HIGHLIGHTS

- 272829
- Continuous chronostratigraphic sequence of 24.5 m covering the last seven millennia.
- Attested anthropogenic impact from the Late Neolithic.
- 31 A dry period is recorded at 4.2 ka cal BP
 - Continuous agricultural practices only evidenced since 4 ka cal BP.
 - Human resilience indicates complex interplay between ecological and cultural factors.

ABSTRACT

The study was conducted in the southern part of the lower Strymon valley, in northern Greece, and revealed up to 25 meters of fluvio-lacustrine sediments deposited over the last seven millennia. This sedimentary record represents a significant opportunity for high-resolution palaeoenvironmental studies of the period from 6 to 3 ka cal BP linked to land use and climate change. The results of geophysical investigations, multi-proxy sedimentological (grain size, magnetic susceptibility, loss-on-ignition), pollen and NPP analyses, based on high-precision radiocarbon dating enabled reconstruction of past landscapes as well as a comprehensive discussion of anthropogenic responses and their impact on the vegetation cover, especially during periods with well-known Holocene Rapid Climate Change events (5.6, 4.2 and 3.2 ka cal BP).

During the 7-5.7 ka cal BP corresponding to the Late and Final Neolithic, wet conditions created an extended lake surrounded by the densely wooded Strymon watershed, followed by a shift to a shallower lake environment that lasted until ca. 4.5 ka cal BP. The continuous presence of

anthropogenic taxa suggests the persistence of human activities even in the absence of formally recognized sites, suggesting the relocation of settlements. The first signs of human disturbance of the landscape at regional scale occurred toward 5.2 ka cal BP (onset of the Early Bronze Age). The so-called « 4.2 ka BP event », which coincided with the end of the Early Bronze Age and the transition to the Middle Bronze Age, is divided into three distinct periods (4.35-4.1, 4.1-3.95 and 3.95-3.75 ka cal BP). The first corresponds to gradual aridification before a period with severe dry conditions that marks a tipping point toward wetland contraction. From this period on, diversification, and multiplication of anthropogenic species including *Olea, Juglans* and *Castanea* reflect a global trend toward cultural landscapes. The later periods are characterized by dramatic climatic change around 3.2-3 ka cal BP, at the end of Late Bronze Age, and increasing impacts of agro-pastoral activities and forest clearing starting at the beginning of Antiquity, around 2.8 ka cal BP (Thracian period). After the 4.2 ka cal BP event and we suggest that climatic adversity may have acted as a stimulus to innovation and relocation rather than retarding societal development in the region. To conclude, environmental factors in the lower Strymon valley were not sufficient on their own to trigger a social crisis similar to that mentioned in the Middle East

Key words: Rapid Climate Changes; 4.2 ka cal BP event; human resilience; northern Aegean; fluvio-lacustrine archive; eastern Mediterranean.

Holocene Rapid Climate Changes (RCCs) characterize periods of 150 to 500 years and are often considered as driving factors of socio-economic and cultural change (Mayewski et al., 2004). Numerous authors discuss the collapse of civilizations in response to some of these abrupt climate changes in the Eastern Mediterranean (e.g. Weiss et al., 1993; Weninger et al., 2009; Büntgen et al., 2011; Drake, 2012; Weiss, 2012; 2017; Kaniewski et al., 2013, 2015, 2018; Wiener, 2014; Knapp and Maning, 2016; Cookson et al., 2019, Florescu et al., 2019). Nevertheless, uncertainties remain about the nature of this RCC, which could involve a combination of orbital, ocean circulation, largescale tropical volcanic eruptions, and solar forcing (Finné et al., 2011; Wanner et al., 2011), and could explain the complexity of the mid-Holocene climate transition (Magny et al., 2013; Triantaphyllou et al., 2009). Furthermore, the impacts of climate change need to be assessed in terms of biophysical and social resilience and/or vulnerability (Butzer and Endfield, 2012). And there is also a need for more site-specific detailed studies focusing on ecological foundations and strategies (Flohr et al., 2016; Lespez et al., 2016). Only such work, closely interlinked to multidisciplinary analyses within archaeological sites, will optimize our perception of forms of socioecological resilience (Berger et al., 2016; Lespez et al., 2016). Research in lakes (Ohrid: Sadori et al., 2016; Sinopoli et al., 2018; Dojran: Francke et al., 2013; Masi et al., 2018; Prespa: Aufgebauer et al., 2012; Panagiotopoulos et al., 2013; 2014) or from marine cores in the Aegean Sea (Kotthoff et al., 2008a; Triantaphyllou et al., 2014) revealed the potential of the southern Balkans and the northern Aegean Sea for obtaining data on climate trends in the eastern Mediterranean basin (Fig. 1; Table 3 in supplementary data). In this context, eastern Macedonia (Greece) offers high potential for studying vegetation changes in response to climatic and anthropogenic processes (e.g., Wijmstra 1969; Greig and Turner, 1974; Tzedakis et al., 2006; Pross et al., 2007; 2009; Peyron et al., 2011).

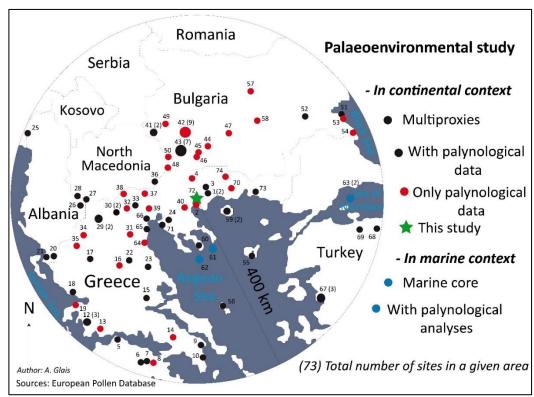

Figure 1: Location of the main previously published palaeoenvironmental investigations discussed in the text within a radius of 400 km around the study area (green star). For a complete list of sites summarized by the numbers on the map and the main reference cited, see supplementary data.

Despite the increasing number of investigations of the relationship between social processes and RCCs, the debate continues concerning their impact on settlement patterns, population dynamics or social adaptations. In eastern Macedonia, the lack of a signature of the 4.2 ka cal BP climatic event in the climatic and environmental proxies studied explains why, until now, the many studies conducted in this area (Atherden et al., 2000; Bottema, 1982; Gerasimidis, 2000; Glais et al., 2016a, b; Greig and Turner, 1974; Lespez, 2003; 2007, Peyron et al., 2011; 2016) have not been able to explain the environmental transformations brought about by the RCC and its impact on societies. This research using multi-proxy palaeoecological studies provides independent lines of evidence of climate change to compare with local archaeological evidence (Hjelle et al., 2012). But archaeological data are subject to biases due to the taphonomic processes that explain variations in the visibility of artefacts, or insufficient/inappropriate temporal resolution (e.g. Surovell et al., 2009; Tsirtsoni et al., 2020a). Accordingly, one of the most difficult challenges is to reconstruct the population trends and to translate them into statistical data, either from a cultural or an ecocultural perspective (Bevan et al., 2019; Lawrence et al., 2021; Weiberg et al., 2019; Whitford, 2018). In our study area (see below for description), i.e. the lower Strymon valley, which, together with the adjacent Philippi-Drama plain and the island of Thasos form the Greek region of Eastern Macedonia, such reconstructions are lacking, despite the great number of known settlements (e.g. Koukouli-Chryssanthaki et al., 2008) and the great number of available radiocarbon dates from archaeological contexts (Tsirtsoni, 2016). From an archaeological perspective, the time interval considered in this study relates to the periods from the Late-Final Neolithic to the onset of Antiquity. Some periods show a dramatic decline in settlement, the most remarkable being the transition from the Neolithic to the Early Bronze Age, which partly coincides with the 5.6-5.2 ka cal BP event. Several authors consider it a major cultural break that also affected other parts of the Aegean and the Balkans (e.g. Todorova, 1995; Coleman 2011; Weiberg et al., 2019), but others tend to minimize it, instead emphasizing signs of continuity (Andreou et al., 1996; Demakopoulou, 1996; see also detailed discussion in Tsirtsoni 2016b, and Lespez et al., 2014; 2016). Another obscure period is the end of the Early and the transition to the Middle Bronze Age, which coincides almost perfectly with the 4.3-3.8 ka cal BP event. Previously less discussed in the local archaeological literature than the preceding period, this apparent gap in settlement has recently received attention (Leshtakov and Tsirtsoni 2016).

In the present study, we use a *one-site* (local) scale, then combine our results with other one-site studies to reach a *one-area* (regional) scale (Mercuri et *al.*, 2014, 2019). We have already used this methodology in our previous studies in Eastern Macedonia (Dikili Tash: Lespez et *al.*, 2000; 2013; Glais et *al.*, 2016a; 2017), as it has also been used in other Mediterranean contexts (Dispilio: Karkanas et *al.*, 2011; Kouli, 2015; La Draga: Revelles et *al.*, 2017). More specifically, the results from one core located close to an archaeological site in the lower Strymon valley are discussed from the perspective of a broader human-environment interaction. Our objective is to examine the nature of palaeoenvironmental transformations during three of the most important RCC events of this period (5.6-5.2, 4.3-3.8 and 3.2-2.8 ka cal BP), and their potential effects on land use by humans.

2. Regional setting and previous research

2.1. Geological, Geomorphological, and environmental setting

The River Strymon is a large permanent fluvial system running roughly north-south with an average stream flow of 80 m³/s. From its source, 415 km upstream in the Vitosha Mountains at an elevation of 2,180 m a.s.l., the watershed covers approximately 18,078 km² across Bulgaria, North Macedonia and Greece and ends where the river flows into the Aegean Sea at Orphanos Bay (Fig. 2). The lower Strymon valley forms an 80 km long, 20 km wide, subsiding basin located along a Cenozoic fault detachment system, between the Serbo-Macedonian massif to the west and

southern Rhodope massif (Pangaion and Menoikion mountains) to the east that rise between 1,300 and 2,100 m a.s.l.. Tectonic activity was high during the Pleistocene and remains high today (Tranos, 2011; Mouslopoulou et al., 2014), although the study area has been relatively stable during the Holocene (Broussoulis et al., 1991). The bottom of the valley is fringed by Neogene hills with calcimagnesic soils and coalescing series of middle and upper Pleistocene alluvial fans, made of gravelly reddish-brown sediments (Psilovikos, 1986). The climate is sub-Mediterranean with a continental influence. Furthermore, local topography plays a significant role during atmospheric disturbance. Despite marked interannual variability, the mean annual temperature is 15 °C and annual precipitation in the plain is 600-650 mm (Horvat et al., 1974).

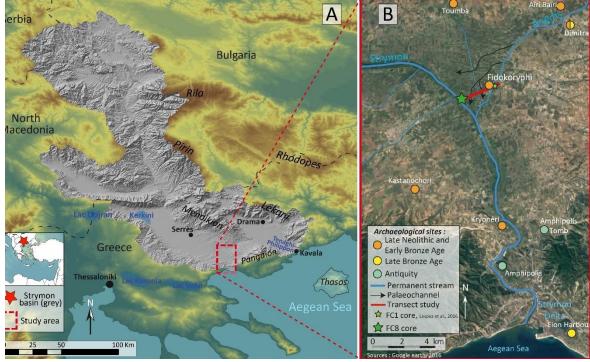

Figure 2: A: Location of the Strymon watershed and the study area; B: Transect study and known archaeological sites in the lower Strymon Valley

The current landscape in the lower Strymon plain was extensively modified by the complete drainage of Achinos Lake, which occupied the valley until 1930s (Lespez, 2008; Fig. 3). Although affected by human disturbance, the vegetation on Mount Pangaion, which dominates the valley eastwards, is divided into vertical vegetation zones with marked diversity resulting from the mesoand microclimate and the different types of substrate (Fig. 3). At lower altitudes (200-600 m a.s.l.), pseudo-maguis dominated by Quercus coccifera is well developed, mainly on slopes with southern exposure that reach higher altitudes in some locations (up to 1,000 m a.s.l.). The pseudo-maquis is gradually replaced by deciduous shrubland at higher altitudes (700-900 m asl), mainly composed of Carpinus orientalis, Fraxinus ornus, Acer monspessulanum, Liqustrum vulgare, Lonicera etrusca, Cornus mas and Ostrya carpinifolia, although this sub-Mediterranean vegetation probably results from human impacts, overgrazing and forest fires (Tsiftsis et al., 2007). Above 900 m a.s.l., xerothermic sub-Mediterranean deciduous oak woodlands are mainly dominated by Quercus frainetto, Q. pubescens and Q. petraea on northeastern slopes. Beech forests (Fagus sylvatica) grow above the oak or localized chestnut forests on gneiss schist, marble, and, more rarely, on granite (Papageorgiou et al., 2014), although at lower altitudes they form mixed stands with oaks (Tsiripidis et Athanasiadis, 2003). On Mount Pangaion, beech forests grow down to 600 m a.s.l., while their upper limits may reach 1,800 m a.s.l. forming the timberline (Fig. 3; Glais et al., 2016c). Above, timberline subalpine calcareous grasslands are well developed (Strid and Tan, 1997; Karagiannakidou et al., 2001), characterized by a diverse flora dominated by perennial grasses and other forbs including Sesleria achtarovii, Asperula petraeus, Dianthus petraeus, Festuca ovina agg., Carex halleriana, Festuca varia, Stipa pennata, Rostraria cristata, Vincetoxicum hirundinaria, Polygala nicaeensis, and Scabiosa ochroleuca.

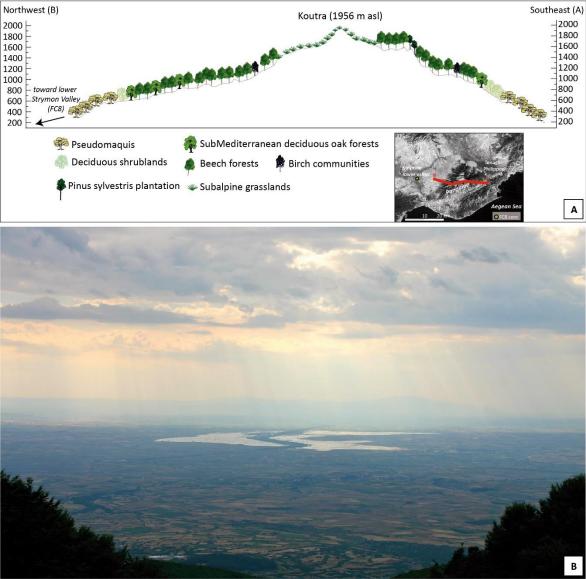

Figure 3: A: Synthetic altitudinal vegetation gradient on Mount Pangaion; B: Photo of the intensively cultivated and temporarily flooded Strymon plain taken from the northwestern slope of Mount Pangaion (May 2015).

2.2. Archaeological background

The Strymon River valley has always been an important communication route and a macro-scale ecological transition zone through the Mediterranean and northern continental climatic zone. This transitional environment was particularly involved in the spread of agricultural practices in Europe at an early stage of the Neolithic period, around 8000 cal BP (ca. 6000 BC: Weninger et *al.*, 2006; Marinova, 2007; Marinova et *al.*, 2012; Berger, 2017; Lespez et *al.*, 2013, 2017; Reingruber et *al.* 2017; Krauss et *al.*, 2017; Ivanova et *al.*, 2018; Whitford, 2018). The two following millennia witnessed a significant increase in the number of sites all along its course (Chohadzhiev, 2007; Todorova et *al.*, 2007). Most of the sites appear to have been temporarily or permanently

abandoned by the end of the 5th millennium BC, i.e. shortly before 6000 cal BP, like in most of northern Greece and Bulgaria (see Tsirtsoni 2016b; 2016d). One millennium later (beginning of the Early Bronze Age) the density of settlements again increased, but remained much lower than during the previous Neolithic and Chalcolithic periods (Grammenos and Fotiadis 1980; Grammenos 1991; Grebska-Kulowa and Kulow 2007). Sites dating from the Late Bronze Age (second half of the 2nd mill. BC, ca. 3500-3100 cal BP) are more numerous and sometimes more monumental than those dating from earlier periods (Atanassov et al., 2012; Soukantos et al., 2012). In fact, sites dating from the Middle Bronze Age (end of 3rd and first half of the 2nd mill. BC, ca. 4300-3500 cal BP) have not been found in the area. The Fidokoryphi settlement is one of the six known Late Neolithic and Bronze Age sites located in the lower Strymon valley within a radius of 10 km from its confluence with the Angitis, its main affluent to the east. The other sites are Dimitra, Aïri Baïri, Toumba, Kastanochori and Kryoneri (Grammenos and Fotiadis, 1980; Grammenos, 1997; Malamidou, 2016: Fig. 2). Only Dimitra and Kryoneri have been partially excavated, the other sites are known only from surface finds (in fact, systematic excavation has started also at Toumba in 2022, but no report is published yet). Consequently, the periods indicated here (Fig. 2B) are only indicative and their true duration of occupation could be substantially longer.

2.3. Previous geoarchaeological research

The lower Strymon valley and the adjacent Drama plain to the east (comprising the former Tenaghi-Philippon marsh) have been the focus of intense geoarchaeological research for several years now and confirmed their archaeological and palaeoenvironmental potential (Gerasimidis, 2000; Lespez, 2003; 2007; Lespez et *al.*, 2013; 2016; 2020; Glais et *al.*, 2016a; 2016b; 2017). Concerning the lower Stymon valley more particularly, a series of cores have been already drilled (maximum 10 meters thick in the current floodplain near the confluence with the Angitis River. The chronostratigraphic framework was established through 31 AMS based on seven cores and one sedimentary cross section of the riverbank and a multiproxy analysis was performed on the FC1 core located at the foot of Fidokoryphi hill on bank of the River Angitis (Glais et *al.*, 2016b; Lespez et *al.*, 2016). The present study continues these investigations while focusing on the results obtained from core FC8, located ca. 2 km from FC1.

3. Materials and methods

3.1. Coring

The reconstruction of the landscape, climate and hydrological condition changes is based on a detailed study of sedimentary deposits extracted by coring. The analysis focused on core FC8, located on the left riverbank of the present Strymon channel (40° 54′ 48.733″ N; 23° 47′54.225″ E) corresponding to the westernmost core of a 2.5 km transect study. The 24.5 m core was obtained in July 2012 using a mechanical Longyear LY34 drill. It replicated a previous core (FC5) made with a hand-driven drill down to a depth of 11 m (Lespez et *al.*, 2016; Glais et *al.*, 2016b). For the present study, the data from the two cores were combined. A written description of core FC8 was produced in the field. Sediment samples were collected and subsampling at 5 cm intervals was performed immediately; the samples were stored at 5 °C prior to laboratory analysis.

3.2. Electrical Resistivity Tomography (ERT)

In addition, in January 2016, an ERT survey was conducted along a 2 km west-east profile (from FC8 to FC1) using a pole-dipole array. This array has not only a good investigation depth but also good horizontal coverage and a strong signal/noise ratio. Electrodes spaced 5 meters apart yielded a depth of investigation of 80 meters, even though the confidence limit was set at 60-70 meters to

account for the fact that few reliable values appear below this depth. The device used a multielectrode system Abem Terrameter LS with 64 electrodes. Data inversion and data interpretation were carried out using Res2dinv software (Loke and Barker 1996).

3.3. Chronology

The chronostratigraphy of the FC5/FC8 core was determined by AMS dating using a series of 21 samples from in-situ wood remains and total organic matter (Table. 1). Radiocarbon ages were calibrated using the IntCal20 atmospheric curve (Reimer et *al.*, 2020). The age-depth model was obtained using Clam2.2 (Blaauw, 2010). The best fit was obtained applying a smooth spline solution. The confidence intervals of the calibrations and the age-depth model were calculated at 95% (2 σ) with 1,000 iterations. Concerning the relative archaeological chronology, for the earlier (7th and early 6th) and later (late 3rd to early 1st mill. BC) periods, we follow the scheme and nomenclature of Tsirtsoni et *al* (2020b). Table 2 in supplementary data provides a comparison with the scheme used in the synthetic study of Weiberg et *al* (2019).

3.4. Sedimentological analyses

To characterize the depositional context and post-depositional processes, we applied standard geomorphic and sedimentological methods that include examination of the texture, structure and geometry of the sedimentary units such as those used by Miall (1996) and Brown (2008). Granulometry was measured on 189 samples collected along the 24.50m core using a laser particle analyzer (Malvern 2000), adjusting for measurements on the >2 mm fraction, after pre-treatments to remove any remaining organic matter and mixed with sodium hexametaphosphate as dispersing agent. Coarse material was removed for the laser analysis but re-integrated for each sample. Deposits were described using several variables including the median, average particle size, sorting index and overall texture. The carbonate and organic matter contents of 187 samples were measured using the loss-on-ignition (LOI) method of Dean (1974). Samples of relatively dry sediment weighing approximately 1 g were taken at intervals of less than 15 cm throughout the 24.50 m sequence. After drying for 24 h at 105 °C to constant weight, the samples were heated at 550 °C for 3 h to estimate organic content. A second heating period at 925 °C for 6 h was used to assess the proportion of carbonate in the sediment.

3.5. Magnetic susceptibility measurements

Magnetic susceptibility measurements were made at CEREGE (Aix-en-Provence, France) using an (Agico) MFK1 magnetic susceptibility meter. The FC8 sediment core was sampled at 7 cm resolution and yielded a total of 365 samples. These samples were placed in 8 x 3 cm plastic boxes, dried and weighed. In addition, measurements of low-field magnetic susceptibility, usually made at a frequency of 976 Hz, were made at 15.616 Hz. The sensitivity of the MFK1 susceptibility meter is \approx 3 x 10.-8 SI at 976 Hz. The magnetic susceptibility values were divided by the density of the dried samples to derive specific susceptibilities (χ). The contribution of the superparamagnetic particles (< 0.03 μ m; Dearing et α l., 1996) is given by frequency dependent susceptibility (Fd %) where χ If and χ hf are the specific susceptibilities measured at low and high frequency, respectively.

3.6. Pollen analysis

Pollen analysis was carried out on 96 samples of sediment weighing 5 to 10 g along the 24.50 m FC8 sequence. Standard pollen extraction techniques were used (Faegri and Iversen, 1989). One Lycopodium tablet per sample was added to calculate the concentration of pollen (grains.cm⁻³)

(Stockmarr, 1971). To reconstruct changes in land cover, analyses focused on the identification of pollen and non-pollen palynomorphs (NPPs). Small aliquots of the residues were mounted in glycerin, sealed with Histolaque and the pollen and spores were identified and counted under a light microscope using 400x or 600x magnification, if necessary. Pollen grains, spores and NPPs were identified by comparing them with the reference collection at the Archaeobiology laboratory of Madrid (CCHS, CSIC), palynological keys and photo atlases (Moore et al., 1991; Reille, 1992; van Geel, 2001; Cugny et al., 2010). Pollen counts of up to 490 grains total land pollen (TLP) per sample were identified, excluding hydro-hygrophytic taxa and NPPs (expressed as percentages of the TLP), while the TLP average was 516 terrestrial pollen grains. Arborean Pollen includes only tree taxa and not shrubby species. Pollen of aquatic or wetland plants as well as spores and non-pollen palynomorphs (NPPs) were excluded from the pollen sum in order to avoid biases from the local pollen representation and their percentages were calculated relative to the total land pollen sum of all terrestrial taxa taken as 100% The pollen diagram based on these data was produced using Tilia and Tilia-Graph v. 2.0.b.5 software (Grimm, 1992, 2004). Local pollen assemblage zones (LPAZ) were defined based on agglomerative cluster analysis of the incremental sum of squares (Coniss) with square root transformed percentage data (Grimm, 1987). Figure 11 summarizes the palynological results coupled with some sedimentological data (Fig. 11).

We merged the species curves according to their ecological affinities. Anthropozoogenous taxa are plants associated with grazing pressure closely linked with human activities such as livestock farming, whereas anthropic-nitrophilous taxa are self-propagating plants associated with disturbed nitrophilous soil and are generally overrepresented in anthropogenic contexts, but are not crop plants (Behre, 1981; Bottema and Woldring, 1990; López-Merino et *al.*, 2009; Florenzano et *al.*, 2012; Marinova et *al.*, 2012). The difficulty involved in identifying region-specific indices of human impact in pollen assemblages has to be taken into consideration due to the lack of standardization (Deza-Araujo et *al.*, 2020). For the NPP groups (coprophilous, eu-mesotrophic, meso-oligotrophic, indicative of erosive processes, fire events or dry conditions) we used the nomenclature of Hugo de Vries (HdV Laboratory, University of Amsterdam), the ecological similarities and specific NPP study references (van Geel, 2001; Carrión and Navarro, 2002; van Geel et *al.*, 2003; van Geel and Aptroot, 2006; Cugny et *al.*, 2010; Gelorini et *al.*, 2011; Miola, 2012; Kołaczek et *al.*, 2013; Revelles and van Geel, 2016).

4. Results

4.1. Geometry of the sediments

The ERT cross-section revealed relatively low resistivity values (< 40 Ohm.m) characteristic of a fine sediment fill. Although low, the dynamics of the observed values allowed us to understand the morphology of the lower Strymon valley (Fig.4). The main unit indicates a gentle slope from the east (Fidokoryphi hill) to the west (Strymon) forming a depression, in which the deepest point was located approximately below the current Strymon channel even though none of the cores reached the base of this sediment layer. Four main geoelectric units (Ge1, Ge2, Ge3 and Ge4) can be distinguished. Ge1 values range from 5 to 25 ohm.m⁻¹ at a depth situated from_ca. 90 and 30 m below the surface and, according to Bennett and Buck (2016), may correspond to the irregular limit between Neogene substratum and Holocene deposits. Ge2 shows the lowest resistivity signal, generally below 5 ohm.m⁻¹, between 40 and 8 m below the surface. Ge3 extends from ca. 8 m deep to the present-day surface topography: the values are generally low, between 5 and 20 ohm.m⁻¹. A local increase in the resistivity signal is observed. In the top five meters, the ERT results show two transition layers with higher resistivity (> 13 Ohm.m⁻¹) located respectively 700-800 m and 950-1100m eastward from the current main Strymon riverbed. Ge4 is located between core FC4 and

the western area of the Fidokoriphi hill and from the surface to a depth of ca. 10 m. Ge4 has the highest resistivity values of the whole profile, ranging from 15 to 35 ohm.m⁻¹, corresponding to the presence of coarser deposits (sandy silt, fine micaceous to coarse sand) and the displacement of Angitis channel during the last millennia. The significant resistivity values (> 20 Ohm.m) situated at a distance of 100 m east of the channel correspond to the riverbank deposits (laminated fine to medium sand) and the artificial levee built during the last century for protection against river floods.

4.2. Chronological and sedimentary sequences

According to the ERT results, the sedimentary sequence analysis of core FC8 and its correlation with the stratigraphy of the drilling set (i.e., Fig.5 FC8/FC5, FC9, FC10 and FC4) shows lacustrine sediments more than 20 m thick deposited over a period of 6000 years. The high-resolution chronological definition (Table 1 and Fig. 7) allowed us to define four sedimentological units corresponding to different hydromorphological dynamics (Fig. 6). However, the sedimentary hiatus identified between a depth of 500 and 450 centimeters should be interpreted with caution due to potential reworking of these sediments attested by two incorrect radiocarbon data and peaks of vesiculate pollen percentages (infra: Fig. 9).

Sample code	Depth (cm)	Material	Laboratory Code	Age BP	Age Cal BP (2σ)	Age Cal BC/AD

Table 1: 21 AMS radiocarbon data calibrated from cores FC5 and FC8. AMS data excluded from the age-depth model are in italics.

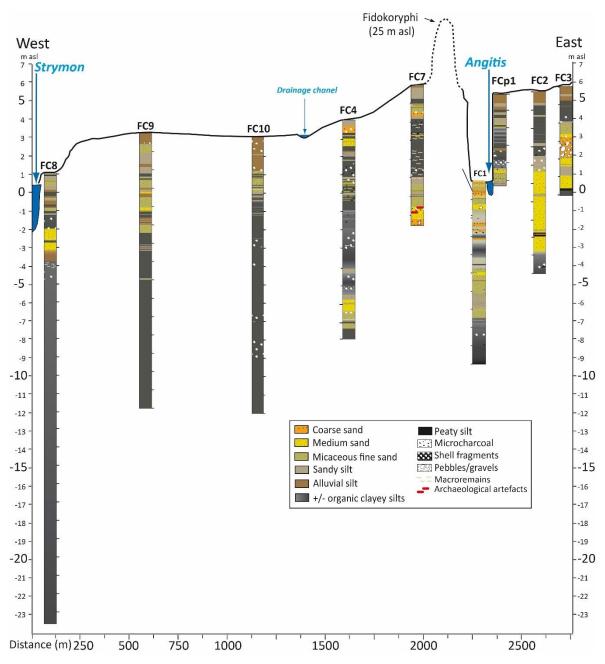

Figure 5: Transect study of the lower Strymon valley sedimentary fill from boreholes modified after Lespez et al., 2016 and Glais et al., 2016b. For chronostratigraphical units, see the second reference.

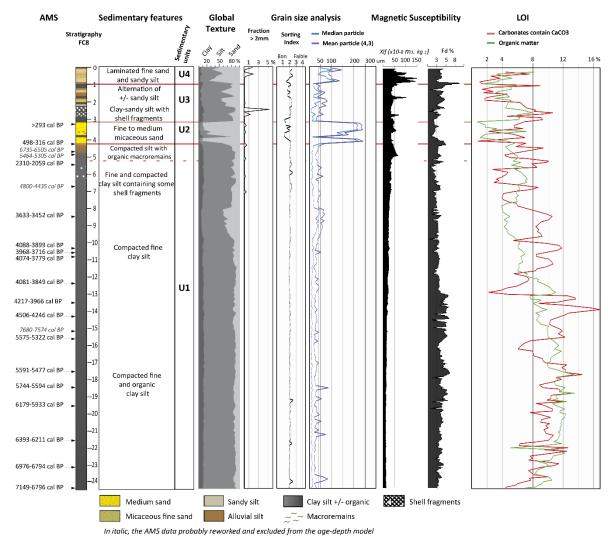

Figure 6: Synthetic log of FC8 and sedimentological proxies: sedimentary features, grain size analysis, magnetic susceptibility and loss on Ignition (LOI).

Sedimentary Unit 1 (2450 to 425 cm; ca. 6950-600 cal BP): compact and homogeneous fine lacustrine silts and clays.

The first sedimentary unit **(U1)** corresponds to fine homogeneous clayey-silt deposits 2,000 cm thick. The sediments are well sorted with a large proportion of silt (73 to 83%) whereas clay and sand percentages fluctuate respectively between 7.5 to 13% and 7 to 21%. The median particle size remains consistent at around 18 μ m (range 9 to 43 μ m) and the mean size oscillates between 21 and 63 μ m, with no more than 0.2% of particles more than 2 mm in size. Only two minor phases interrupt this homogeneous pattern. The first one occurs at the bottom between 2,400 and 1,850 cm (*ca.* 6900-5700 cal BP) during which several peaks of fine sand particles are recorded (50 to 87 μ m). The second occurs between 950 and 795 cm, corresponding to 3800-3430 cal BP and is characterized by a temporary increase in the sandy fraction from 20 to 41.5%. Along this unit, the magnetic susceptibility (χ If) signal is lo with a gradual increase from 10.10-8 to 40 x 10-8 m³.kg¹ around 1600 cal BP. After which, χ If values rapidly reached 67 x 10-8 m³.kg¹ while at the same time, we observe the presence of organic macro remains and ochre marks in the sediments. Two incorrect AMS results at this depth suggest hydromorphological change and a disruption of the deposition process.

On the other hand, the contribution of superparamagnetic particles (Fd %) revealed another pattern. From 2,450 to 1,325 cm (*ca*. 6950-4030 cal BP), the frequency dependent susceptibility underwent a consistent increasing trend, from 2.5% to 6% with an average of 4.2% for this period. Then, between 1,325 and 425 cm (*ca*. 4030-600 cal BP), the trend was reversed with a decrease from 3.7% to 1.6% (average 2.4%). Loss on ignition data showed a similar trend even though amplitude had a stronger effect. From 2,450 to 1,780 cm (*ca*. 6950-5575 cal BP), the trend in carbonate and organic matter content generally increased at relatively high values, between, respectively, 4.2% to 14.4% and 7% to 13.4%. From 1,780 to 780 cm the general trend of organic percentages gradually decreased to reach 4%, while carbonate content reached its maximum (16.7%) at 1,400 cm (*ca*. 4290 cal BP). The tipping point for frequency dependent susceptibility occurred around 1,325 cm which corresponds to an abrupt drop in carbonate content from 16.7% to 2.2%. Between 1,175 and 425 cm, the carbonate percentages fluctuated significantly (range 11.8-2.7%) with a decreasing tendency, while organic matter remained relatively stable at around 6%, between 780 and 425 cm.

Sedimentary Unit 2; 425 to 315 cm; ca. 600-80 cal BP — Fine to medium micaceous sand: alluvial inputs.

U2 is composed of micaceous and well-sorted sand, i.e. a significant change compared with the first unit (SU1). During this stage, the percentage of sand oscillated between 42% and 90.6%. The sand was fine to medium, characterized by median and mean particle size values ranging between 125 and 240 μm. Only a thin layer (373-362 cm) of silt (79.8%) containing sand (10.5%) and clay (9.5%), similar to previous lacustrine silty deposits, interrupted the second unit. Sandy sediment corresponded to the lowest percentages of organic matter (< 2%). Carbonate content fluctuated between 5.5 to 7%.

Sedimentary Unit 3; 315-100 cm; later than 80 cal BP – Alternating clay silt and sandy silt.

U3 shared similar features with SU1, its overall texture was dominated by silt 52-84.8%), sand (15-45%) and clay (2.5-11.8%). Nevertheless, sedimentary and pedological features revealed some differences. The deposit corresponded to alternating millimeter thick layers of silt containing indeterminate shell fragments and microcharcoals. The percentages of organic matter and carbonate content followed the same decreasing tendency from 7.8/10.5% to 3.5/1.5%, while the frequency dependent susceptibility showed the opposite trend, although interrupted by peaks, suggesting pedogenesis.

Sedimentary unit 4: 100-0 cm; undated, probably contemporary – Alternating fine sand and sandy silt.

The last unit identified (**U4**) corresponds to the most recent, including modern, sediment accumulation following intensive drainage of the lake in the 1930s. The alternation of fine sand and silty sand ranging between 85 and 135 μ m mean particle size, representing proximal floodplain deposits. Frequency dependence values reached their maximum (9.2%) at bottom of this layer at a depth of around 96 cm while low frequency susceptibility reached 152.10 8 m³. Kg⁻¹ at a depth of around 66 cm.

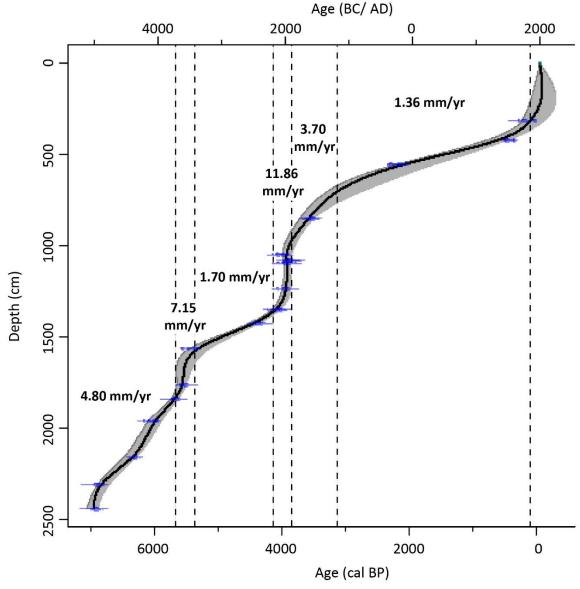

Figure 7: Age-depth model of FC5/FC8 core from 17 AMS radiocarbon data.

4.3. Pollen analysis

The concentration of pollen was always good, as can be seen in the synthetic concentration diagram (Fig. 8) but due to the lacustrine to fluvio-lacustrine nature of the sedimentation, it varied, indicating aerial and fluvial inputs. The average concentration was 68,235 grains/g, despite a clearly defined separation between the 1,320 upper centimeters corresponding to the least rich samples (16,200 grains/g) and the 1,130 deeper centimeters, where the average concentration was more than 108,000 grains/g. Further, the high taxa diversity (50 taxa minimum constitute the TLP), pollen and NPPs in a perfect state of preservation and the similarity between the percentage curves and concentration curves for each taxon confirmed that conditions were favorable at the time of the sediment deposits. The FC8 core provides particularly interesting data for this time interval, thanks to very high-resolution analysis of approximately 6 meters of sediment between 4.5 and 3.5 ka cal BP (a total of 25 samples were analyzed), something that was never previously possible in the eastern Mediterranean. This sequence provides a multi-decadal resolution for this period within the LPAZ3 and LPAZ4 palynozone (Table 3).

Palynozone	Depth	Estimated chronology	Palynological trend
LPAZ1	2450- 2170 cm	6950-6380 cal BP	The forested landscape (AP: 71.4-83.6%) comprised <i>Quercus pubescens</i> type (14.2-30%), <i>Q. ilex</i> type (2.5-13.3%), <i>Pinus sylvestris</i> type (8.8-17.7%) and <i>Ostrya/Carpinus orientalis</i> type (6.3-15.6%) as the main representative <i>species</i> . <i>Abies, Carpinus betulus, Corylus</i> and <i>Quercus suber</i> percentages fluctuated between 2 and 6.5%. The increase in mixed oak forest was to the detriment of other mesophilous taxa. Riparian trees were not much affected (<i>Alnus</i> : 2.3-5.1%; <i>Salix</i> : 0.5-3.3% and <i>Ulmus</i> : 1.2-2.7%). Shrub vegetation accounted for less than 5%. Herbaceous vegetation (13.3-28.5) was mainly composed of grasses (7.2-14.2%). Hydro-oligotrophic-hygrophytic taxa represented 6.5-12.2%. NPPs were subject to open water conditions: meso-oligotrophic (<i>Pediastrum simplex</i> and Anabaena: 15.8-103.9%) or eu-mesotrophic (mainly <i>Pediastrum boryanum</i> up to 73.9%).
LPAZ2	2170- 1810 cm	6380-5620 cal BP	Arboreal Pollen (AP) fluctuated between 64% and 85.3% while shrubby pollen were weakly represented (1.1-3.4%). There was a slight increase in <i>Abies</i> (5.2 to 7.8%), <i>Fagus</i> (> 1% and occasionally 3.5-4.5%) evergreen <i>Quercus</i> type (4.7-12.6%), along with the temporary appearance of <i>Castanea</i> and a decrease in <i>Corylus</i> (< 3.3%). Herbaceous pollen percentages (12.1-32%) were mainly composed of grasses (7.1-14.2%). Major changes were observed in <i>wetland</i> indicators: aquatic condition NPPs (<i>Anabaena</i> , <i>Botryococcus</i> and <i>Tetraedron</i>) and high values of <i>Pediastrum simplex</i> (60.4%-253.8% of total land pollen TLP) and <i>Pediastrum boryanum</i> (35.8%-13.8% of TLP). <i>At</i> the end, peak of coniferous and altitudinal forest (<i>Abies</i> : 14.2% and <i>Pinus sylvestris</i> type: 16.8%) and drop of thermophilous taxa (<i>Quercus ilex</i> type: 2.2% and <i>Quercus suber</i> : 0.2%).
LPAZ3	1810- 1320 cm	5620-4020 cal BP	On average: AP, 73.8%, Shrubs, 3.7% and Herbaceous species 22.5%. Mixed oak forests were composed of Quercus pubescens type (17.5-30.3%), Ostrya/Carpinus orientalis type (3.6-14.3%), Quercus ilex type (2.6-12.5%), Q. suber (1.5-5.7%), Carpinus betulus (1-5.1%), Corylus (1-2.9%), Tilia (0.2-2%) with more frequent occurrences of Castanea. Altitudinal forest was composed of coniferous (Abies: 1.9-8.1% and Pinus sylvestris type: 4.2-19.1%) and Fagus (0.7-6.4%). Erica arborea type (0.4-2%) and Juniperus type (0.4-4.6%) were the main components of shrubby vegetation. The herbaceous taxon assemblage was dominated by grasses (7.4-14.2%). More frequent occurrence of Cerealia type percentages (< 1%). Based on wet NPP indicators, eu-mesotrophic conditions (45-220% of TLP; Pediastrum boryanum, Tetraedron, Botryococcus and Spirogyra) appeared to predominate over meso-oligotrophic conditions (32.8-160% of TLP; Pediastrum simplex and Anabaena). The percentages around 1,410 cm (4340 cal BP) characterized a reversal of wet indicators until the end of LPAZ3 (1,320 cm; 4,020 cal BP), concomitant with marked decrease in the total pollen concentration (124,825 to 43,964 pollen grains/g of sediment). During these two and a half centuries, the percentages pf hydro-hygrophytic taxa increased from 9.6% to 15% and several herbaceous taxa, like Amaranthaceae, Polygonum aviculare type, Artemisia and Cichorioideae, also increased even though their percentages never reached more than 5%. Between 0.2% and 3.9% of Coprophilous NPPs were observed almost continuously.

LPAZ4	1320- 665 cm	4020-2920 cal BP	The beginning of LPAZ4 represents a tipping point in all pollen diagrams (Fig.7; Fig.8; Fig.9 and Fig.10). The percentage of woodland no longer dominated, falling from 63.3% to 45% . The <i>deciduous Quercus</i> curve declined and reached only 5.8% while <i>Tilia</i> almost disappeared. Likewise, <i>Carpinus-Betulus, Ostrya/Carpinus orientalis</i> type, <i>Pinus sylvestris</i> type, <i>Quercus ilex</i> type and <i>Fagus</i> decreased (respectively between 2% and 9%), even if in the case of the last three, the decline was only temporary. Woodland showed evidence of taxonomic diversification, with the spread of xerothermophilous species and progressive replacement of mesophilous forest by a thermo-Mediterranean vegetation cover. Initially, the percentage of shrubs was still low at around 3.3% . Then, starting from 1,215 cm (3920 cal BP), the spread of these taxa fluctuated (5.3% - 9.2%). Changes in wooden species occurred in parallel with a steep increase in the percentage (from 33% to 56.3%) of herbaceous species . The biggest increases occurred in perennial pasture plants (Brassicaceae, Caryophyllaceae and Fabaceae), anthropozoogenous taxa (Amaranthaceae, <i>Plantago lanceolata</i> type and <i>Polygonum aviculare</i> type), anthropic-nitrophilous taxa (<i>Aster</i> type and Cichorioideae), <i>Artemisia</i> and cultivated taxa such as Cerealia type (0-1.5%). The continuous presence of <i>Glomus</i> (HdV-207) and <i>Pseudoschizaea circula</i> , the increase in coprophilous NPPs (<i>Coniochaeta, Podospora</i> and <i>Sordaria</i> sp.) and NPPs is indicative of dry or fire events (<i>Chaetonium, Gelasinospora, Pleospora</i> and HdV-200). At around 751 cm (3290 cal BP), the rapid change mostly affected wet indicators and <i>Pediastrum</i> colonies practically disappeared. A dry event caused temporary drying up of the wetland before a return to initial conditions at the end of the zone.
LPAZ5	665- 220 cm	2920-200 cal BP	Throughout the palynozone (excluding the 500-450 cm interval of probable sedimentary reworking), the proportion of forest taxa remained relatively low (33-52.9%), while the bushlike vegetation cover (5-9.5%) was dominated by <i>Juniperus</i> type, <i>Erica arborea</i> type and <i>Olea</i> . The process of opening up of the landscape that started during LPAZ4 intensified and the majority of mesophilous taxa declined. The percentages of NPPs indicative of dry or fire events (0.6-3.8%), coprophilous NPPs (3.2-8.6%) and herbaceous taxa (Cerealia type: 0.4-3.2%; anthropic-nitrophilous taxa: 4-30%; anthropozoogenous taxa: 3-12%; perennial pasture plants: 4.5-10%) confirmed increasing anthropization. From a hydrological point of view, the decrease and subsequent disappearance of <i>Pediastrum</i> colonies at the end of the zone in parallel with the increase in the percentage of hydrohygrophytic taxa (from 14.5% to 28.2%) and in the percentage of NPPs of erosive processes (from 0.9% to 6.9%) is evidence for the intensification of alluviation and aggradation processes. Riparian taxa spread (<i>Alnus, Salix</i> and <i>Ulmus</i>) after the sedimentary hiatus phase.
LPAZ6 Table 3: Palyn	220-0 cm	200-50 cal BP	LPAZ6 was characterized by the continued degradation of woodland except riparian forest which increased significantly (<i>Alnus</i> from 3.7% to 24.3%; <i>Salix</i> from 1.7% to 4.3% and <i>Ulmus</i> from 0.2% to 2.8%). This reflected the drying up of the wetland that allowed the development of a post-pioneer tree stratum. Nevertheless, despite having dried out, the alluvial valley was frequently flooded because the NPPs indicative of eu-mesotrophic conditions continued at a rate ranging between 5.4% and 17.2 % and maximum percentages of NPPs indicative of erosion processes (3.2%-9.8%). Similarly, the percentage of pioneer hydrohygrophytic vegetation remained stable at between 16.4% and 25.1% (mostly Cyperaceae and <i>Equisetum</i>). Access was easy and the vegetation was suitable for livestock rearing as indicated by coprophilous NPPs (4.1-15.2%). The foothills were probably covered by shrubby species (9.3-15.4%), type Phrygana or thermo-Mediterranean forest.

Table 3: Palynological results

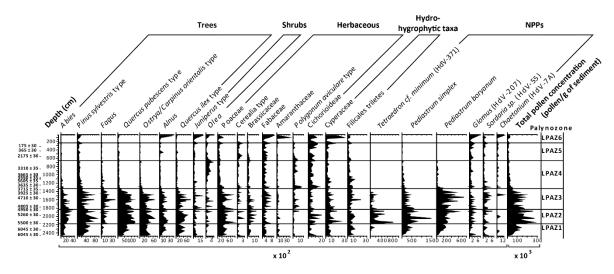

Figure 8: Pollen concentration curves from the FC8 core. The taxa shown correspond to representative taxa from various ecological associations.

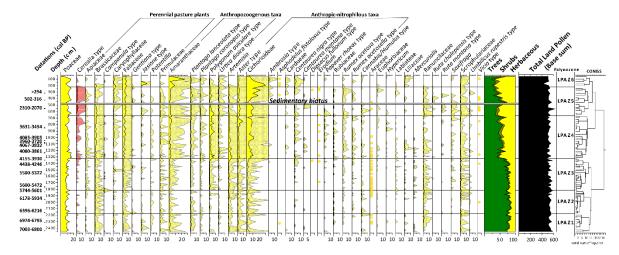

Figure 10: Pollen diagram of herbaceous taxa showing percentages of TLP from the FC8 core. Light color curves represent a tenfold exaggeration of the original curves. Species representing 0.5% and 1% are represented by dots, while species whose percentage was below 0.5% are not shown.

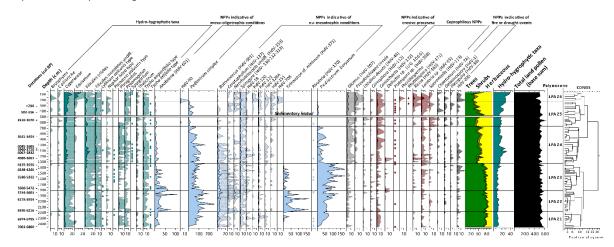

Figure 11: Hydro-hygrophytic taxa and non-pollen Palynomorph (NPP) pollen diagram showing percentages of TLP from FC8 core. Light color curves result from a tenfold exaggeration of the original curves. Species representing 0.5% and 1% are represented by dots, while species whose percentage was below 0.5% are not shown.

5. Discussion

5.1. Wet conditions, site and scale effects in the detection of landscape anthropization (ca. 7-4.5 ka cal BP)

5.1.1. From 7 to 5.7 ka cal BP, (ca. 5050-3750 BC)

The onset of this period corresponds to relatively wet conditions, also observed in the eastern Mediterranean region (Digerfeldt et *al.*, 2007; Finné et *al.*, 2011; 2019; Francke et *al.*, 2013; Miebach et *al.*, 2016; Triantaphyllou et *al.*, 2014). This resulted in a huge lake (former Achinos Lake) with eu-mesotrophic conditions, like in the neighboring Dojran (Masi et *al.*, 2018). The exact palaeodepth of the lake is difficult to estimate. Nevertheless, around 7 ka cal BP (ca. 5050 cal BC), it was probably several meters deep at the location of core FC8 considering the relatively low percentages of hydro-hygrophytic taxa and the difference in altitude (*ca.* 20 meters) between the level of sedimentation in the center of the valley (FC8) and on the margin of the wetland, two kilometers to the east (FC1; Glais et *al.*, 2016b; Lespez et *al.*, 2016). Taking the lower valley substratum morphology and topography into account (Fig.4), subsidence and compaction, even though pronounced at the center of the basin, are not enough to explain this range (Bennett and Buck, 2016). A gradual sea level rise may explain the increase in the water level in the lower Strymon

valley and may have played a key role in maintaining the lacustrine context by blocking surface freshwater (Lespez et *al.*, 2016). Despite the densely wooded Strymon watershed, these hydrological conditions support aggradation into the lower valley. The average accumulation rate was 4.8 mm.yr⁻¹ during the period 7-5.7 ka cal BP (ca. 5050-3750 cal BC). The wetland was surrounded by riverine forest, with mixed oak and deciduous forest on the lower slope and coniferous forest on the upper part of the surrounding mountains. This vegetation pattern agrees with other regional data (e.g. Tenaghi-Philippon; Ioanina, Iznik, Dojran, etc.; Bottema, 1974; Greig and Turner, 1974; Willis, 1994; Lawson et *al.*, 2004; Miebach et *al.*, 2016; Masi et *al.*, 2018; Weiberg et *al.*, 2019).

5.1.2. From 5.7 to 4.5 ka cal BP (ca. 3750-2550 cal BC)

During this period, the long-lasting presence of wetland corresponds to a shallow lake environment, despite some previously outlined hydrological fluctuations (Lespez et al., 2016) and a period of enhanced aridity. This pattern occurs during the transitional period (5.3-4.9 ka cal BP) from the overall wetter conditions of the Early Holocene to generally drier conditions in the Balkan region in the Late Holocene (Finné et al., 2019). Around 5.7 ka cal BP (ca. 3750 cal BC), an aggradation period (Fig.7) considerably increased the sedimentation rate (ca. 7.15 mm.yr⁻¹) for approximately 3 centuries, followed by 15 centuries with a sedimentation rate of 1.7 mm.yr⁻¹. This hydro-sedimentary change was confirmed by variations in carbonate content and by fluctuations in the pollen diagram. The obvious instability of the tree curves (particularly of the altitudinal forest taxa: Fagus, Quercus pubescens type and xerothermophilous taxa) confirms this hypothesis, which matches the short-term minimum of non-coniferous arboreal pollen percentages in the northern Aegean (Kotthoff et al., 2008a; 2008b). Furthermore, the instability of hydrological and environmental data probably corresponds to enhanced fluvial activity, previously identified at the wetland margins during 5.8-5.7 cal BP (ca. 3850-3750 cal BC) (Lespez et al., 2016). The enhanced flow resulted from an incursion of cold air masses to eastern Mediterranean and from a more intense/pronounced anthropogenic activity in the studied area. Despite the relative instability, the average percentage of arboreal pollen at Fidokoryphi (76.4%) during the 7-5.2 cal BP period (ca. 5050-3250 cal BC) remained noticeably higher than the mean AP percentage in the whole northern region of Greece prior to major human conversion of the land cover about 4 ka cal BP (ca. 2050 cal BC) (62.51%; Roberts et al., 2019a).

5.1.3. Human impact at regional scale

At the end of the Late Neolithic I and during the Late Neolithic II (7-6.4 ka cal BP, (ca. 5050-4450 BC), anthropogenic pressure on the landscape was only visible close to population settlements. Population spread and the increase in the number of settlements has been confirmed by archaeological data all over northern Greece (Weiberg et al., 2019), and in particular, in the Philippi-Drama and Strymon plains (Koukouli-Chryssanthaki et al., 2008), but according to the regional pollen record, had only modest effects. For the first time, a significant landscape anthropization signal was recorded synchronously in the Lower Strymon Valley and on the eastern edges of Tenaghi-Philippon from 6.45-6.3 ka cal BP (4500-4350 BC) (Lespez et al., 2016; Glais et al., 2017), in a period during which no climate changes have been recorded (Kotthoff et al., 2008b; Peyron et al., 2011, 2016). At Dikili Tash (Glais et al., 2016a), opening of the vegetated landscape coincided with cereal cultivation, an increase in erosion, a local fire signal and, even if in a less significant proportion, the development of shrubby Mediterranean vegetation, as recorded at Dispilio in western Macedonia (Kouli et Dermitzakis, 2008; Kouli, 2015, Karkanas et al., 2011). During the 6-5.2 ka cal BP interval (ca. 4050-3250 BC), in which none of the known archaeological sites of the

lower Strymon Valley appear to have been occupied, fluctuations in the regional vegetation cover revealed no significant anthropogenic change. This pattern corresponds to local persistence of agropastoral practices, like those recorded at Zazari Lake with the spread of *Fagus sylvatica* accompanied by *Pistacia* (Gassner et *al.*, 2019).

Anthropogenic pollen indicators in Bronze Age landscapes correspond to a continuous cereal signal (0.3-1%). Furthermore, the marked decrease in oak woodland, the intensification of pastoralism, the increase in maquis and in indicators of erosion as well as the dominance of anthropozoogenous, anthropic-nitrophilous and perennial pasture plants in open environments are attested. Even though these agropastoral activities are well documented, the first indicators of a human-made landscape recorded at regional scale indicate no widespread woodland clearing, since tree taxa remain largely dominant. From the beginning of the Early Bronze Age (*ca.* 5.2 ka cal BP, 3250 BC), many sites were again settled (Maniatis et *al.*, 2014) following a period with sparse knowledge of the settlement pattern, (Koukouli-Chrysanthaki, 1998; Weiberg et *al.*, 2019).

Except for a few palynological sequences located close to Neolithic settlements such as Dikili Tash (Glais et al. 2016a) and Dispilio (Kouli, 2015) in Macedonia, the first signs of landscape change of anthropogenic origin in regional records appeared progressively. In central Greece, an anthropogenic signal is attested between 6.2 and 5.5 ka cal BP at Kopais Lake (Greig and Turner, 1974) and about 5.5 ka cal BP at Voulkaria Lake (Jahns, 2005), while in northern Greece, human pressure has been recorded since 5.15 ka cal BP at Ioannina (Lawson et al., 2004), since about 5 ka cal BP at Nisi (Lawson et al., 2005), between 5-4.5 ka cal BP at Dojran (Athanasiadis et al., 2000; Masi et al., 2018; Thienemann et al., 2017) and in Epirus (Gerasimidis et al., 2009). Other sites in northern Greece showed an agropastoral impact later, at around 4.5 cal BP at Giannitsa (Bottema, 1974) like in the region of Maliq Lake in Albania (Denèfle et al., 2000), since 3.85 ka cal BP at Tenaghi-Philippon (Greig and Turner, 1974) and between 3.5 and 3 ka cal BP at Gramousti, Rezina (Willis, 1992; 1994) and Edessa (Bottema, 1974). In northwestern Anatolia, evidence for human activities became more solid after the Early Bronze Age, at around 4.8 cal. BP (Miebach et al., 2016). In southwestern Bulgaria, like in our study area, the first anthropization indicators were observed early close to settlements, i.e., between 7.5 and 7 ka cal BP, but a regional impact was only perceived after 3.35 ka cal BP (ca. 1400 BC) (Marinova et al., 2012).

To summarize, evidence for anthropization from pollen studies challenges assumptions concerning the intensity of human pressure from the Neolithic on in northern Greece. In the Lower Strymon Valley, the time interval between recordings of cereal cultivation on the margins of Neolithic sites (FC1; Lespez et al., 2016) and its recording at core FC8, less than 2 km away, is two millennia. This can be explained by both landscape and environmental factors. It is likely that cereals have long been cultivated on the thick, hilly soil (near FC1), far from the center of the lake basin the location of core FC8. Given that cereal pollen grains have a low dispersal capacity and low productivity (Berglund, 1985; Diot, 1992), it is not possible to record the presence of Cerealia in a more distant environment. In any case, the anthropization signal in pollen records from lake or swamp sites located far from cultivated areas is delayed compared to regional agricultural activities, as attested by archaeological analyses (Greig and Turner, 1974; Gerasimidis, 2009; Masi et al., 2018). For this reason, the anthropogenic signal record is highly dependent on the location of the core, highlighting the inability of some lacustrine records to capture the dynamics of landscape anthropization. The research conducted in the Lower Strymon valley, concludes that the thresholds for this detection remain highly dependent on local conditions of agricultural development and survey sites.

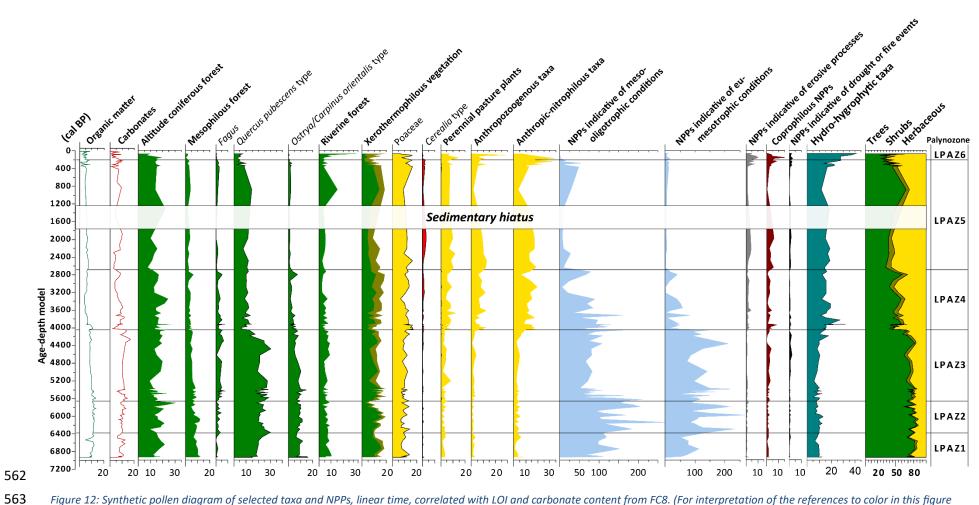

Figure 12: Synthetic pollen diagram of selected taxa and NPPs, linear time, correlated with LOI and carbonate content from FC8. (For interpretation of the references to color in this figure legend, see the web version of this article).

5.2. Welcome to Meghalayan (Late Holocene): reinforcement of anthropization signal around 4.3-3.8 ka cal BP

All records obtained in eastern Macedonia during the period 4.3-3.8 ka cal BP (ca. 2350-1850 BC) show readjustment of wetland pollen and hydrosedimentary records (Greig and Turner, 1974; Glais et *al.*, 2017; Lespez et *al.*, 2016).

5.2.1. Climate changes

Records of this period in the Mediterranean basin are frequently lacking (e.g. Combourieu-Nebout, 2009; Dormoy et *al.*, 2009; Fleitmann et *al.*, 2003; 2009) and the reading of the climate remains the subject of debate (Magny et *al.*, 2009; Wanner et *al.*, 2008; 2011; Bini et *al.*, 2019). The 4.2 ka RCC is often subdivided into three distinct time periods: in the central Mediterranean (Magny et *al.*, 2009; 2013), the western Mediterranean (Hinz et *al.*, 2019; Schirrmacher et *al.*, 2020), and the Levant (Kaniewski et *al.*, 2018). The results obtained from core FC8 also show such tripartition. Between **4.35** and **4.1** ka cal BP, there was a drop in NPPs indicative of eu-mesotrophic conditions, and the deciduous oak forests on the piedmont and lower slopes were replaced by beech woodland, coniferous forest and xerothermophilous vegetation. This change corresponds to gradual aridification probably associated with decreasing temperatures as observed by Kotthoff and *al.* (2008a), and also coincides with the beginning of an erosive phase about 4.15 ka cal BP, also attested at Zazari Lake (Gassner et *al.*, 2019), in Greece and in western Mediterranean areas (Finné et *al.*, 2019; Walsh et *al.*, 2019).

The second period, **4.1-3.95 ka cal BP**, corresponding to the LPAZ3-LPAZ4 transition (Fig.12) is synchronous with that recorded in central Mediterranean areas (Magny et *al.*, 2009). This period was characterized by a severe dry period that is detectable in a wide range of palaeo-indicators/proxies and is indicative of a lowering of the Achinos water level. According to NPPs, wetland transformed eumesotrophic into meso-oligotrophic conditions. The lowering of the water level coincides with an inflexion point in the sediment curve (Fig.7), and with colonization of the margins of the wetland by hygrophilous and herbaceous taxa. Conversely, woodland underwent an abrupt decrease and deciduous forest was particularly affected. Reduced magnetic susceptibility, carbonate content and organic matter confirm these hydroclimatic changes (Fig.6; ca. 13m). These features, which characterize pronounced drought, indicate a period of intensive climate change (Jung and Weninger, 2015) similar to the records from Ohrid Lake (Wagner et *al.*, 2009; Vogel et *al.*, 2010), Dojran Lake (Masi et *al.*, 2018), Iznik Lake (Miebach et *al.*, 2016), Van Lake (Wick et *al.*, 2003) and Soreq cave in the Middle East (Bar-Matthews *et al.*, 1999). They confirm the global scale of these hydroclimatic transformations corresponding to the 4.2 event.

The last period, between **3.95 and 3.75 ka cal BP**, was characterized by a return to wetter conditions and the expansion of woodland taxa, like in the Tenaghi-Philippon marsh (Peyron et *al.*, 2016). Nevertheless, the woodland ratio did not reach the level observed before the 4.2 ka RCC. In the Central Mediterranean area, an increase in erosion was recorded between 3.95 and 3.8 ka cal BP (Magny et *al.*, 2009, 2013). This trend was not as apparent in the NPPs but was perceptible in the temporary increase in sediment grain size and in the percentage carbonate content from 3.8 ka cal BP (Fig.6). The same overall pattern was observed farther west for the Dojran, Ohrid and Prespa lakes (Fig.13). A decline in forest cover due to drought can increase the vulnerability of Mediterranean soil and its sensitivity to erosion, as suggested at Dojran (Thienemann et *al.*, 2017).

Thus, although our study area is located at latitude 40° 54′ N, the hydrological pattern recorded at FC8 is better suited of the southern 40°N trend recorded in the Central Mediterranean area with a dry trend inferring lowering of the water level in the lake (Desprat et *al.*, 2013; Magny et *al.*, 2011; 2013; Sadori et *al.*, 2011). This observation is consistent with the eastern Mediterranean pattern characterized by marked dry period (e.g. Bar-Matthews et *al.*, 2003; Eastwood et *al.*, 2007; Kotthoff et

al.,2008a; Roberts et al., 2001, 2011; Francke et al., 2013; Kaniewski et al., 2013; 2018). Nevertheless, no clear latitudinal contrast is visible in the results obtained in the Aegean area (Fig.13), whereas Triantaphyllou et al (2014) exhibited an N-S transgressive aridification gradient around the Aegean Sea, most probably associated with the reorganization of the general atmospheric circulation during the Mid-Holocene. In any case, even the "tripartite" event is the subject of debate (Zanchetta et al., 2016; Bini et al., 2019): it is dominated by the lower lake level that supports the hypothesis of a significantly drier period. The results obtained from the FC8 core confirm the few existing palynological data indicative of this abrupt climate change (Masi et al., 2018). The 4.2 event certainly represents a climatic tipping point showing the beginning of Meghalayan period in the Mediterranean basin, characterized by drying of the climate (Finné et al., 2019) with locally different climatic expression (Bini et al., 2019). Fluctuating aridity between 4.1-3.95 cal BP lasted no more than a few decades but appears to have caused long-term changes in hydrological features with precipitation failing to return to its level before the dry period.

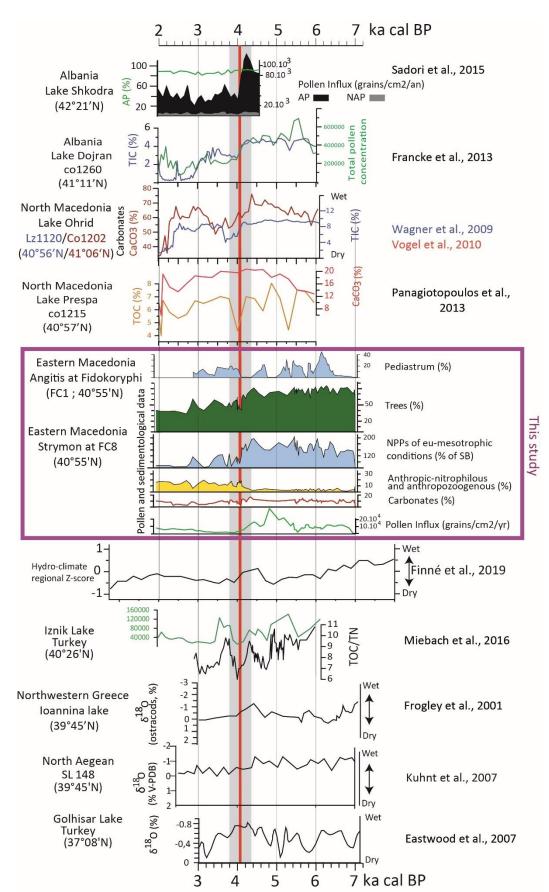

Figure 13: Comparison of environmental changes recorded by selected analyses in the Aegean and eastern Mediterranean regions. Study period of the so-called "4.2 ka BP event" determined by Bini et al., 2019 is highlighted by the gray shaded area and by the red vertical line for the driest phase.

The FC8 sequence showed contrasting anthropization signals compared to the previous regional picture (Lespez et al., 2016; Glais et al., 2017; Masi et al., 2018). During the first period from 4.3 to 4.1 ka cal BP (2350-2150 BC), the lake shores emerged and cultivated plants, erosion, pastoralism, and fire use signs are clearly recorded in core FC1 (Lespez et al., 2016). In the FC8 core, collected in the center of the shallow lake, the anthropogenic signal recorded an increase in secondary indicators of anthropization such as anthropozoogenous and anthropogenic-nitrophilous taxa curves (Fig.14), like at Zazari lake (Gassner et al., 2019). There was no clear change in primary anthropization indicators, and the reduction in oak forest cannot be directly linked with human pressure based on data available today. From the beginning of the driest intermediary phase toward 4.1 ka cal BP (2150 BC), all indicators of agropastoralism increased rapidly. This is in apparent agreement with the regional demographic pattern (Walsh et al., 2019). Cereals represented 1% and remained continuously around this value for several centuries, in contrast to the pollen spectra from the wetland margin, where cereal pollen were missing (Lespez et al., 2016). The percentage of perennial pasture plants, anthropozoogenous and anthropic-nitrophilous taxa reached levels two or three times higher than before the 4.2 ka cal BP event. This reinforcement of anthropogenic pressure was made possible by the contraction of open water wetlands. Likewise, the development of coprophilous fungi indicates the expansion of pastoralism. Scrubland vegetation grew on the slopes and erosive processes associated with high sedimentation accumulation rate are recorded for the first time in the lake center during this period like in central Anatolia (Roberts et al., 2019b). During the first decades of the last stage of the event, between 3.95 and 3.75 ka cal BP (2050-1850 BC), anthropozoogenous and anthropic-nitrophilous taxa declined sharply before reaching a new peak at the end of this interval. This sudden decrease may be linked with the temporary passage of wetter conditions (Peyron et al., 2016) including extension of the lake. In other respects, erosive processes recorded during previous phase could have been heightened under wetter conditions and by the extensive clearing of the landscape in the region. In fact, palynological analyses of Lake Dojran (Athanasiadis et al., 2000; Masi et al., 2018) and other pollen studies in mountainous areas in southwestern Bulgaria (Marinova et al., 2012) for the first time reported permanent anthropogenic signal (cereals, cultivated plants and secondary indicators). Hence, indicators of a decrease in population (Weiberg et al., 2019) coexist with high values for anthropogenic pollen indicators, suggesting a complex and unknown pattern of societyenvironment dynamics. The reinforcement of the anthropogenic signal in the environmental record during the EBA-MBA transition could be explained by several factors, perhaps in combination:

- An increase in human activities in the Strymon watershed or an increase in the number of settlements. However, this trend goes against the overall settlement model defined for northern Greece at the beginning of MBA (Fig. 14 from Weiberg et al., 2019).
- Displacement of activities as an adaptation to the new hydrological conditions that modified land occupation and use of the soils. In a large flat plain (<1%), in which extensive areas were previously subjected to seasonal fluctuations were no longer under water, means fertile land was available for cultivation using the pre-existing agricultural pattern. This shift toward wetland is the opposite of the pattern described for the end of the Chalcolithic in the south Balkans (Todorova, 1995; 2007). Nevertheless, it is consistent with the idea of a possible extension and intensification of crop/pastoral activities in previously unexploited and sensitive areas coinciding with a period of climate change (Walsh et al., 2019).</p>
- Reduction of wetlands favors human presence on their margins, especially in summer. This pattern favors the recording of the impact of anthropization on the landscape, thanks to the reduced distance between the exploited land and the recording sites. This facilitates also the representation

of pollen with low dispersal capacity or low pollen productivity like the Cerealia type in pollen diagrams.

• Clearing and opening of the landscape, especially of riparian trees, which cannot play a crucial role as pollen filters. The contemporary decrease in total pollen flow (Fig. 13) indicates a reduction in overall plant biomass like that observed in Shkodra (Sadori et *al.*, 2015) or Lake Dojran (Francke et *al.*, 2013; Masi et *al.*, 2018).

Before and after the 4.2 ka cal BP event, records from the lake shore in the lower Strymon valley (Lespez et al., 2016) contained anthropogenic signals, although discontinuous. In the present study, anthropogenic evidence became stronger after the beginning of the 4th millennium BP, as regionally indicated by anthropogenic pollen index and pastoral indicators (Mercuri et al., 2019; Walsh et al., 2019). The natural slowing down of the sea level rise combined with human-induced sedimentation had a significant effect on the creation of productive wetland and agricultural land, which in some cases, may have had significant demographic consequences (Bruckner et al., 2006). Resilient societies are thought to have adopted new strategies to cope with these environmental changes (Berger et al., 2016; Grove and Rackham, 2001; Walsh, 2013; Walsh et al., 2019). Unlike some regional case studies such as at Lake Shkodra (Mazzini et al., 2016), the water level rise cannot explain the lack of Bronze Age settlement. A dryer climate could bring about or favor the transformation and relocation of agricultural activities. If the local particularities and variabilities of climatic and ecological data are not excluded (Whitford, 2018), the continuity and reinforcement of agropastoral practices suggest a period of socioeconomic development at regional scale. Societies that develop in lowlands located close to wetlands are certainly more resilient than populations living in more sensitive contexts. For example, thinner soils, more clayey and sensitive to erosion or drought, are not fertile (e.g. southern Greece, Levant). This result addresses the question of the best scale to use in order to understand the social processes underway during climatic change. This is not to say that this period of RCC could not have negative societal consequences at annual or decadal timescales. At a centennial timescale, on the other hand, as suggested by Roberts et al. (2019a), our results suggest that this climatic adversity may have acted as a stimulus to innovation and relocation rather than retarding societal development in the region. Ultimately, the apparent paradox of fewer settlements but increased anthropogenic activity in the record could be explained if the settlements were simply of shorter duration, which is by no means synonymous with a more nomadic way of life. As already mentioned, in the lower Strymon valley, like in most other plains in northern Greece and in the southern Balkans, the majority of known Neolithic and Early Bronze Age settlements belong to the multi-layered type, i.e. are sites where the successive layers of occupation are mainly displayed vertically. Even the so-called "flat" settlements (as opposed to tells) usually comprise at least two or three layers one on top of the other (e.g. Kryoneri: see Malamidou 2016). Sites that develop horizontally could either have been overlooked by classical archaeological research, or wiped out due to erosion, subsequent activities, or be buried under more recent sediments. This hypothesis, which has already been put forward to explain the 4th millennium BC hiatus (the Neolithic-BE transition: Lespez et al., 2016; Tsirtsoni 2016c; 2016d), could also be supported here. In the neighboring Thracian plain in present-day Bulgaria, the existence of flat sites dating from the late Early Bronze Age to the Middle Bronze Age (late 3rd-early 2nd millennium BC) has been evidenced in recent years, and, in one case, even the horizontal development of the site between this period and the following LBA period (Leshtakov and Tsirtsoni 2016; Tsirtsoni 2021).

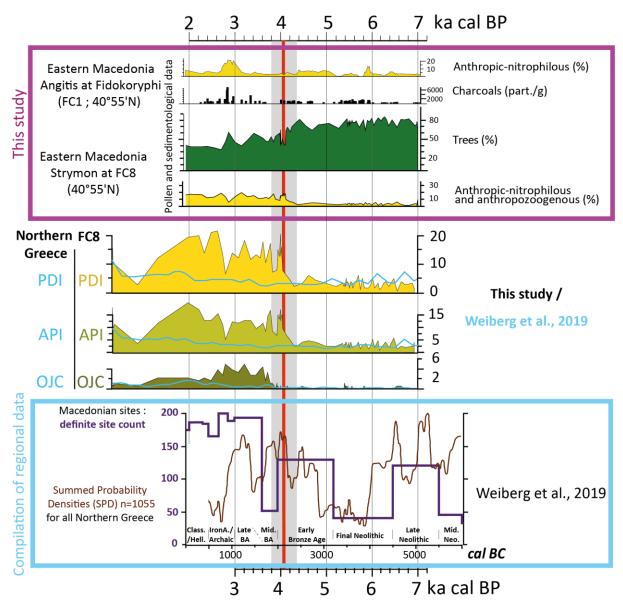

Figure 14: Comparison of anthropization signal from FC8 and FC1 pollen data compiled from regional archeological data. The study period of the so-called "4.2 ka BP event" determined by Bini et al., 2019 is highlighted by the gray shaded area. Pollen Disturbance Index (PDI: Centaurea + Cichorioideae, Plantago, Ranunculus acris type, Polygonum aviculare type, Sarcopoterium, Urtica dioica type and Pteridium; Mercuri et al., 2013b; Kouli, 2015); Anthropogenic Pollen Index (API: Artemisia, Centaurea, Cichorioideae, Plantago, cereals, Urtica and Trifolium type; Mercuri et al., 2013b); Olea-Juglans-Castanea (Mercuri et al., 2013a).

5.3. Late Holocene, intensification of human impacts

5.3.1. Toward a cultural landscape

During the Middle Bronze Age (3.95-3.55 ka cal BP: 2000-1600 cal BC), despite the displacement of agropastoral activities toward wetlands, the vegetation cover was still dominated by woodland with no clearance trend, as recorded in the Tenaghi-Philippon marsh (Greig and Turner, 1974). From a sociocultural point of view, the Middle to Late Bronze Age transition, around 3.55 ka cal BP (ca. 1600 BC), is considered to have taken place gradually with no significant cultural interruptions, mainly in comparison with what was observed in neighboring areas, since local data are lacking (Koukouli-Chryssanthaki, 1993; Andreou, 2010). Indeed, unlike the other region of northern Greece (Treuil et al., 2008; Weiberg et al., 2019), archaeological data from the Strymon watershed, particularly in the Philippi-Drama plain, indicate weak settlement density compared to the EBA period (Koukouli-

Chryssantakhi et *al.*, 2008) in accordance with paleoenvironmental records. For example, a clear release of anthropogenic pressure around Dikili Tash (no more cultivated plants, a decline in anthropogenic taxa and a low fire signal) is recorded, in agreement with the lack of occupation on the tell during the Middle Bronze Age (Glais et *al.*, 2017).

From the beginning of the Late Bronze Age, woodland records gradually decreased, particularly mesophilous taxa, such as Ostrya/Carpinus orientalis type or Quercus pubescens type (Fig. 9 and 12), in agreement with pollen data from Tenaghi-Philippon (Greig and Turner, 1974). Beech forest spread probably benefited from pastoral pressure on slopes and in mountainous areas, as also observed in Bulgaria (Marinova et al. (2012). This pattern is consistent with archaeozoological data indicating greater reliance on livestock (sheep and goats) adapted to this environment (Koukouli-Chryssanthaki, 1993). According to Gerasimidis (1995; 2000), the transfer of these activities to the mountainous regions was associated with political changes that forced the inhabitants of the lowlands to seek refuge in the mountains. Concurrently, palynological data show diversification and development of introduced taxa (walnut, chestnut, grape, olive) already recorded in the Balkans (Bottema and Woldring, 1990; Athanasiadis et al., 2000; Glais et al., 2017; Gassner et al., 2019) and suggested by archaeobotanical data (Marinova and Valamoti, 2014). This agrees with evidence from mainland northern Greece, where Juglans is positively correlated with the Summed Probability Densities according to Weiberg et al (2019). Diversification and multiplication of these anthropogenic species show a global trend toward cultural landscapes that was not limited to the surrounding of settlements (Mercuri et al., 2012). Since the LBA, increased anthropogenic indicators have been recorded throughout Greece and around the Aegean Sea, suggesting economic expansion in line with an increased number of sites and inferred population growth (Miebach et al., 2016; Weiberg et al., 2019).

At the end of the Bronze Age, the vegetation cover remained relatively wooded at regional scale, despite being increasingly fragmented by anthropogenic activities. This mosaic of increasingly diversified environmental contexts was subjected to a climatic event around 3.2-3 ka cal BP (Mayewski et al., 2004), corresponding to another dry period in the Mediterranean basin (e.g. Drake, 2012; Finné et al., 2011; Kaniewski et al., 2013; Magny et al., 2009; 2013; Roberts et al., 2011). In the lower Strymon valley, this RCC was characterized by more arid conditions, reduced fluvial activity and a drop in the water level. However, the pollen assemblage does not record a significant or lasting transformation except for a decrease in altitudinal coniferous forest and riparian forest, species that are considered to depend on hydrological inputs. The increase in environmental disturbance during the Bronze Age/Iron Age transition calls into question the spread of collapse patterns observed in southern Aegean and Middle East after the 3.2 ka cal BP event (e.g. Drake, 2012; Kaniewski et al., 2013). The decline or disappearance of numerous economic centers in southern Greece (Drake, 2012), the Middle East (Kaniewski et al., 2013) and more generally in Europe (Risch and Meller, 2015), for which climate changes are often mentioned to explain, do not obviously apply to communities in northern Greece. Some disturbances could have had negative effects on crops or hydrologically sensitive uses of the environment, but socio-environmental dynamics point to growing production and trade and to the intensification of land use at regional scale.

At the beginning of Antiquity around 2.8 ka cal BP (ca. 850 BC) there was both a local and regional increase in indicators of erosion, a decrease in mesophilous forest (except riverine taxa) probably replaced by degraded phrygana shrubs, in parallel with the increased impact of agro-pastoral activities and clearing of the forest using fire during the Thracian occupation (Athanasiadis et *al.*, 2000; Glais et *al.*, 2016b; Masi et *al.*, 2018). Contemporaneously, beech forests, located at higher altitudes (from 600 m to the timberline at 1,800 m a.s.l.) decreased dramatically for the first time since anthropization during the Late Neolithic. This beech woodland pattern is the opposite of the Limni Zazari pollen record (Gassner et *al.*, 2019). Nevertheless, the openness of the woodland cover is in agreement with

reinforcement of sediment aggradation that started earlier and was widely recorded (Francke et *al.*, 2013; Benito et *al.*, 2015; Glais et *al.*, 2016b; Roberts et *al.*, 2019b; Styllas, 2020; Walsh et *al.*, 2019). In the Strymon valley, this detritism probably originated from land use intensification on the slopes rather than due to climatic driving factors. In fact, contrary to central Mediterranean records above 40°N where a wetter period is attested between 2.7 and 2.3 ka cal BP (Magny, 2013; Magny et *al.*, 2007; 2012) no significant climatic trend is attested in the Aegean area (e.g. Finné et *al.*, 2011; Kuhnt et *al.*, 2007; Rohling et *al.*, 2002).

As only a few archaeological excavations have focused on this period (Koukouli-Chryssanthaki, 1998), the population dynamics is not well known and has only been deduced from a few data including some evidence of Thracian activities (Vokotopoulou et Koukouli-Chryssanthaki, 1993). According to Bulgarian investigations, this is probably linked to the development of farming practices using more mountainous areas than alluvial plains (e.g. Marinova et Tonkov, 2012; Marinova et *al.*, 2012; Tonkov et *al.*, 2008). Local tribes, settled in the middle or upper Strymon basin (Bulgaria), moved to high altitude lands during this period (Bozhkova et Delev, 2002; Lazarova et *al.*, 2015). In eastern Macedonia, this settlement pattern could explain the low percentage of cultivated plants in all records, contrary to increasing pastoral evidence elsewhere (Glais et *al.*, 2017; Lespez et *al.*, 2016). In contrast, North Aegean colonization by Greek populations since 2.31 ka cal BP (Amphipolis was conquered in 356 BC and Philippi in 352 BC) corresponds to significant landscape re-arrangement characterized by increasing clearance, increase in maquis and in anthropogenic impacts (cultivated plants, erosion and coprophilous NPPs), resulting in a notable decrease in the extent of volume of the body of water, in agreement with sedimentary data (Fig.6; Glais et *al.*, 2016b).

5.3.2. Olive tree records: cultural and climatic models?

The first local occurrence of Olea pollen was recorded about 5.1 ka cal BP at Dikili Tash (Glais et al., 2017), whereas Olea pollen at FC8 reached 1% from 3.9 ka cal BP and more than 3% from 3.7 ka cal BP in the lower Strymon valley (Fig.9). Furthermore, the rise in the Olea pollen curve around 3.9 ka cla BP was not accompanied by an increase in pollen percentages of other xerothermophilous taxa curves, in contrast to other records for example, in Apulia (Italy), where the rise of Olea pollen curve is contemporaneous with an increase in Phillyrea, Pistacia, Erica undiff. and evergreen Quercus (Di Rita and Magri, 2009). This suggests that the development of olive cultivation in the Lower Strymon valley not only reflects favorable climatic conditions (Fig.9). In addition, in the Strymon delta (Orphano site, several km downstream of FC8), its cultivation is widely attested during the Late Bronze Age with percentages reaching 30% (Atherden et al., 2000). This is not to say that climate changes did not have a significant influence on these particular species, but it does imply that arboreal pollen and particularly the OJCV (Olea-Juglans-Castanea-Vitis) group percentages are unlikely to signal Holocene climatic variations in the Mediterranean (Mercuri et al., 2019; Roberts et al., 2019a). Microclimatic conditions and the geographical context of the Strymon catchment basin are probably not the main factors that explain the location of introduced plants. Conversely, introduction due to anthropogenic practices is worth considering showing that the reinforcement of socio-economic exchanges played a key role around the Aegean basin involving different agronomic choices, specialization and more complex agropastoral management from the Bronze age on than during the Bronze age (Marinova, et al., 2012; Valamoti, 2004; 2015; Valamoti et al., 2018). Our data fit the regional spread pattern of olive even if it is not well defined in palynological studies (Langgut et al., 2019). Olive cultivation began in 6-5.5 ka cal BP in Crete (Bottema and Sarpaki, 2003; Canellas-Bolta et al., 2018) and in the island of Zakynthos (Avramidis et al., 2013), around 4.2-3.8 ka cal BP in southern Greece (Atherden et al., 1993; Jahns, 1993; Kouli, 2012; Lazarova et al., 2012), around 4.6-4.5 ka cal BP in north-western Anatolia (Miebach et al., 2016). Nevertheless, it only cropped up about 3.2 ka cal BP in southwestern Anatolia

(Eastwood et al., 1999) and during Antiquity from 2.6 ka cal BP in western Greece (Lake Voulkaria -Jahns, 2005; Gramousti - Willis, 1992), for example in the vicinity of Lake Dojran, where olive cultivation probably began at 2.5 ka cal BP (Masi et al., 2018). Finally, the early cultivation of olive in northeastern Macedonia (Atherden et al., 2000; Greig and Turner, 1974) from the Middle or Late Bronze Age on remains to be evidenced with new archaeobotanical data. Indeed, except for the discovery of some olive pits at Stravroupoli (Central Macedonia - Margaritis, 2002), archaeological sites in northern mainland Greece are characterized by the almost complete absence of olive macro-botanical remains during the Neolithic and Bronze Age (Valamoti et al., 2018). Even though northern Greece does not belong to the natural bioclimatic area of wild olive tree, socio-economic exchanges and cultivation practices probably extended its distribution area (Langgut et al., 2019). It is likely that diversification of cultivated plants and the introduction of exogenous taxa (e.g. Juglans, Lallemantia; Valamoti and Jones, 2010) indeed result from these exchanges on both sides of the Aegean Sea and Balkan Mountains. Like the Axios river in Central Macedonia, used by the Mycenians to transport wood from huge oak groves located upstream to supply coastal shipyards (Athanasiadis et al., 2000), Strymon could also have been a transport route between Central Europe and the Aegean world. The foundation of Eion harbor in the mouth of Strymon, and the Mycenian material discovered there, confirm this hypothesis (Atherden et al., 2000). Sharing of knowledge and of agricultural practices is less known than the exchange of products with culturally characteristic features such as ceramics, jewelry, tools, or housing style, but they probably followed the same processes as those suggested for olive groves in the Mediterranean basin (e.g. van Zeist, 1980; Zohary et Hopf, 2000; Kaniewski et al., 2012; Kouli, 2012; Weiberg et al., 2016). As a perennial crop, olive and other cultivated trees were buffers against year-to-year fluctuations in rainfall and hence provided some freedom from the direct dependence of cereal-based agriculture on climate (Roberts et al., 2019a).

Core FC8 provides a new high-resolution reference sequence, particularly for the period 6-3 ka cal BP. Anthropogenic impacts are attested around the wetlands in the lower Strymon valley by palaeoenvironmental evidence from the Late Neolithic (c. 7.2 ka cal BP, or 5250 BC). Pollen records indicate the emergence of cereal cultivation on the eastern periphery of the ancient lake from 6.35 ka cal BP on (Lespez et al., 2016), while in the center of the depression, agricultural practices are clearly and continuously attested only from 4 ka cal BP on. This time lag is evidence for the complex interplay between ecological and cultural factors, and for the need for a multi-scale approach to identify the dynamics of ecosystem anthropization. The climatic event of 4.2 ka cal BP is indeed a tipping point in regional vegetation dynamics, but it is still not clear whether the anthropogenic pressure on ecosystems detected by the palynological results is (1) actual or exacerbated by climate change; (2) corresponds to population growth and/or climatic instability; or (3) transcribes societal adaptation to drier conditions, in particular through land-use changes and population shifts toward northern mountainous areas and/or retreat from wetlands. However, the causal link between decreasing precipitation and the political-economic collapse of cereal-dependent societies, which is often mentioned in the eastern Mediterranean (Arz et al., 2006; Cullen et al., 2000; Drysdale et al., 2006; Kaniewski et al., 2013; Staubwasser et al., 2003; Straubwasser and Weiss 2006; Weiss et al., 1993), is not yet proven by palaeoenvironmental data in eastern Macedonia. For this period, the lack of known archaeological sites or extensive archaeological excavations severely complicates interpretations when discussing the resilience and continuity of Bronze Age occupations. Nevertheless, we need to consider that the geographical setting of eastern Macedonia has resulted in physically highly contrasted environments, where it is often sufficient to move very short distances to find different environmental conditions and to develop local adaptations to global climate change (Lespez et al., 2013; 2016). Therefore, local studies have a key role to play. Indeed, they are the only studies capable of exploring the concrete responses of rural societies to climatic or environmental changes and of considering the chain of causality. This knowledge should now inspire new multidisciplinary, local research to validate the results obtained through the multiplication of modeling or regional syntheses that discuss the link between demographic, climatic or environmental trends on a basis that remains essentially conceptual.

8. Acknowledgements

This study is part of the international PaleoMex-INEE Research Program, a component of the "Mediterranean Integrated Studies at Regional and Local Scales" [MISTRALS] program supported by the INEE and INSU of the CNRS. Funding was also provided by the "Balkans 4000" ANR project (ANR-07-JCJC-072). The GFG (French Group of Geomorphology) and APLF (French Language Palynological Association) contributed through mobility grants to A. Glais. We are grateful to the following laboratories that performed the analyses: LETG-Caen UMR 6554 CNRS (grain size analysis and LOI), LGP-Meudon UMR 8591 CNRS (electric resistivity tomography), CEREGE UMR 7330 CNRS (magnetic susceptibility) and CSIC-Madrid (pollen analysis). For their assistance, we also thank the heads of the Ephorate of Prehistoric and Classical Antiquities of Serres (Ministry of Culture, Greece). Special thanks to Francisca Alba-Sánchez for advice with the age-depth model and collaboration and to Daphne Goodfellows for English editing. We also want to thank the three anonymous reviewers for their helpful comments in improving the manuscript.
