6 cm.
- 4. We observed a fast postseismic slip (uplift) ranging between 22-33% of the co-seismic slip value. This is primarily due to fault shallow afterslip as it is recorded within the first 10-days since the mainshock. Postseismic uplift is an important process that should be included in earthquake deformation studies.
- The effects of the earthquake included liquefaction, rock falls, rock slides, road
 cracks and deep-seated landslides, all due to the strong ground motion and
 associated down-slope mobilization of soil cover and loose sediments.
- 746 6. The Samos earthquake demonstrates that (when available) GNSS station data
 747 (offsets) across strike of dip-slip ruptures should be considered first in magnitude748 scaling estimates.
- 749

750 Acknowledgements: We thank Brendan Crowell, Nicolas Chamot-Rooke, Ross Stein, Marco 751 Meschis, Tuncay Taymaz, Diego Melgar, George Papathanassiou, Evi Nomikou, Isidoros Kampolis, Ioannis Kassaras, Antonio Avallone, Eirini Efstathiou, Thekla Thoma and Efthimios 752 753 Lekkas for comments and discussions. Sentinel-1 and Sentinel-2 satellite imagery was acquired through European Space Agency and Copernicus, and WorldView imagery 754 755 through Maxar Open Data program. We are indebted to ESA, Geohazards Lab and Terradue for providing access to Geohazards Exploitation Platform (GEP) for InSAR cloud processing. 756 757 GNSS data were provided by Ktimatologio SA, Hexagon SmartNET and Uranus (Tree) networks of Greece. We thank Tuncay Taymaz and Semi Ergintav for sharing Turkish GNSS 758 759 data. We thank the Samos local authorities for their help. Several figures were created by 760 use of GMT (Wessel et al. 2019).

1008 Text S2:

1009 AIPS (http://aips.space.noa.gr) is a platform for routine (updated in every new acquisition) 1010 and on-demand SENTINEL-1 interferogram processing service. It provides freely the 1011 original, the filtered, using the adaptive power spectrum filter of Goldstein and Werner 1012 (1998) with a coherence threshold of 0.3, interferograms as well as its amplitude in UTM/WGS Transverse Mercator projection, at full resolution (25 m), in GEOTIFF format. It 1013 is based on ESA's SNAP (http://step.esa.int/main/) software version 6.0. The multiblock 1014 factor is 6 in range and 2 in azimuth. Moreover, it produces figures and raw images in PNG 1015 format as quick-look products. The digital elevation model (DEM) used for the processing 1016 is the Shuttle Radar Topography Mission (SRTM) 1 Arc-Second Global (doi number: 1017 /10.5066/F7PR7TFT). During the stage of processing, the interferogram was formed by 1018 cross-multiplying the post-event acquisition image) with the complex conjugate of the pre-1019 event image). The resulting phase represents the difference between the two images. 1020 1021 Currently the routine processing includes four tracks of central Greece and one-track form 1022 Etna in Sicily, Italy but there is the flexibility to extend the processing upon request. It keeps a rolling-archive with old data stored offline. The on-demand service is triggered upon a 1023 moderate or big earthquake in the Euro-Mediterranean region. For the case of the Samos 1024 1025 earthquake the interferometric products can be found at http://aipsp.space.noa.gr/Samos/products/ 1026

1027

1029 Table S1.

- 1030 List of the pre-seismic, co-seismic and post-seismic interferograms of the track 131, 29
- 1031 and 36, produced by AIPS and stored at <u>http://aips-p.space.noa.gr/Samos/products/</u>. The
- 1032 interferograms in bold and framed are used to produce the average interferograms of
- 1033 track 29 and 36 that were used in the inversion modelling.

Fig. S1: Seismicity map (EMSC data) showing both magnitude and depth distribution of events.

Fig. S2: The initial co-seismic differential interferograms (wrapped phase; cropped swath 1059 1060 of ascending track 131; Ganas et al. 2020a) over Samos island, produced exploiting the 1061 Geohazards Exploitation Platform. Top panel shows the image pair 24 Oct. – 30 Oct., 2020. 1062 Bottom panel: 18 Oct. – 30 Oct., 2020. The fringes in the differential interferogram show a 1063 pattern that supports more the north-dipping plane as the density and the curvature of the 1064 fringes indicates. These data show that Samos moved towards the satellite in the LOS with the exception of a coastal strip from Agios Konstantinos to Kokkari that moved away. The 1065 1066 interferograms are draped over Google Earth imagery.

- Fig. S3: (a) Best interferogram of Track 36 (D) spanning the dates 10 June 11 November
 2020, (b) the unwrapped one, (c) the average interferogram of the best four and (d) the
 unwrapped one.

Fig. S4: Graphs with time series of GNSS coordinates of the SAMO (a) and 093A (b) GNSS
 station across the day of the earthquake (red vertical line in a).

(b)

Fig. S5: Synthetic models of ground surface displacement using Okada-type dislocations in elastic half-space. The modeled dislocation (from Ganas et al. 2020a) has length/width of 36 km / 18 km, a finite slip of 1.82 m and a strike/dip/rake: 276°/37°/-90° (see GCMT and USGS moment tensor solutions from Table 1 on the main paper). Top panel) North-South displacement bottom panel) Up-Down displacement. Values are in m. Yellow star is the epicentre of the mainshock.

1092

1094 Fig. S6: Picked values in the two averaged interferogram (a) ascending track 29 and b)1095 descending track 36/

Fig. S7. Divergence diagrams of the set of inversions for a) fault azimuth (strike), b) depth
to top-fault, c) length, d) width and e) normal slip.

Fig. S8. Fault model from the InSAR data (synthetic model; descending orbit). The dip-direction is towards north. Arrows indicate GPS offset vectors (observed vs. predicted). The formation of the interferogram is at the notion of post-event minus pre-event image, thus phase decreasing towards satellite.

Fig. S9. Displacement profile onshore Samos showing a comparison of the InSAR observed
values (LOS; track 29) versus the modelled values (see Fig. 8 of the main paper). The
location of the profile is shown in Fig. 3.
