18 **Abstract.** Reaching high selectivity at high conversion and high rate in the industrially
19 important selective hydrogenation of α,β -unsaturated aldehydes is a challenging task. Among
20 current approaches reported in the literature, high selectivity towards the unsaturated alcohol
21 or saturated aldehyde is generally achieved at the expense of activity. The use of bimetallic
22 systems can lead either to selectivity or to activity enhancement, but generally not to both.
23 Herein, we show that, for cinnamaldehyde hydrogenation, combining Ni nanoparticles (Ni_{NP})
24 and Ru single atoms (Ru_{SA}) on CNTs allows improvement of the hydrocinnamaldehyde

1 selectivity, while obtaining a remarkable activity. The STY of Ru_{SA}-Ni_{NP}/CNT is
2 approximately 60 times higher than that of the Ru_{SA}/CNT and 10 times higher than that of the
3 Ni_{NP}/CNT. Importantly, the resulting catalyst shows 94% selectivity at 99% conversion and a
4 good stability in flow. Insights into the cooperative “cocktail”-type catalysis between Ni_{NP}
5 and Ru_{SA} were revealed from density functional theory calculations.

8 spillover

9

10 1. Introduction

11 Controlling catalyst’s selectivity while maintaining its activity is a difficult task, especially
12 in selective hydrogenation reactions of organic substrates. The selective hydrogenation of α,β -
13 unsaturated aldehydes is a representative example that arouses interest both from the
14 academic and industrial sides. First, it can be used to probe geometric, electronic or
15 confinement effects,[1] and second, the corresponding products are widely used in several
16 segments of the chemical industry. Cinnamaldehyde (CAL) is a classical model substrate, and
17 the main hydrogenation products, hydrocinnamaldehyde (HCAL) and cinnamyl alcohol
18 (COL) can be used as pharmaceutical intermediates, chemicals, perfumes or fragrances. The
19 performance of Pd, Ru or Ni supported catalysts have been evaluated for this reaction.[2]
20 Among these metals, Pd is by far the most active, and generally showed high HCAL
21 selectivity ($S_{\text{HCAL}} > 80\%$).[3] Ru is less active and is generally preferred to produce COL,
22 although with moderate selectivity.[4] Non-promoted transition metals of the first row such as
23 Ni show low activity and are, as Pd selective, for HCAL production. The selectivity trend

1 could be correlated with the metal *d*-band width,[5] the larger the *d*-band, the higher the
2 selectivity to the unsaturated alcohol (Ru > Pd ≈ Ni).

3 An efficient strategy to tune catalytic performance for selective hydrogenation reactions
4 involved the use of bimetallic or dilute alloy catalytic systems.[6, 7] The promotion by
5 addition of a second metal can be explained by: i) geometric/electronic effects; ii) appearance
6 of mixed active sites; and/or iii) a weakening of the M–H bond. Generally, the bimetallic
7 systems combined a metal that can activate H₂ and another one, usually more electropositive,
8 which can improve the catalytic performance. An intimate contact between the two metals is
9 not mandatory as long as hydrogen spillover[8] (diffusion of mobile H species from the metal
10 to the support) can occur, which is the case on reducible oxides,[9, 10] and carbon
11 materials.[11, 12] The exact nature of these H species (atomic H, H⁺, H⁻) depends on the
12 nature of the support and is still the subject of studies.[10, 13, 14] The systems involving H-
13 spillover can be classified into four categories (Scheme 1).

15 **Scheme 1.** Different pathways for H-spillover induced cooperative catalysis (see text for
16 description and examples).

17 The first category follows the *pathway A*. In that case, molecular hydrogen is easily
18 dissociated on a noble metal nanoparticle (NP) and the activated hydrogen reached the

1 hydrogenating site (a non-noble metal NP) *via* H-spillover. Such mechanism was reported for
2 the selective hydrogenation of CAL to HCAL on Ni-Ir/TiO₂ bimetallic catalysts.[15] Here,
3 the role of Ir_{NP} was to produce activated hydrogen, while CAL hydrogenation occurs on the
4 Ni_{NP}, whose electronic structure is eventually modified upon addition of Ir. This Ni-Ir system
5 was significantly more active than the monometallic ones, but less selective. A similar
6 mechanism was also reported for crotonaldehyde hydrogenation on Pt-Sn bimetallic catalysts,
7 in which Pt_{NP} activated H₂. [16] For the second and third categories (*pathways B* and *C*),
8 metallic NPs are associated to isolated metal single atoms (SAs), resulting in a “cocktail” of
9 catalysts with species of different nuclearity. It is worth mentioning that in that case, the
10 system is not necessarily bimetallic. Although the use of single atom catalysts in (selective)
11 hydrogenation is quite widespread,[17, 18] these catalysts often suffer from difficulties in
12 activating H₂ due to their electrodefficiency resulting from a strong charge transfer with the
13 support. Consequently, specific sites (most of the time a heteroatom such as O[19, 20] or
14 N[21]) should be present at their vicinity on the support for heterolytic H₂ activation to
15 proceed. To overcome this drawback, metal SAs can be associated with metallic NPs that will
16 initiate the H-spillover. *Pathway B* has been proposed for the selective hydrogenation of CAL
17 on Ni/C catalysts, for which Ni_{NP} activated H₂, and H-spillover on the carbon support
18 provided hydride species to Ni_{SA}, on which CAL is selectively hydrogenated into HCAL.[22]
19 *Pathway C* involves the cooperativity between noble metal NPs that activate H₂ and metal
20 SAs that perform the hydrogenation. Although this pathway has not yet been reported for
21 selective hydrogenation reactions, it has already been described on supported Pd catalysts for
22 C=C[23] and C=O[24] bond hydrogenation, as well as for hydrodeoxygenation reactions.[25]
23 In the last category (*pathway D*), the metal SA is directly deposited on a metal NP, resulting
24 in single-atom alloy (SAA) catalyst, for which H-spillover occurs on the surface of the metal
25 NP. This mechanism has been proposed for Pt_{SA}-Cu_{NP} systems that selectively promote the

1 hydrogenation of C=O bonds in unsaturated aldehydes.[26, 27] For this latter category, the
2 NP can be also a noble metal NP, as for Pt_{SA}-Au_{NP} systems for HCAL production.[28] In
3 these SAA systems, H₂ activation is proposed to occur on Pt_{SA} and hydrogenation on the
4 surface of the NP.

5 In the continuation of our studies on the cooperative catalysis between metal SAs and NPs[23,
6 29-32] herein, the catalytic performance of a Ru_{SA}/CNT catalyst (CNT: carbon nanotubes) for
7 CAL hydrogenation in apolar solvent is first evaluated in order to produce HCAL.[4] Then,
8 the catalytic performances of this catalyst were compared compared to the ones of Ru_{SA}-
9 M_{NP}/CNT catalysts (M = Ru, Pd, Ni) that can follow different pathways (*B*, *C* and/or *D*). The
10 main aim of the present work is to discuss the interaction between the active species as well as
11 the role of the M_{NP} in the Ru_{SA}-M_{NP}/CNT catalysts for selective hydrogenation. Insights into
12 the cooperative catalysis between Ni_{NP} and Ru_{SA} for CAL hydrogenation were revealed from
13 density functional theory calculations.

14

1 **2. Material and methods**

2 **2.1. Carbon nanotube synthesis**

3 The carbon nanotubes were produced by catalytic-CVD in a fluidized bed reactor using
4 ethylene as carbon source. An AlCoFeO₄ catalyst was first pre-reduced under hydrogen
5 during 30 min at 650 °C. A typical experiment was carried out with ethylene (600 mL min⁻¹)
6 for 30 min to produce CNTs. The produced CNTs were purified (catalyst dissolution) by an
7 aqueous solution of H₂SO₄ (50 vol%) under reflux for 3 h. Finally, the CNTs were
8 functionalized by a treatment of purified CNTs with HNO₃ under reflux at 140 °C for 3 h. The
9 mixture was then filtered and washed with deionized water until pH ≈ 7. The final product
10 was collected and dried at 120 °C overnight.

11 **2.2. Monometallic catalyst preparation**

12 A dry impregnation method was used to prepare the ruthenium catalyst supported on CNTs
13 (Ru_{SA+NP}/CNT). The desired amount of ruthenium(III) nitrosyl nitrate solution was added to
14 acetone (10 mL) containing 1 g of CNTs to introduce 1.2 % w/w of metal phase. The solution
15 was sonicated at room temperature for 1 h and magnetically stirred overnight. The solution
16 was then filtered and washed with acetone. The resulting solid was dried in an oven at 120 °C
17 overnight. Finally, the 1.2 % Ru_{SA+NP}/CNT catalyst was reduced in a horizontal tube oven
18 under a nitrogen and hydrogen flow (20 vol% H₂) at 300 °C for 2 h (25 °C to 300 °C at 10 °C
19 min⁻¹). The same procedure was followed for the 1.2 % Pd_{NP}/CNT and the 1.2 % Ni_{NP}/CNT
20 catalysts, prepared using palladium(II) nitrate Pd(NO₃)₂·2H₂O and nickel(II) nitrate
21 Ni(NO₃)₂·6H₂O, respectively.

22 For the 1.2 % Ru_{SA}/CNT catalyst synthesis, the process consists in: i) creating carboxylic
23 groups on the CNT support by nitric acid oxidation (step I); ii) decomposing these groups

1 under an inert atmosphere to produce CO₂, some H₂ and carbon vacancies (step II); and iii)
2 depositing the metal on this defective support (step III).[33] Before the step III, the desired
3 amount of (η^4 -1,5-cyclooctadiene)(η^6 -1,3,5-cyclooctatriene) ruthenium(0) [Ru(COD)(COT)]
4 was added to 30 mL of purified pentane under an inert atmosphere. Then, the solution was
5 added on the support (step III). The mixture was stirred for 1 h and washed with purified
6 pentane. The solid was dried under vacuum overnight. Finally, the catalyst was treated under
7 a nitrogen and hydrogen flow (20 vol% H₂) at 80 °C for 1 h.

8 **2.3. Bimetallic catalyst preparation**

9 To prepare the bimetallic 2 % Ru_{SA}Ni_{NP}/CNT catalyst, the desired amount of nickel(II)
10 nitrate Ni(NO₃)₂.6H₂O was added to an acetone solution (10 mL) containing the Ru_{SA}/CNT
11 catalyst to introduce 1 % w/w of the Ni metallic phase. After sonication (1 h at room
12 temperature) and stirring (overnight at ambient temperature), the sample was filtered, washed
13 with acetone, and dried in an oven at 120 °C. Finally, the 2 % Ru_{SA}Ni_{NP}/CNT catalyst was
14 reduced in a horizontal tube oven under a nitrogen and hydrogen flow (20 vol% H₂) at 300 °C
15 for 2 h (25 °C to 300 °C at 10 °C min⁻¹). The same procedure was followed for the 2 %
16 Ru_{SA}Pd_{NP}/CNT catalyst using Pd(NO₃)₂.2H₂O as Pd precursor.

17 **2.4. Characterization**

18 The metal content in the catalytic materials was measured by inductively coupled plasma
19 optical emission spectroscopy (ICP-OES) performed on a Thermo Scientific ICAP 6300
20 instrument.

21 TEM analyses were performed by using a JEOL JEM 1400 electron microscope operating at
22 120 kV. The high-resolution analyses were conducted by using a JEOL JEM 2100F
23 microscope equipped with a field emission gun (FEG) operating at 200 kV with a point

1 resolution of 2.3 Å and a JEOL JEM-ARM200F Cold FEG operating at 200 kV with a point
2 resolution of > 1.9 Å. The particle size distribution was determined through a manual
3 measurement of enlarged micrographs from different areas of the TEM grid (at least 300
4 particles). The SA/NP ratio (a number ratio) was measured from the STEM–HAADF analyses
5 (around 30 STEM micrographs) of 5000-10000 elements, according to the sample.

6 The X-ray absorption spectra were recorded on the B18 beam line at the DIAMOND
7 synchrotron (Oxfordshire, UK). The samples, in the form of powder, were diluted with
8 polyvinylpyrrolidone (PVP) in an appropriate concentration inside a glove box and pressed to
9 form a pellet, which was then sealed in an aluminum pouch to avoid any oxidation. Spectra at
10 the Ru K-edge were collected at room temperature in fluorescence mode using a Si(311)
11 monochromator. The monochromator energy scale was calibrated via a third ion chamber
12 with a reference foil. The data analysis was performed using the ATHENA and ARTEMIS
13 software.[34] With ATHENA, the absorption edge, E_0 , is determined, and the absorption due
14 to the isolated atom is subtracted, by fitting the pre-edge and post-edge regions to obtain $\chi(k)$.
15 The software ARTEMIS is used to perform the fit of the EXAFS region to scattering models
16 in R-space obtained by FEFF, validated on standard compounds; the amplitude reduction
17 factor S_0^2 was fixed to 0.9 during fitting. The number of fitted parameters was always lower
18 than the number of independent points. The samples were also analyzed by X-ray
19 photoelectron spectroscopy using a VG Escalab MKII spectrophotometer, which operated
20 with a non-monochromatized Mg K_α source (1253.6 eV).

21 **2.5. Cinnamaldehyde hydrogenation in stirred tank batch reactor**

22 Hydrogenation reactions were performed in a Top Industrie high pressure and temperature
23 stainless steel autoclave with a temperature/stirring/pressure controlling system. In a typical
24 experiment, a mixture of catalyst (0.004 mmol), nonane (1.5 mmol, 200 mg, as internal

1 standard), trans-cinnamaldehyde (4.0 mmol, 528 mg), and 30 mL of dioxane as a solvent was
2 ultrasonicated for 5 min, and then transferred into the high-pressure autoclave. The autoclave
3 was purged 3 times with N₂. Then, the autoclave was heated to 100 °C and pressurized with
4 20 bar of H₂, setting the stirring rate at 1000 rpm. The reaction test duration was 6 hours.
5 Samples of the reaction mixture were taken periodically. The products were analyzed on a
6 PerkinElmer gas chromatograph equipped with Elite-5MS capillary column (30 m x 0.32 mm
7 x 0.25 mm) with a flame ionization detector. For recycling experiments, the same procedure
8 was followed. Between each cycle, the catalyst was separated by filtration and washed three
9 times with dioxane before being reused. TOF were calculated based on total surface metal
10 considering the presence of metal single atoms and when relevant metallic NPs. The metallic
11 dispersion for NPs was calculated from a universal mathematical relationship between the
12 average relative size of metallic crystallites and their dispersion.[35]

13 **2.6. Coating of open-cell solid foam substrates with RuNi/CNT catalyst**

14 Metallic open cell solid foams (OCSF) NiCr 2733 from RECEMAT (3010 m² m⁻³
15 geometrical specific surface and 92 % porosity determined thanks to X-ray tomography) were
16 precisely cut into cylinders (diameter: 4.3 mm and length: 25.0 mm) through electric arc
17 discharge machining. These objects were washed in acetone under sonication for 15 min at
18 room temperature and dried overnight. Then, the cleaned OCSF substrates were heated (5 °C
19 min⁻¹) up to 600 °C under air atmosphere, followed by a 4 h plateau at this temperature.
20 Natural cooling down to room temperature completed the activation of the objects. A pre-
21 reduced 2 wt.% Ru_{SANiNP}/CNT catalyst (300 °C, H₂ atmosphere, 2h) was used to prepare a 60
22 g L⁻¹ suspension in water accordingly to the following procedure adapted from previous
23 works[36]: in a planetary ball mill (Retsch PM100), 20 mL of deionised water are mixed with
24 0.4 g of dextrin (Sigma-Aldrich) for 5 min at 300 rpm. Then, 0.4 g of triton X (Sigma-
25 Aldrich) are added and mixed again for 5 min at 300 rpm. Finally, 1.2 g of the RuNi/CNT

1 catalyst are put in the mill and the mixture was ball-milled for 45 min at 500 rpm (3x15 min
2 with change in rotational direction). This suspension was used to dip coat a series of activated
3 foam cylinders. Excess suspension was removed by a careful air flow through the coated
4 structures. The samples were then dried overnight at 80 °C and weighed. A similar catalyst
5 content of $29.0 \pm 3.0 \text{ g}_{\text{RuNi/CNT}} \text{ L}_{\text{foam}}^{-1}$ was obtained for the different foam pieces,
6 corresponding to an estimated mean layer thickness of 15 μm (assuming a homogeneous
7 coverage). Coating homogeneity was characterized through optical microscopy (Keyence
8 VHX-6000) and SEM-EDX measurements help to confirm the mean thickness of the
9 coatings. Additional characterizations of the fresh coated catalysts were performed using
10 HAADF-STEM to check the impact of coating procedure on Ru-Ni active particles (size and
11 spatial distribution).

12 **2.7. Cinnamaldehyde hydrogenation in continuous flow reactor**

13 4 coated foam objects were inserted in a home-made stainless steel milli-reactor (4.4 mm
14 internal diameter, length of active zone of 100 mm) corresponding to an involved mass of 42
15 mg of RuNi/CNT catalyst. The reactor was operated in co-current up-flow of gas and liquid.
16 The liquid solution is precisely fed thanks to a HPLC pump (Shimadzu, LC2 0 AD) and the
17 H₂ gas flow is controlled thanks to a mass-flow controller (Bronkhorst Elflow Prestige). Gas
18 and liquid feeding lines met at a simple T-junction upstream of the reactor. The liquid is
19 preheated in a stainless-steel loop with a thermoregulated oil bath to the desired temperature
20 before entering the reactive zone. Temperature and pressure were controlled and monitored
21 (Labview) through a regulated electrical oven and an equilibar back pressure regulator,
22 respectively. Downstream, gas-liquid separation and liquid collection and sampling were
23 made through a simple gravity driven separator. Liquid phase analysis was made offline
24 periodically thanks to a GC-FID equipment (Shimadzu Nexis GC2030).

1 In the continuous experiments, the catalytic foam objects were conditioned *in situ* under H₂
2 flow (100 N mL min⁻¹) at the reactor temperature and pressure (160 °C and 20 bar) for 15
3 min. Then, the H₂ gas flow rate was set to 20 N mL min⁻¹ and the liquid was set to the desired
4 flow rate. The liquid mixture consists of a solution of 0.133 M of CAL (Sigma Aldrich, 99%)
5 and 0.032 M of tetradecane (Sigma Aldrich, 99%), used as internal standard, was prepared in
6 absolute ethanol (Sigma Aldrich) as solvent. Liquid flow rates varying between 0.2 and 1.0
7 mL min⁻¹ have been experienced, corresponding to contact times between 5.1 and 25.5 h
8 mol_{CAL}⁻¹ mol_{Ni+Ru}⁻¹.

9 **2.8. Test to assess hydrogen spillover**

10 To check for the H-spillover, WO₃ is used to diagnose the activation of H₂ in the various
11 catalysts, because the spilled-over hydrogen migrates and readily reacts with the yellow WO₃
12 to form dark blue H_xWO₃.^[37] Samples made with 1 g of WO₃ were mixed (or not) with 5 mg
13 of catalyst and treated with H₂ (100 mL min⁻¹) at 100 °C for 2 min.

14 **2.9. Computational details**

15 Periodic Density Functional Theory (DFT) calculations were performed using the *ab initio*
16 plane-wave pseudopotential approach, as implemented in the Vienna Ab initio Simulation
17 Package (VASP; version 5.4).^[38, 39] The exchange–correlation potential was approximated
18 with the generalized gradient approximation to the Perdew-Burke-Ernzerhof functional^[40]
19 and van der Waals interactions were taken into account through the D3 correction method of
20 Grimme *et al.*^[41] The core electrons were modeled using the Projector Augmented Wave
21 (PAW) approach,^[42, 43] and the valence monoelectronic states were expanded using a plane
22 wave basis set with a cutoff energy of 450 eV. Partial occupancies were estimated with a
23 Gaussian smearing (σ) of 0.05 eV during all relaxations and extrapolating the energies to $\sigma =$
24 0.00 eV. As recently computationally modeled and described in our group,^[44] the supported

1 metal catalyst consists of an O-functionalized graphene (including experimentally probed
2 abundant oxygen functional groups and point defects) as carbon support, together with a
3 single Ru atom in a single vacancy and a small M_{13} nanoparticle ($M = \text{Ru, Pd, Ni}$) as
4 supported metal catalysts, the latter being hydrogenated with a ratio between adsorbed
5 hydrides and surface metal atoms above unity. Γ -Centered ($3 \times 3 \times 1$) k -point mesh generated
6 using the Monkhorst–Pack method was employed,[45] with spin polarization on the nickel-
7 containing systems. A vacuum region by at least 10 Å between the periodically repeated slabs
8 was added to eliminate spurious interactions, and a dipole correction along the z -direction has
9 been considered.[46] All structures were optimized until forces were less than $0.015 \text{ eV \AA}^{-1}$.
10 Transition states were first located using the Climbing Image version of the Nudged Elastic
11 Band, CI-NEB, method,[47, 48] and then properly optimized using the Quasi-Newton
12 algorithm. Finally, they were proven to show a single imaginary frequency by the
13 diagonalization of the numerical Hessian matrix with a step of 0.015 \AA in both positive and
14 negative directions of each coordinate.

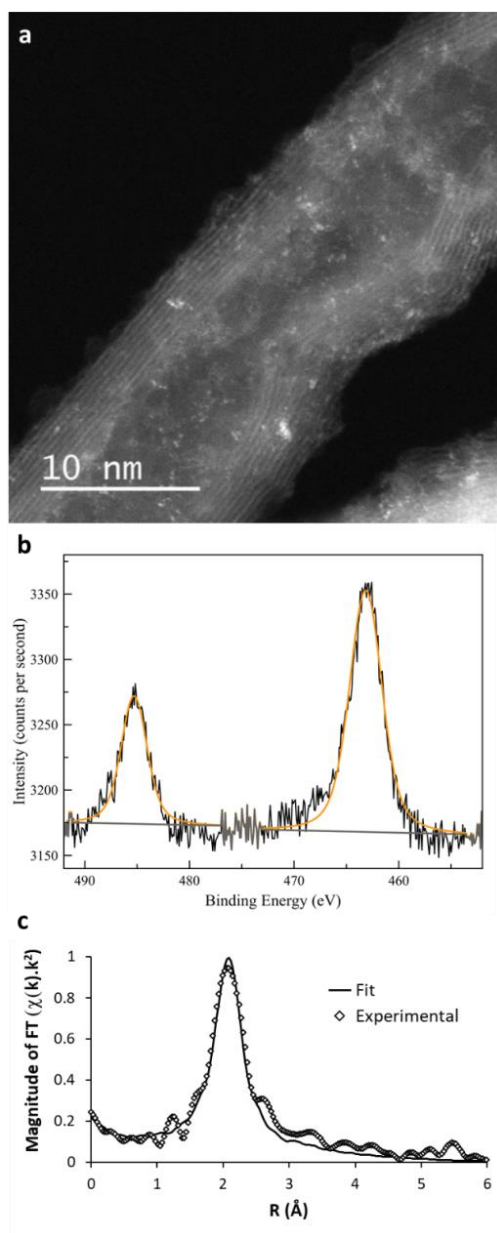

1 3. Results and discussion

2 This study involves the preparation of catalysts based on isolated SAs, metallic NPs or
3 mixtures of SAs and NPs with metal loading conventionally used for the CAL hydrogenation
4 reaction (1-2% w/w). The preparation and characterization of this type of catalysts on carbon
5 supports is not trivial. First, most carbon supports present in variable quantities sites capable
6 of stabilizing SAs.[49] Consequently, most carbon-supported NP-based catalysts (including
7 commercial ones) contain SAs, which can be easily visualized by aberration-corrected
8 scanning transmission electron microscopy (AC-STEM).[50] On the other hand, the
9 preparation and characterization of catalysts containing exclusively SAs with significant
10 metal loading (≥ 1 % w/w) is difficult.[51] In particular, the presence of clusters in such
11 catalysts is not always easy to demonstrate, even by combining several techniques, such as
12 high-angle annular dark-field STEM imaging (HAADF-STEM), EXAFS, and XPS (DRIFTS
13 analysis of carbon surfaces coupled to a probe molecule proves to be very challenging).[52]

14 3.1. Monometallic Ru_{SA}/CNT and Ru_{SA+NP}/CNT systems

15 A 1.2 % Ru_{SA}/CNT catalyst is prepared by a reported method that involves creating carbon
16 vacancies on the CNT support to stabilize the Ru_{SA}. [33] For this catalyst, the (η^4 -1,5-
17 cyclooctadiene)(η^6 -1,3,5-cyclooctatriene) ruthenium(0) [Ru(COD)(COT)] precursor is used to
18 deposit ruthenium. ICP-OES analysis showed a metal content of 0.94 % w/w. The sample is
19 characterized by HAADF-STEM, XPS, and EXAFS. Fig. 1a shows a representative HAADF-
20 STEM image of the catalyst (lower resolution images are shown in Fig. S1(a-b)). This catalyst
21 contains almost exclusively Ru_{SA} (92 at%, see Fig. S1(c-d) for NP size distributions based on
22 total number of NPs and total number atoms[53]). In addition to Ru_{SA}, very few clusters
23 presenting a mean size of 0.8 nm are detected (number ratio Ru_{SA}/Ru_{NP} = 201). EDX analysis

1 demonstrates that the Ru species are homogeneously distributed on the CNT support (Fig.
2 S2).

3
4 **Figure 1.** Characterizations of the Ru_{SA}/CNT catalyst (a) HAADF-STEM image (scale bar
5 = 10 nm). (b) High-resolution Ru 3p XPS spectrum. (c) Fourier transform magnitude of the
6 experimental Ru K-edge EXAFS $k^2\chi(k)$ and fit results (phase-shift corrected).

7 XPS analysis is performed with introduction of the Ru_{SA}/CNT sample by a vacuum transfer
8 cell from a glove box under a controlled argon atmosphere, whereby any oxidation of the

1 sample by air can be excluded. The Ru 3p binding energies at 463.2 and 485.3 eV (Fig. 1b)
2 are exceedingly high to correspond to Ru⁰ on the carbon support (Ru 3p_{3/2} = 461-462 eV[54,
3 55]), and should be associated to a significant charge transfer from Ru to each of the
4 neighboring C atoms of the support. First-principles studies are carried out to model and
5 describe the geometric and electronic properties of O-functionalized graphene (as model
6 support) decorated with metal NPs and/or metal SAs.[44] In this case, the Ru-supported
7 catalyst model (Fig. 2) is used to interpret the XPS results obtained with the Ru_{SA}/CNT
8 sample.

9

10

11 **Figure 2.** Top and side views of atomistic structure of the Ru_{SA+NP} catalyst model. Atomic
12 Color Scheme: Ru (Celadon Green); O (Candy Apple Red); C (Philippine Gray); H (White).

13 Analyzing the electronic distribution, a partial atomic charge around +0.9|e| is observed for a
14 Ru_{SA} anchored to a single vacancy; highlighting the Ru-to-C charge transfer (see Fig. S3 for
15 the detailed characterization of the Ru_{SA+NP} system).

1 To gain insight into the dispersion of the Ru species on the Ru_{SA}/CNT catalyst, the
2 coordination environment of Ru is investigated using EXAFS (Fig. 1c). The sample shows
3 only one shell centered around 2.1 Å and no detectable peak due to Ru-Ru interactions which
4 would appear at 2.6-2.7 Å, where only termination ripples can be observed. These results are
5 indicative of Ru_{SA} or very small clusters. The EXAFS data were fitted with a single
6 coordination sphere of C atoms to keep the number of fit parameters to a minimum. The Ru–
7 C bond coordination numbers in this coordination sphere are estimated to be 7.0 at a distance
8 of 2.12 Å, suggesting that the Ru_{SA} lies on a Stone-Wales defect (5775 pair).[56] However, a
9 simplified atomistic model (Model-I, see Fig. S4a) shows that Ru_{SA} initially in the 7-
10 membered ring converges towards a CN = 5 at a distance of 2.16 Å, as well as being
11 thermodynamically infeasible (binding energy of +50.2 kcal·mol⁻¹). Therefore, other more
12 stable models with CN as close to 7 as possible are explored, with Ru_{SA} in a multiple vacancy
13 of the O-functionalized carbon support (Model-II to -IV, see Fig. S4(b-d)). The
14 thermodynamically more stable model, with Ru_{SA} in a single vacancy of the same carbon
15 support, is also studied (Model-V, see Fig. S4e). The DFT models have been used in
16 ARTEMIS³² to generate FEFF paths to be compared with the experimental EXAFS data as
17 shown in Fig. S5. The Ru–O/Ru–C distances in the Model-I and Model-IV are the ones that
18 give the best agreement with the experiment. The distances in Model-V do not seem enough
19 compatible with the experimental EXAFS data, since there is a large discrepancy between the
20 oscillations produced by the model with those of the experiment, which are in phase
21 opposition. Thus, due to the average information provided by the EXAFS technique, the
22 coexistence of Model-I, Model-IV, and Model-V is feasible, the latter being the minority
23 species compared to the first two. Because of the steric hindrance observed around the metal
24 center in Model-I and Model-IV, Model-V is the most suitable model to carry out the

1 selective hydrogenation of CAL (further details about this choice will be provided at the end
2 of this section).

3 The selective hydrogenation of CAL is performed on the 0.94 % Ru_{SA}/CNT catalyst at 100 °C
4 under 20 bar of H₂ in dioxane. Besides the main products COL and H_{CAL}, further
5 hydrogenation leads to the formation of hydrocinnamyl alcohol (HCOL). Diacetal formation
6 is not observed, since it requires the use of alcoholic solvents.[57] The catalytic performances
7 are presented in Table 1. This catalyst shows very low activity for CAL hydrogenation at 100
8 °C, with a TOF_{1h} of 8 h⁻¹ and a S_{H_{CAL}} of 73% at 5% conversion. The lack of reactivity of the
9 Ru_{SA}/CNT catalyst can be explained by the fact that electron-deficient Ru_{SA} are not able to
10 dissociatively chemisorb H₂. In fact, the coordination of H₂ is feasible with an adsorption
11 energy of up to -12 kcal·mol⁻¹, but neither the homolytic dissociation of H₂ on the Ru atom
12 alone (H–Ru–H) nor the heterolytic one by Ru_{SA} and adjacent C atoms (RuH+CH) are
13 achieved. While the former gives H₂ recombination, the latter is not favorable from
14 thermodynamics, with reaction energies in the range of 4-28 kcal·mol⁻¹ (see Fig. S6a).

15 Therefore, to improve the reactivity of Ru_{SA} *via* H-spillover, the reactivity of Ru_{SA} combined
16 with Ru_{NP} deposited on the same support is first examined. A catalyst containing a mixture of
17 Ru_{SA} and Ru_{NP} is prepared from a solution of ruthenium(III) nitrosyl nitrate. HAADF-STEM
18 analysis of this 1.21 % Ru_{SA+NP}/CNT catalyst shows: 8 at% Ru_{SA}, a ratio Ru_{SA}/Ru_{NP} = 5, and
19 a Ru_{NP} size = 1.1 nm (Fig. S7). The use of this catalyst allows an improvement of activity
20 (TOF_{1h} = 181 h⁻¹) but not of selectivity (S_{H_{CAL}} = 72%).

Table 1. Catalyst performance for cinnamaldehyde hydrogenation.

Catalyst	NP size (nm)	Ratio SA/NP	CAL conversion at 1 h (%)	STY (h ⁻¹) ^a	TOF (h ⁻¹) ^b	S ₂₀ (%) ^c		
						HCAL	HCOL	COL
0.94 % Ru _{SA} /CNT	0.72 ± 0.05	201	0.6	8	8	73 ^c	13 ^c	14 ^d
1.21 % Ru _{SA+NP} /CNT	1.15 ± 0.46	5	15.2	154	181	72	6	22

2 % Ru _{SA} Pd _{NP} /CNT	1.87 ± 1.22	8	74.1 ^d	3085 ^e	5406 ^e	90.4	8	1.6
1.2 % Ni _{NP} /CNT	9.56 ± 2.87	12	4.7	46	307	91.8	8.2	0
2 % Ru _{SA} Ni _{NP} /CNT	1.29 ± 0.49	17	53.8	487	637	94.8	5.2	0

^a STY (mol_{CAL} mol_{metal}⁻¹ h⁻¹) at 1 h reaction. ^b TOF (mol_{CAL} mol_{surf.metal}⁻¹ h⁻¹) at 1 h reaction. ^c Selectivity at 20% conversion. ^d At 5% conversion. ^e At 15 min reaction time.

For H-spillover-induced cooperative catalysis to operate, H-spillover from Ru_{NP} to Ru_{SA} should be feasible. However, the H-spillover on the Ru_{SA+NP} system is unfavorable from a thermodynamic point of view. All H atoms from Ru_{NP} susceptible of experiencing spillover (*i.e.*, located close to an oxygenated functional group) were tested, the reaction energies obtained being positives and ranged from 3 to 12 kcal·mol⁻¹ (see Fig. S6b for a detailed description). Since it is not possible to activate H₂ on Ru_{SA} and H-spillover from Ru_{NP} to Ru_{SA} is hampered, Ru_{SA} in the Ru_{SA+NP}/CNT catalyst should be poorly active for hydrogenation due to the lack of Ru_{SA}-H species. For this reason, the hydrogenation of CAL on Ru_{SA} is not computationally studied. The absence of H-spillover on this catalyst was also experimentally evidenced. Spilled over H species readily reacts under mild conditions with WO₃ (yellow powder) to form dark blue H_xWO₃.^[58] As shown in the photographs of Fig. S8a, the WO₃ alone exhibited an unchanged color after H₂ treatment for 10 min. at 100 °C. When mixed with the Ru_{SA+NP}/CNT catalyst, no change of color is noticed (Fig. S8b). As the H-spillover cannot operate between Ru_{NP} and Ru_{SA} on the CNT support, the performance of the 1.21 % Ru_{SA+NP}/CNT catalyst should be attributed mainly to Ru_{NP}. The reaction mechanism for the semi-hydrogenation of CAL to HCAL and COL on Ru_{NP} is studied by DFT (the energy profile is summarized in Fig. S9, and Fig. S10 shows the structures corresponding to the reaction profile). The CAL adsorption can occur through the C=C or the C=O double bond, the first mode being especially favorable (-57 and -45 kcal·mol⁻¹, respectively). The hydrogenation process is thermodynamically favorable for the two possible products, with reaction energies ranging from -19 for COL to -28 kcal·mol⁻¹ for HCAL. The kinetically most energy-demanding step according to the two preferred mechanisms is always the first H insertion, with average energy barriers around 25 kcal·mol⁻¹. This could explain the small increase in activity (at 100 °C the reaction can occur) as well as the still not too high selectivity

(Ru_{NP} could give both products because both are energetically similar). Even so, it seems that Ru_{NP} gives H_{CAL} as the main hydrogenation product, since the species are more strongly adsorbed, making the H-insertions surmountable. The TOF obtained with this catalyst (TOF_{1h} = 181 h⁻¹) is in the same range as those obtained with Ru/C catalysts containing Ru_{NP} for CAL hydrogenation (15-450 h⁻¹).^[4] Consequently, *pathway C* (Scheme 1) cannot operate between Ru_{NP} and Ru_{SA} on carbon support. Finally, the H-spillover operability was also verified for the different models of Ru_{SA} anchored in an MV proposed previously (Fig. S4). On the one hand, through an energy decomposition analysis for Ru_{SA} in a SV (*Model-V* and Ru_{SA+NP} system, see Fig. S11), it is found that the only model capable of experiencing H-spillover from thermodynamics is *Model-II*. However, neither of the two coordination modes for CAL (C=C or C=O) is favorable on the Ru_{SA}-H species of this model. On the other hand, the *Model-IV* does allow the adsorption of CAL (only through the aldehyde function) but the H-spillover is not favorable on this model (around 13 kcal·mol⁻¹). Therefore, the most thermodynamically stable model with Ru_{SA} located in a SV (*Model-V*) is the only model that leads to the formation of the Ru_{SA}-H species and to the coordination of CAL. This model therefore seems the most relevant to explore the reactivity of the system.

As *pathway C* cannot operate between Ru_{NP} and Ru_{SA}, cooperative catalysis with two other metals associated in the form of NPs to Ru_{SA}, palladium and nickel, is therefore addressed in the following.

3.2. Heterobimetallic Ru_{SA}Pd_{NP}/CNT and Ru_{SA}Ni_{NP}/CNT systems

Palladium is much more active than ruthenium for this reaction and usually produces H_{CAL} with good selectivity. Supported Pd catalysts are also known to promote H-spillover,^[59] and

since this phenomenon has been reported for a Pd-Ru/C catalyst,[60] a cooperativity between Pd_{NP} and Ru_{SA} could be expected. It is verified by DFT that, in the case of the Ru_{SA}Pd_{NP} system, the H-spillover process can occur due to the slightly favorable thermodynamics, between -4 and -9 kcal·mol⁻¹ depending on the H atom (see Fig. S12 for the characterization of Ru_{SA}Pd_{NP} catalyst model, and Fig. S13 for a detailed description on the computed values). A 1.2 % Pd/CNT catalyst is first prepared from palladium nitrate (4 at% Pd_{SA}, ratio Pd_{SA}/Pd_{NP} = 3, Pd_{NP} size = 1.5 nm, Fig. S14) to assess the reactivity of Pd_{NP}. Considering the very low concentration of Pd_{SA} in this sample, it is named 1.2 % Pd_{NP}/CNT. This catalyst is very active for CAL hydrogenation (TOF_{15min} = 7130 h⁻¹), and as expected it presented a high S_{H_{CAL}} of 84.3 %. Hydrogenation of CAL at 150 °C and 50 bar on 5%Pd-1% Ru/CNT catalysts containing metallic NPs has already been reported in the literature.[61] On this bimetallic catalyst, the conversion of CAL and the S_{COL} were better than on the monometallic counterparts. To probe for possible cooperativity between Pd_{NP} and Ru_{SA}, 1 % Pd w/w palladium is deposited from Pd nitrate on the 0.94 % Ru_{SA}/CNT catalyst to produce 2 % Ru_{SA}Pd_{NP}/CNT (0.82% Ru + 1.03% Pd from ICP). This catalyst shows 1.7 at% Ru_{SA}, a ratio SA/NP ratio of 8, and a Pd_{NP} size of 1.9 nm (Fig. S15). In such a heterobimetallic catalyst, Ru_{SA} should act as reactive nucleation centers for Pd deposition. Thus, in addition to predeposited Ru_{SA}, many Pd_{NP} are found to be associated to Ru_{SA} (Fig. S16 for EDX analysis). Consequently, both *pathways C* (Pd_{NP}+Ru_{SA}) and *D* (Ru_{SA}@Pd_{NP} SAA catalyst) could coexist in this system. XPS analysis performed on this sample did not allow distinguishing isolated Ru_{SA} from Pd_{NP}@Ru_{SA} SAA. Indeed, the Ru 3*p* spectrum of this sample (Fig. 3, blue line) is similar to that of the Ru_{SA}/CNT catalyst (Fig. 3, black line), pointing either to the absence of a significant charge transfer in the SAA or to a high proportion of isolated Ru_{SA} in the sample. It was experimentally verified that H-spillover is operative on this catalyst (Fig.

S8c). The combination of Ru_{SA} and Pd_{NP} allows S_{HCAL} to be increased, reaching 90.4 %. The TOF decreased (TOF_{15min} = 5406 h⁻¹) compared to the 1.2 % Pd_{NP}/CNT catalyst (TOF_{15min} = 7130 h⁻¹), suggesting lower activity for Ru_{SA} compared to Pd_{NP} or activated Pd_{SA} (that is, Pd_{SA}-H species after an H-spillover mechanism from Pd_{NP}). If it appears that cooperative catalysis induces a better selectivity for HCAL thanks to Ru_{SA} (present on the support or on the Pd_{NP}), the very high activity of Pd_{NP} makes it difficult to decide on the activity of the Ru_{SA}-H species. For this, a metal with an activity significantly lower than Pd is used for the hydrogenation of CAL: nickel. Although less efficient than Pd because of a stronger M-H bond,[62] carbon-supported Ni catalysts are also active for H-spillover.[63-66]

Figure 3. Comparison of the Ru 3p XPS spectra of the Ru_{SA}/CNT, Ru_{SA}Pd_{NP}/CNT, and Ru_{SA}Ni_{NP}/CNT catalysts.

It was independently verified by DFT that H-spillover can operate in the Ru_{SA}Ni_{NP} system, resulting in a thermodynamically favorable process with reaction energies between -4 and -7 kcal·mol⁻¹, very similar to the values obtained for the Ru_{SA}Pd_{NP} system (see Fig. S17 for the characterization of Ru_{SA}Ni_{NP} catalyst model, and Fig. S18 for a detailed description on the computed values). It is worth noting that in systems where Ru and Ni are directly associated, it has been reported that it is Ru that activates H₂ to provide H species to Ni, which contributes to higher catalytic performance.[67-70] For CAL hydrogenation on Ni-Ru systems, contrasting results were reported. 99% Ni-1% Ru bimetallic NPs, in which small amounts of Ru were deposited by galvanic displacement on the Ni_{NP} surface, were investigated by Zhang *et al.*[71] This catalyst, which could contain Ru_{SA} on Ni_{NP} (SAA type) shows, at 100 °C and 15 bar, a conversion similar to that obtained with Ni_{NP}, but is more selective towards H_{CAL} (S_{H_{CAL}} = 79.1 % for the Ni-Ru system and 54.1 % for Ni_{NP}). Surprisingly, at 150 °C and 10 bar, a selectivity of 97.5 % to H_{COL} was reported for a Ni-Ru catalyst containing magnesium/aluminum hydrotalcite.[72]

A 1 % Ni/CNT catalyst (1.02 % Ni from ICP) is prepared from nickel nitrate (≈ 0 at% Ni_{SA}, ratio Ni_{SA}/Ni_{NP} = 12, Ni_{NP} size = 9.5 nm, Fig. S19). The low Ni dispersion on this catalyst is in accordance with mean Ni_{NP} size reported in the literature for Ni/CNT catalysts.[73-75] This catalyst shows low activity (TOF_{1h} = 306 h⁻¹), and presented a high S_{H_{CAL}} of 91.8%, in accordance with the reactivity of Ni/C catalysts for CAL hydrogenation.[76-78] To probe cooperativity between Ni_{NP} and Ru_{SA}, 1 % Ni w/w nickel nitrate is deposited on the 0.94 % Ru_{SA}/CNT catalyst to yield 2 % Ru_{SA}Ni_{NP}/CNT (0.72% Ru + 1.07% Ni from ICP). A loss of Ru occurs during catalyst preparation. Ruthenium leaching could be due to dissolution with nitrate salts of Ru clusters presenting Ru atoms of high surface energy during the impregnation

procedure. This catalyst shows 3 at% Ru_{SA}, a ratio SA/NP = 17, and a Ni_{NP} size = 1.3 nm (Fig. S20). We do not believe that Ni_{SA} could be easily formed during the preparation of this bimetallic catalyst since the stabilizing sites for SAs (the carbon vacancies) are already occupied by the Ru_{SA}, or have been passivated during the reduction of the Ru_{SA}/CNT catalyst. In addition, galvanic replacement is unlikely as the Ru_{SA} are already oxidized, and for Ni it will be favored in the opposite configuration.

The occurrence of H-spillover on this catalyst was experimentally evidenced at 100 °C. As shown in the photographs of Fig. S8d, when mixed with the Ru_{SA}Ni_{NP}/CNT catalyst, the WO₃ changed of color upon H₂ treatment, pointing to its reduction to H_xWO₃ by H spillover species. The color change is however much less marked than in the case of the Ru_{SA}Pd_{NP}/CNT sample (Fig. S8c). In this heterobimetallic system, the Ru_{SA} act as nucleation centers for Ni deposition. The first consequence of a high nucleation rate is that Ni_{NP} are significantly smaller in Ru_{SA}Ni_{NP}/CNT catalyst (1.3 nm) than in the Ni_{NP}/CNT one (9.5 nm). The EDS elemental mappings of the Ru_{SA}Ni_{NP}/CNT catalyst present on Figure 4a and Figure S21 illustrate a highly dilute Ru phase on Ni_{NP}, suggesting the presence of Ru-Ni SAA (Ru_{SA}@Ni_{NP}). The EDS elemental mapping of quasi SAA involving Pd on Ni_{NP} shows a much higher contribution of Pd,[79] compared to the Ru contribution we have measured. In addition, a number of atom-sized bright spots (highlighted by the yellow circles on Figure 4a,b) have been attributed to individual Ru atoms distributed on the surface of Ni_{NP}. [80] Although we cannot ruled out the presence of low nuclearity Ru clusters/patches on Ni nanoparticles, the STEM-HAADF micrographs clearly indicate the presence of Ru_{SA} on Ni_{NP}. Thus, the 2 % Ru_{SA}Ni_{NP}/CNT catalyst contains a cocktail of isolated Ru_{SA} and Ru-decorated Ni_{NP}, Ru_{SA}@Ni_{NP} (see Fig. S22 for representative HAADF-STEM images).

Figure 4. (a) STEM-EDX analysis of the Ru_SA Ni_{NP}/CNT catalyst. (b) STEM-HAADF micrograph of the Ru_SA Ni_{NP}/CNT catalyst.

Consequently, both *pathways B* ($\text{Ni}_{\text{NP}}+\text{Ru}_{\text{SA}}$) and *D* ($\text{Ru}_{\text{SA}}@\text{Ni}_{\text{NP}}$, SAA catalyst) could proceed in this system. XPS analysis performed on this sample allows distinguishing isolated Ru_{SA} from $\text{Ru}_{\text{SA}}@\text{Ni}_{\text{NP}}$ SAA. In fact, the Ru 3*p* spectrum of this sample (Fig. 3, red line) is different to that of the $\text{Ru}_{\text{SA}}/\text{CNT}$ catalyst (Fig. 3, black line). For the $\text{Ru}_{\text{SA}}\text{Ni}_{\text{NP}}/\text{CNT}$ catalyst, two species are present, the isolated Ru_{SA} showing a Ru 3*p*_{3/2} binding energy at 463.2 eV as in the $\text{Ru}_{\text{SA}}/\text{CNT}$ catalyst, and a new species at 459.2 eV. This new peak can be attributed to Ni_{NP} -interacting Ru species in SAA. It is worth noting that the significant binding energy shift compared to what is expected for the Ru^0 species on carbon (Ru 3*p*_{3/2} = 461-462 eV[54, 55]) points to a significant charge transfer from Ni_{NP} to the Ru atoms ($\text{Ru}^{\delta-}$ species). The presence of electron-rich Ru species has already been reported in the case of the Ni-Ru[81, 82] and Co-Ru[83] bimetallic systems, as well as in the case of Ru-Ni SAA catalysts.[80] Thus, in a 0.5 %Ru-5 %Ni/MMT catalyst (particle size in the range of 1.5-4.5 nm) in which each Ru_{SA} was surrounded by three or four Ni atoms, the Ru 3*p*_{3/2} binding energy was measured at 458.8 eV.[81] The Ni 2*p* high-resolution XPS spectrum (Fig. S23) shows mainly the presence of nickel oxide (NiO and/or Ni_2O_3),[84, 85] with a binding energy at 855.6 eV. This high binding energy can be explained by the high sensitivity towards oxidation of small Ni particles due to the most reactive low-coordinated metallic Ni sites,[86] and/or by the charge transfer from Ni to Ru and/or from Ni to carbon.[87] The single-atom alloy catalyst model is based on the previous $\text{Ru}_{\text{SA}}\text{Ni}_{\text{NP}}$ system by replacing one Ni atom of the Ni_{NP} with one of ruthenium, resulting in a Ni_{NP} -coated surface Ru (the formation energy, E_{form} , of each possible Ni–Ru exchange is presented in Fig. S24). The thermodynamics of all these substitutions is favorable, so the formation of this type of SAA model can take place. According to the calculations, it is determined that the most stable configuration occurs with the Ru atom located in the upper-middle part of the Ni_{NP} (*Ni146*

configuration). Analyzing the electronics of this Ru_{SA}Ni_{NP} SAA system (see Fig. S25 for atomistic structure and charge distribution), a partial atomic charge around +0.8 and +1.5|e| is observed for Ru_{SA} and the Ru_{SA}@Ni_{NP} species in SAA, respectively. The difference comes mainly from a charge transfer by the surrounding Ni atoms, in addition to the presence of hydrides species on the nanoparticle surface.

The 2 % Ru_{SA}Ni_{NP}/CNT catalyst shows an activity (TOF_{1h} = 637 h⁻¹) much higher than that of 0.94 % Ru_{SA}/CNT (TOF_{1h} = 8 h⁻¹) and twice that of 1.2 % Ni_{NP}/CNT (TOF_{1h} = 306 h⁻¹). In addition, the S_{H_{CAL}} reaches a value of 94.8 %, which is the highest obtained among all the investigated systems. It is worth mentioning that smaller Ni_{NP} supported on carbon are not expected to activate H₂ more easily than large NP.[88, 89] In addition, several works in the literature have shown that for hydrogenation reactions, an optimal size of Ni particles is around 10 nm; smaller particles being less active.[90, 91] Consequently, we did not believe that a Ni particle size effect can explain the higher performance of the Ru_{SA}Ni_{NP}/CNT catalyst compared to the Ni_{NP}/CNT catalyst.

Remarkably, S_{H_{CAL}} remains very high even at high CAL conversion (Fig. 5), as a selectivity of 94 % to H_{CAL} was achieved at 99 % CAL conversion with this catalyst at 100 °C and a pressure of 20 bar. In other words, the product selectivity was independent of conversion, which is generally not observed in this reaction with carbon-supported Ru catalysts.[92-95] This catalyst ranks above the Ru-based catalysts described in the literature, both in term of activity and H_{CAL} selectivity.[4] It also shows good stability, since no modification in activity or selectivity was noted after five recycling experiments. It has been shown that the presence of Ru can promote the reduction of Ni oxides on Ni/CNT catalyst.[74] However, the increased performance of the Ru_{SA}Ni_{NP}/CNT catalyst compared to the Ni_{NP}/CNT catalyst cannot be attributed to a better

reduction of Ni in the bimetallic catalyst, since it is known that Ni/CNT catalyst prepared from nickel nitrate are efficiently reduced at 300 °C[73, 74].

Figure 5. Evolution of CAL conversion and product selectivity on the 2 % Ru_SANi_{NP}/CNT catalyst. S_HCAL (red diamonds); S_HCOL (blue triangles); and S_COL (orange squares).

3.3. Operability of the Ru_SANi_{NP}/CNT catalyst in continuous flow

The Ru_SANi_{NP}/CNT catalyst has been wash coated on millimeter-scale NiCr foam substrates in order to test its ability in continuous flow operation (see experimental details for the procedures). These continuous tests are also interesting to discuss catalyst stability with easy access to relatively high turnover number (TON). Fig. S26 presents typical optical photographs of foam objects used in this study before and after the coating step. A relatively homogeneous covering has been obtained, also validated by SEM analyses (Fig. S27). STEM-HAADF analyses show that the coated Ru_SANi_{NP}/CNT catalyst has not been significantly affected by the coating process

(Fig. S28). A slight increase in Ni mean particle size (2 nm after coating for 1.3 nm before coating, Fig. S29) and decrease in SA/NP ratio (13 after coating for 17 before coating) were noticed. Continuous flow experiments have been performed for different liquid flow rates at constant temperature and constant pressure with an excess of hydrogen. Fig. 6 depicts the results obtained in this series of experiments. Fig. 6a and Fig. 6b show the evolution of CAL conversion with time on stream and the corresponding selectivity-conversion profile, respectively. It can be seen that a decrease in liquid flow rate tend to increase the CAL conversion and to decrease the HCAL selectivity in a scheme of consecutive reactions. It is noticeable that the decrease in selectivity starts at a lower conversion in continuous flow in comparison to the batch reactor. Non-ideal plug flow hydrodynamics with a small amount of liquid back-mixing may contribute to explained part of this result. Nonetheless, possible changes in the fine catalyst structure due to the coating process cannot be excluded but they were not sensible to the available characterizations techniques. It can be seen also that conversion is stable for each liquid flow rate, and a return to the initial flow rate of 1.0 mL min^{-1} at the end of the sequence leads to an identical conversion close to 30%. The results obtained can be reworked to be plotted as a function of contact time, typical of continuous catalytic reactor operation (Fig. 6c). This representation clearly makes appearing a linear behavior typical of a pseudo-zeroth order for CAL when conversions lower than 90% are obtained. This behavior tends to become closer to first order for the highest conversions ($> 90\%$). The Site Time Yield (STY) observed in the continuous experiments is plotted against the Turn-Over Number (TON) in Fig. 6d. For the lower conversions, because of the pseudo-zeroth order, this average activity along the catalyst bed appears independent of the concentration (or conversion level) and is representative of the constant local activity.

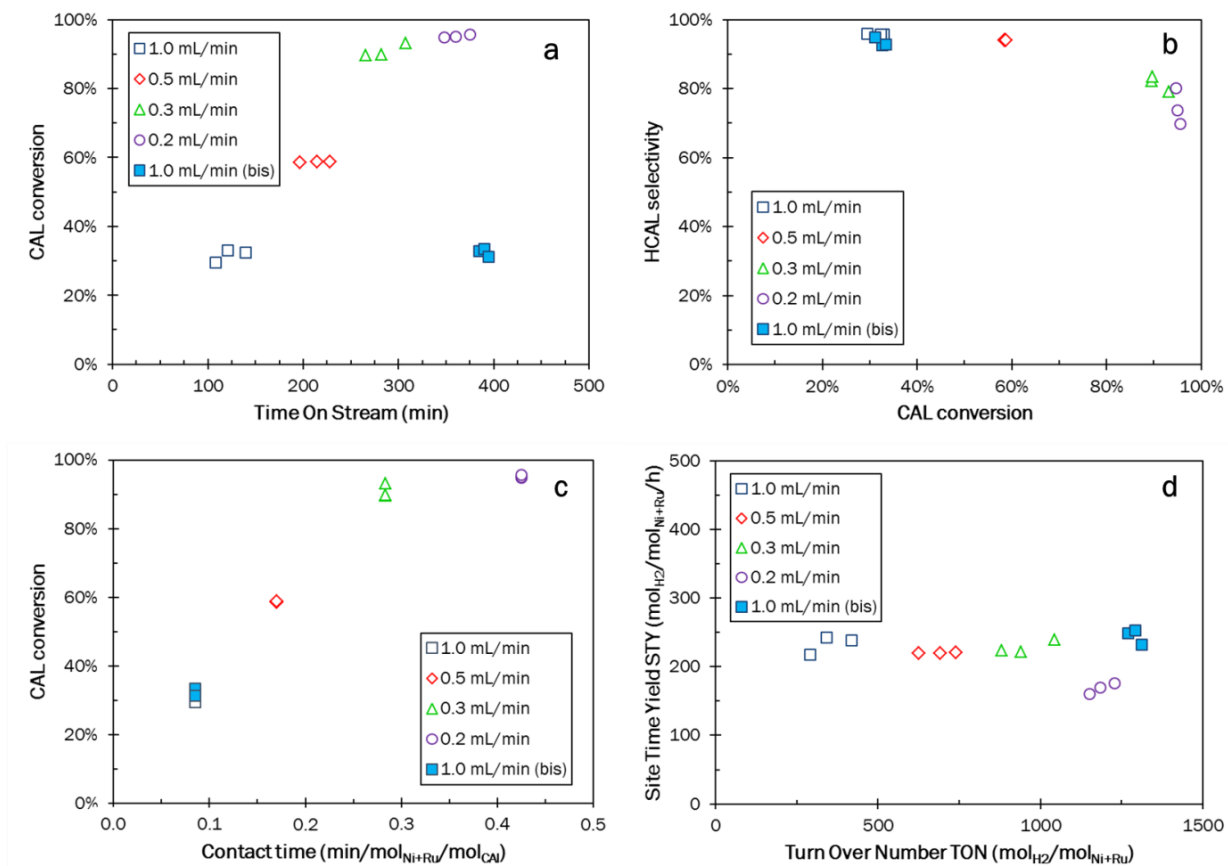

Figure 6. a) Time on stream evolution of CAL conversion in continuous flow experiments. b) Corresponding HCAL selectivity vs CAL conversion. c) Evolution of CAL conversion with contact time. d) Evolution of Site Time Yield (STY) with Turn-Over Number (TON).

A stable STY profile is obtained, up to a relatively important TON of 1300 mol_{H₂} mol_{Ni+Ru}⁻¹, indicating a good stability of the coated catalyst. The lower STY obtained at a liquid flow rate of 0.2 mL min⁻¹ is not to link with deactivation, but with the change in apparent order with the high conversion obtained at this point. This is confirmed with the control experiment repeated at 1.0 mL min⁻¹ at the end of the sequence, where a similar STY is reached again. Overall, the catalyst

appears stable after the coating process, and can be operated in continuous flow, wash coated on structured internals.

Mechanistic study on the Ru_{SA}Ni_{NP}/CNT system

DFT calculations are used to understand whether the observed effect is related to the presence of activated isolated Ru_{SA} (*pathways B* - Ni_{NP}+Ru_{SA}) or to Ru atoms bound to the Ni_{NP} (*pathways D* - Ru_{SA}@Ni_{NP} in SAA catalyst). Consequently, the metal species present in the Ru_{SA}Ni_{NP} SAA system are the Ni atoms of the Ni_{NP} and the Ru atom bound to the Ni_{NP} (Ru@Ni_{NP}) as a model of SAA (see Fig. 7 for the atomistic structure and Fig. S24 for a detailed electronic and electric characterization of the most stable catalyst model), as well as the activated isolated Ru_{SA}.

Figure 7. Top and side views of atomistic structure of the Ru_{SA}Ni_{NP} SAA catalyst model. Atomic Color Scheme: Ru (Celadon Green); Ni (Apple); O (Candy Apple Red); C (Philippine Gray); H (White).

To further understand the experimental observations, the reaction mechanism for the selective hydrogenation of CAL on the three metal species of the SAA catalyst model is studied in the DFT framework. Starting from the role of nickel in Ni_{NP}, the coordination of 1,4-dioxane as the solvent used is first considered (see Fig. S30a), resulting in an adsorption energy of -21.4 kcal·mol⁻¹. After, the energy profile and the corresponding structures are summarized in Fig. S31 and Fig. S32, respectively (the energy profiles are presented as potential energies, thus, not considering entropies). On **3** (representing the Ru_{SA}Ni_{NP} SAA catalyst model, see Fig. S31 and Fig. S32), the reaction begins by a π coordination of the alkene or carbonyl function of CAL. In both cases, the resulting intermediates are strongly adsorbed on the Ni_{NP} surface (**4**_{CHCH}^{NP} at -43.2 and **4**_{CHO}^{NP} at -35.8 kcal·mol⁻¹, respectively) by the π interaction of the double bond with a Ni atom (in a top adsorption site), and by the presence of two H-bonds between the organic substrate and -COOH functional groups of the support. Therefore, solvent molecules should be easily decoordinated from the Ni atoms by the presence of CAL.

Because the atoms forming the double bonds have different connectivity, the first H addition on both atoms is considered additionally for all studied cases. Additionally, given the high coverage conditions, where there are several H atoms around CAL, the H attacking the organic moiety is always the closest. From **4**_{CHCH}^{NP}, the first hydrogenation step is thermodynamically relatively unfavorable on both carbon atoms, being the preferred on the carbon connected to -CHO group by about 10.8 kcal·mol⁻¹ (**4**_{CHCH₂}^{NP}, red pathway in Fig. S31). In both cases, the energy barrier is practically identical and around 40-42 kcal·mol⁻¹, so the first step is hardly achievable from the kinetic point of view. The situation changes particularly in terms of reaction energy for the second H addition (**4**_{CH₂CH₂}^{NP}), favored by thermodynamics, regardless of the obtained reaction intermediate. The energy barriers, moreover, are notably lower than those of the first, around 15

kcal·mol⁻¹. On the other hand, starting from $\mathbf{4}_{\text{CHO}}^{\text{NP}}$, the first hydrogenation step is only slightly thermodynamically unfeasible on the oxygen atom ($\mathbf{4}_{\text{CHOH}}^{\text{NP}}$, dark yellow pathway in Fig. S31) by around 5.7 kcal·mol⁻¹, while the energy barriers remain kinetically difficult to access, at around 36-38 kcal mol⁻¹. Both thermodynamics and kinetics are favored in the second hydrogenation step of the C=O bond ($\mathbf{4}_{\text{CH}_2\text{OH}}^{\text{NP}}$), especially the latter, with drops in the energy barrier down to 15-25 kcal mol⁻¹. Once HCAL or COL is obtained, it is strongly coordinated on the surface (average desorption energy of 39 kcal·mol⁻¹) due to the interaction of Ni_{NP} with the aromatic ring through the $\eta^2(\text{C})$ coordination mode. Finally, the catalyst can be recharged under H₂ pressure by a thermodynamically favorable process. Therefore, the hydrogenation of CAL is difficult on Ni_{NP}, the first hydrogenation always being the most energy-demanding step.

Concerning the role of ruthenium in the Ru_{SA}@Ni_{NP} SAA model, the coordination of the solvent 1,4-dioxane is only -1.9 kcal·mol⁻¹ (see Fig. S30b), which gives the Ru atom greater availability as active site. The energy profiles and the corresponding structures are summarized in Fig. 8 (most favorable mechanisms), Fig. S33 (complete hydrogenation pathways), and Fig. S34, respectively. From **3** (Fig. S33 and Fig. S34), the adsorption of CAL ($\mathbf{4}_{\text{CHCH}}^{\text{SAA}}$ and $\mathbf{4}_{\text{CHO}}^{\text{SAA}}$ depending on the coordinating C=C or C=O function, respectively) is favorable from the thermodynamic point of view in both cases, and higher in the case of C=C coordination (binding energies of -23.8 and -14.0 kcal·mol⁻¹, respectively). The π coordination of the organic substrate on the Ru embedded in Ni_{NP} is very similar to those previously found on Ni_{NP}, while no H-bonds are observed since the active center is relatively far from the functionalized carbon support.

Once CAL is adsorbed, the possibility of first hydrogenating one carbon or another of the alkene group, as well as the carbon or oxygen atoms of the aldehyde group, opens up again. From a

thermodynamic point of view, the first hydrogenation turns out to be slightly endothermic for the C=C bond, and slightly exothermic for the C=O bond, with reaction energies between 0.7

($4_{\text{CH}_2\text{CH}}^{\text{SAA}}$, wine pathway in Fig. 8) and $-2.2 \text{ kcal}\cdot\text{mol}^{-1}$ ($4_{\text{CHOH}}^{\text{SAA}}$, dark yellow pathway in Fig. 8).

The importance lies in the kinetics of the reaction, since both paths are energetically low. In fact, with an activation barrier of $16.9 \text{ kcal}\cdot\text{mol}^{-1}$, hydrogenation of the easiest C atom of the alkene group can occur under operating conditions (temperature of $100 \text{ }^\circ\text{C}$). However, the activation barrier of the aldehyde group ($23.2 \text{ kcal}\cdot\text{mol}^{-1}$), although also affordable, is above the desorption energy of the reactant ($14.0 \text{ kcal}\cdot\text{mol}^{-1}$). Therefore, a high activity on $\text{Ru}_{\text{SA}}@\text{Ni}_{\text{NP}}$ is expected with respect to C=C hydrogenation due to the low competition between the coordination of both functions, in addition to the C=O decoordination process. The second hydrogenation step of the alkene to obtain HCAL ($4_{\text{CH}_2\text{CH}_2}^{\text{SAA}}$) is slightly disadvantaged from thermodynamics by $7.7 \text{ kcal}\cdot\text{mol}^{-1}$, although the reaction kinetics are reasonably fast as in the first step ($21.8 \text{ kcal}\cdot\text{mol}^{-1}$). In the case where the first step of the aldehyde hydrogenation reaction takes place, the second step leading to the formation of COL ($4_{\text{CH}_2\text{OH}}^{\text{SAA}}$) is thermodynamically favorable ($-4.3 \text{ kcal}\cdot\text{mol}^{-1}$), while from a kinetic viewpoint is also accessible with an energy barrier value of $14.1 \text{ kcal}\cdot\text{mol}^{-1}$. Finally, the desorption of HCAL and COL from the $\text{Ru}_{\text{SA}}@\text{Ni}_{\text{NP}}$ site entails a low energy cost around 18.6 and $23.3 \text{ kcal}\cdot\text{mol}^{-1}$, respectively, which further reinforces the preferential activity and selectivity of HCAL in the Ru-based SAAs.

Figure 8. Reaction profile of CAL semi-hydrogenation to HCAL (in wine) and COL (in dark yellow) on the Ru@Ni_{NP} site of the Ru_{SA}Ni_{NP} SAA catalyst model (black for the initial common step). The energy is referenced with respect to the hydrogenated (Ru–Ni)-supported catalyst (3) and CAL_(g).

Regarding the role the isolated Ru_{SA} site of the Ru_{SA}Ni_{NP} SAA system, the coordination of 1,4-dioxane on the Ru_{SA} and Ru_{SA}-H species is -31.2 and -4.1 kcal·mol⁻¹, respectively (see Fig. S30(c-d)), clearly chemisorbed in the case of the bare Ru_{SA}. Subsequently, the energy profiles and the corresponding structures are summarized in Fig. S35 and Fig. S36, respectively.

Unexpectedly, the formation of the active species $\text{Ru}_{\text{SA}}\text{-H}$ by means of an H-spillover process ($\mathbf{3}_{\text{H}}$) turns out to be somewhat unfavorable from thermodynamics, unlike the $\text{Ru}_{\text{SA}}\text{Ni}_{\text{NP}}$ system (4.1 vs -7.0 kcal·mol⁻¹, respectively). The presence of the Ru atom on the Ni_{NP} is causing a subtle strengthening of the metal-H interactions, as in the case of the monometallic $\text{Ru}_{\text{SA}+\text{NP}}$ system. The integrated pCOHP (IpCOHP), an average bond strength index, is 55.2, 25.7, and 27.1 kcal·mol⁻¹ per metal-H interaction in the $\text{Ru}_{\text{SA}+\text{NP}}$, $\text{Ru}_{\text{SA}}\text{Ni}_{\text{NP}}$, and $\text{Ru}_{\text{SA}}\text{Ni}_{\text{NP}}$ SAA catalyst models, respectively. This fact limits the possibilities of $\text{Ru}_{\text{SA}}\text{-H}$ being an active species for CAL hydrogenation. In the case of an H-spillover phenomenon (as experimentally evidenced, since some Ni_{NP} do not contain Ru), the reaction begins only by the favorable C=O bond coordination of CAL on $\text{Ru}_{\text{SA}}\text{-H}$ ($\mathbf{4}_{\text{H-CHO}}^{\text{SA}}$, binding energy of -18.5 kcal·mol⁻¹). Coordination of the C=C bond is not observed, mainly because of steric hindrance, along with a preference for H-bonds with the support away from the Ru_{SA} . It should be noted that on Ru_{SA} only the $\eta^1(\text{O})$ coordination mode is observed, distinct from Ni_{NP} or $\text{Ru}_{\text{SA}}@\text{Ni}_{\text{NP}}$, for which the $\eta^2(\text{C=O})$ one is favored over others. Nevertheless, the study of CAL hydrogenation on Ru_{SA} is especially relevant to rule out the formation of COL in SAA catalysts, as observed experimentally.

Starting from $\mathbf{4}_{\text{H-CHO}}^{\text{SA}}$, the first hydrogenation step is a thermodynamically favorable process for both pathways, the average reaction energy being around -19 kcal·mol⁻¹. In contrast, neither pathway is kinetically easy, since although the lowest energy barrier is 28.3 kcal·mol⁻¹, the transition states of both pathways greatly exceed the adsorption energy of the organic substrate. In the case of being able to overcome them (thanks to the experimental reaction conditions), from any of the reaction intermediates, the second hydrogenation step proceeds exclusively by using molecular H_2 (wine and red pathways in Fig. S35). If a second H-spillover occurs, the processes would be energetically very unfavorable (orange and dark yellow pathways in Fig.

S35). Finally, hydrogenation thanks to dihydrogen could give rise to the formation of COL ($4^{\text{SA}}_{\text{CH}_2\text{OH-H}}$), which remains coordinated through the hydroxyl group. According to these results, the isolated Ru_{SA} species seem not to be sufficiently active and, therefore, the production of the alcoholic compound is rather scarce.

4. CONCLUSIONS

Carbon nanotube supported Ru single atoms have been associated to metal nanoparticles (Ru, Pd, Ni) to probe H-spillover assisted cooperative catalysis in cinnamaldehyde hydrogenation. The $\text{Ru}_{\text{SA}}/\text{CNT}$ catalyst shows poor performance for this reaction ($\text{TOF} = 8 \text{ h}^{-1}$, $S_{\text{HCAL}} = 73 \%$) due to its difficulty to active H_2 . No cooperativity was observed when Ru_{SA} are associated to Ru_{NP} because H-spillover cannot operate in the $\text{Ru}_{\text{SA}+\text{NP}}/\text{CNT}$ system for thermodynamic reasons. The performance of this catalyst ($\text{TOF} = 181 \text{ h}^{-1}$, $S_{\text{HCAL}} = 72 \%$) should be consequently associated to the Ru_{NP} . The association of Ru_{SA} to Pd_{NP} allows H-spillover to operate to produce $\text{Ru}_{\text{SA-H}}$ species. For this $\text{Ru}_{\text{SA}}\text{Pd}_{\text{NP}}/\text{CNT}$ catalyst, the selectivity towards HCAL is improved ($S_{\text{HCAL}} = 90 \%$) compared to the $\text{Ru}_{\text{SA}}/\text{CNT}$ ($S_{\text{HCAL}} = 73 \%$) and $\text{Pd}_{\text{NP}}/\text{CNT}$ systems ($S_{\text{HCAL}} = 84 \%$). However, the very high activity of Pd_{NP} precludes probing the activity of $\text{Ru}_{\text{SA-H}}$ species. The deposition of Ni on the $\text{Ru}_{\text{SA}}/\text{CNT}$ catalyst results in a system containing two distinct Ru species: isolated Ru_{SA} and Ru_{SA} associated to Ni_{NP} ($\text{Ru}_{\text{SA}}@\text{Ni}_{\text{NP}}$, SAA). The hydrogen spillover from Ni_{NP} to isolated Ru_{SA} can operate but is not favorable from $\text{Ru}_{\text{SA}}@\text{Ni}_{\text{NP}}$ to Ru_{SA} . The $\text{Ru}_{\text{SA}}\text{Ni}_{\text{NP}}/\text{CNT}$ catalyst shows much better performances in terms of activity and selectivity compared to the $\text{Ru}_{\text{SA}}/\text{CNT}$ and $\text{Ni}_{\text{NP}}/\text{CNT}$ systems. This $\text{Ru}_{\text{SA}}\text{Ni}_{\text{NP}}/\text{CNT}$ catalyst also shows excellent recyclability and promising performances in a lab-scale flow reactor. DFT calculations

revealed that the selective hydrogenation of CAL to HCAL is a slightly endothermic reaction, kinetically accessible only by the Ru site on the $\text{Ru}_{\text{SA}}@\text{Ni}_{\text{NP}}$ single atom alloys. The $\text{Ru}_{\text{SA}}\text{-H}$ species does not allow HCAL formation due to steric reasons, however it favors the production of COL through a kinetically limited pathway. In the SAA, the activation barriers for the hydrogenation reaction on $\text{Ru}_{\text{SA}}@\text{Ni}_{\text{NP}}$ ($21.8 \text{ kcal}\cdot\text{mol}^{-1}$) is much lower than on Ni_{NP} ($39.5 \text{ kcal}\cdot\text{mol}^{-1}$). The introduction of Ru_{SA} on the Ni_{NP} greatly reduced the barriers necessary for the first H addition and the HCAL desorption.
