#### Abstract

This article proposes a new decision tree algorithm that accounts for time-varying covariates in the decision-making process. Traditional decision tree algorithms assume that the covariates are static and do not change over time, which can lead to inaccurate predictions in dynamic environments. Other existing methods suggest workaround solutions such as the pseudo-subject approach, discussed in the article. The proposed algorithm utilizes a different structure and a time-penalized splitting criterion that allow a recursive partitioning of both the covariates space and time. Relevant historical trends are then inherently involved in the construction of a tree, and are visible and interpretable once it is fit. This approach allows for innovative and highly interpretable analysis in settings where the covariates are subject to change over time. The effectiveness of the algorithm is demonstrated through real-world data analysis, highlighting its potential applications in various fields, including healthcare, finance, insurance, environmental monitoring, and data mining in general.

Key words: decision tree, time-varying covariate, data mining, longitudinal study, algorithm

## 1 Introduction

Decision trees are a popular machine learning tool for data mining as well as classification and regression predictions. Growing such a tree is a data-driven process based on a set of input covariates and a target variable. The most famous decision tree algorithm is arguably Classification and Regression Trees (CART), introduced by Breiman et al.[5]. CART constructs a binary tree by recursively partitioning the feature space into smaller and smaller subsets, based on a splitting criterion that maximizes the separation between the target variable's values in each subset. However, traditional decision tree algorithms like CART assume that the input features or covariates are static and do not change over time. In many real-world settings, this assumption is unrealistic, and the time-dynamic nature of the covariates is highly informative and should be included in the tree construction. In such settings, not accounting for dynamic features results in information loss, hence a loss of accuracy and richness of analysis.

Other data-driven approaches can already efficiently seize the time dimension of features in prediction and data-mining settings. One can think of neural networks (see [29] or [44] for instance). Yet conventional parametric statistical models or machine learning approaches such as logistic regression or most tree-based models cannot handle time-varying covariates straightforwardly. They assume that individual observations are independently distributed. Because of the longitudinal structure of a time-varying dataset (see Section 2.2 for more details), this independence hypothesis cannot be met: different observations of a single subject are naturally

[^0]strongly correlated. To address this limitation, some existing tree-based methods suggest workarounds such as the pseudo-subject approach in survival trees ([16]), which create artificial left-truncated and right-censored subjects by pooling observations over time, or the inclusion of a mixed effect model structure around a tree-based core ( $[19,39,20]$ ). Such computationally intensive methods proved to yield competitive results in many prediction frameworks, yet we argue in the following sections that they are not entirely satisfying in terms of interpretability.

In this article, we propose Time-penalized Tree ( TpT ), a new decision tree algorithm that accounts for time-varying covariates in the decision-making process. Our algorithm utilizes a different structure and a time-penalized splitting criterion that allows for recursive partitioning of both time and the features space. We detail the algorithm and show simulated real data-mining and visualization applications. However, it is crucial to underscore the inherent limitations in the current scope of this study. Recognizing the need for further refinement, this work primarily concentrates on introducing and demonstrating the applicability of $\mathrm{Tp} T$. Nevertheless, two crucial aspects remain unaddressed: firstly, the imperative need for a comprehensive exploration into the statistical properties and theoretical foundations of this new tool; and secondly, the essential comparative analysis of TpT results against existing longitudinal techniques, trained on well-studied datasets and evaluated with consistent indicators. This introduction sets the stage for future investigations, acknowledging the identified gaps and emphasizing their significance in shaping the future trajectory of our research.

The rest of this paper is structured as follows. We recall the basics about classification and regression trees as well as time-varying covariates analysis in Section 2, we also briefly present existing approaches and frame their interpretability flaws. Then we detail the specificities of TpT in Section 3 and explain its benefits, which is the main contribution of this work. In Section 4, we show a concrete application of our framework on a real-world life-insurance dataset, with visuals and illustration work, demonstrating the interpretability properties of TpT. Eventually, Section 5 concludes this paper and details future works.

## 2 Preliminaries

### 2.1 Classification and regression trees

In this section, we briefly describe the mechanisms of a simple yet powerful data-mining and prediction model: decision trees, and more specifically, classification and regression trees or CART [5]. Here, we assume that all covariates are time-independent. Let $\mathcal{D}=\left(\boldsymbol{x}^{(i)}, y^{(i)}\right)_{i=1}^{N}$ be a dataset of $N$ individuals with $\boldsymbol{x}^{(i)}=\left(x_{1}^{(i)}, \ldots, x_{p}^{(i)}\right)$, the vector of $p$ covariates and $y^{(i)}$ the target variable for the $i$-th subject. The covariates and target spaces are respectively denoted $\mathcal{X}$ and $\mathcal{Y}$. Decision trees create a recursive partitioning of $\mathcal{X}$ based on binary decision rules. This partitioning can be visualized directly in the case where there are two covariates $x_{1}$ and $x_{2}$ (see Figure 1). In that case, individual observations are represented as dots that are eventually clustered into $n_{L}$ distinct, non-overlapping regions of $\mathcal{X}$ denoted ( $L_{1}, \ldots, L_{n_{L}}$ ).

Figure 1: Decision tree recursive partitioning
More generally it can be visualized as a tree (see Figure 2), with yes/no questions within each node and terminal nodes - or leaves - corresponding to the $n_{L}$ regions of the covariates space. Because the regions defined by leaves are non-overlapping, every individual $i$ belongs to a single leaf, and a unique prediction is made for all individuals falling in a specific leaf. More generally, let $g$ be a node, at $g$, we define $\mathcal{D}(g) \subseteq \mathcal{D}$ such as $\mathcal{D}(g)=\left\{\left(\boldsymbol{x}^{(i)}, y^{(i)}\right) \subseteq \mathcal{D} \mid \boldsymbol{x}^{(i)} \in g\right\}$, the set of observations in the node $g$. The quantity $\mathcal{N}(g)=|\mathcal{D}(g)|$ is then the number of individuals in the node.

Figure 2: Decision tree example
In a classification context, the label given by the tree $\mathcal{T}$ for subject $i$, falling in leaf $L$ is given by

$$
f_{\mathcal{T}}\left(\boldsymbol{x}^{(i)}\right)=\operatorname{mode}\left(\left\{y^{(i)}, \forall i \mid \boldsymbol{x}^{(i)} \in L\right\}\right)=f_{\mathcal{T}}(L) .
$$

In a regression context, the label given by the tree $\mathcal{T}$ for subject $i$ in leaf $L$ is given by

$$
f_{\mathcal{T}}\left(\boldsymbol{x}^{(i)}\right)=\text { mean }\left(\left\{y^{(i)}, \forall i \mid \boldsymbol{x}^{(i)} \in L\right\}\right)=f_{\mathcal{T}}(L) .
$$

In both cases, a decision tree yields a single constant label ${ }^{1}$ for an entire region: its mode or mean. The accuracy of a tree is then based on its ability to minimize the error it commits when assigning labels. Among all possible trees - thus, all possible partitions of $\mathcal{X}$ - the optimal one should maximize a predetermined objective measure (such as the label assignment accuracy, for instance). Such a tree theoretically exists but cannot generally be found in a computationally reasonable time. Therefore algorithms like CART use a top-down greedy approach: they start from an initial node - the root - containing all observations in $\mathcal{D}$. Then they find the covariate $x_{j}$ and the threshold $d^{2}$ such that they optimize a splitting criterion. The root is then split into those two child nodes for which the same splitting process is repeated until a stopping criterion is triggered. Once grown, this tree is called maximal tree. From an algorithmic perspective, growing a maximal CART can be summarized as such:

Such a tree overfits the data, and predictions made on observations that were not used to grow the tree are usually inaccurate. That is why a last step is required: the maximal tree is pruned to a subtree that has better generalization abilities. The pruning step is described in Section 2.1.3. A decision tree is therefore defined by its splitting criterion, stopping rule(s), and its pruning process.

[^1]```
Algorithm 1 Growing a maximal CART
    Input: Training dataset \(\mathcal{D}\)
    Output: Maximal CART \(\mathcal{T}_{\text {max }}\)
    Initialize the root node \(g\) with the entire dataset \(\mathcal{D}\)
    Grow (g)
    Function \(\operatorname{Grow}(g)\) :
    if Stopping criteria met (e.g., maximum depth, minimum samples) then
        Let \(g\) be a leaf with the prediction \(f_{\mathcal{T}}(g)\).
    else
        For all possible covariates and thresholds find the pair \(\left(x_{k}, d\right)\) that obtain the best splitting
        criterion.
        Split the node \(g\) along covariate \(x_{k}\) at threshold \(d\) into two child nodes \(g_{r}\) and \(g_{l}\).
        \(\operatorname{Grow}\left(g_{r}\right)\)
        \(\operatorname{Grow}\left(g_{l}\right)\)
    end if
```

### 2.1.1 Splitting Criterion

Originally, CART produces, at every node, a split that minimizes the heterogeneity regarding the target variable within each child node. Equivalently, the optimal split is to maximize the loss of heterogeneity between the considered node and its child nodes: the so-called goodness-on-split. Therefore, measures of heterogeneity are needed when the target variable is categorical (for classification tasks) and when it is numerical (for regression tasks).

Classification: In a $P$-classes classification problem, let us define $p_{l}, l \in\{1, \ldots, P\}$ as the proportion of observations of class $l$ in $\mathcal{D}$. We extend this idea by defining $p_{l}(g)$ as the proportion of observation of class $l$ in $\mathcal{D}(g)$. An impurity function $\phi$, is a function measuring the heterogeneity, defined for $p_{l}, l \in\{1, \ldots, P\}$, with $p_{l} \geq 0$ and $\sum_{l} p_{l}=1$ such that:

- $\phi\left(p_{1}, \ldots, p_{P}\right) \geq 0$,
- The minimum of $\phi$ is reached whenever any of the $p_{l}=1$, then $\phi\left(p_{1}, \ldots, p_{P}\right)=0$,
- The maximum of $\phi$ is reached for $\phi\left(\frac{1}{P}, \ldots, \frac{1}{P}\right)$,
- $\phi$ is symmetric with regard to its arguments.

For CART, usual classification impurities are $\operatorname{Gini}\left(\phi\left(p_{1}, \ldots, p_{K}\right)=-\sum_{i} p_{i} \log \left(p_{i}\right)\right)$, the entropy $\left(\phi\left(p_{1}, \ldots, p_{K}\right)=\frac{1}{2} \sum_{i} p_{i}\left(1-p_{i}\right)\right)$ or the twoing measure. For our purposes, no further specificities are needed and in full generality, the impurity - or heterogeneity - of node $g$ is measured by $I(g)=\phi\left(p_{1}(g), \ldots p_{K}(g)\right)$. At each node of a CART, the optimal split is chosen as the split that reduces the impurity the most. That is to say, the split that maximizes the following gain function by splitting the parent node $g_{p}$ into the two child nodes $g_{l}$ and $g_{r}$ is

$$
\begin{equation*}
G\left(g_{p} ; g_{l}, g_{r}\right)=I\left(g_{p}\right)-\left(\frac{\mathcal{N}\left(g_{l}\right)}{\mathcal{N}\left(g_{p}\right)} I\left(g_{l}\right)+\frac{\mathcal{N}\left(g_{r}\right)}{\mathcal{N}\left(g_{p}\right)} I\left(g_{r}\right)\right) . \tag{1}
\end{equation*}
$$

Of course, various other criteria and ideas for splitting exist. This paper does not aim to review all of them but we refer the astute reader to such comparisons of splitting methods (see [30], [8],
[4], [40] or [12] for instance). The efficacy of each splitting criterion has been discussed but no definitive consensus over which one is the finest exists. All measures prove desirable properties in particular scenarios while demonstrating drawbacks in others.

Regression: In a regression context, the best split can be chosen with the target variable empirical variance or mean squared error, a natural choice of heterogeneity measure. We define $M S E(g)$ the mean squared error at node $g$, as

$$
\begin{equation*}
\operatorname{MSE}(g)=\sum_{\left\{i \mid \boldsymbol{x}^{(i)} \in g\right\}}\left(\overline{y_{g}}-y^{(i)}\right)^{2}, \tag{2}
\end{equation*}
$$

with $\overline{y_{g}}=\frac{1}{\mathcal{N}(g)} \sum_{\left\{i \mid \boldsymbol{x}^{(i)} \in g\right\}} y^{(i)}$.
Then, the gain function to maximize when splitting the parent node $g_{p}$ into the two child nodes $g_{l}$ and $g_{r}$ is obviously

$$
\begin{equation*}
G\left(g_{p} ; g_{l}, g_{r}\right)=M S E\left(g_{p}\right)-\left(\frac{\mathcal{N}\left(g_{l}\right)}{\mathcal{N}\left(g_{p}\right)} M S E\left(g_{l}\right)+\frac{\mathcal{N}\left(g_{r}\right)}{\mathcal{N}\left(g_{p}\right)} M S E\left(g_{r}\right)\right) \tag{3}
\end{equation*}
$$

Even if technically, $M S E$ is not an impurity function, we clearly see that Equation 3 is the perfect regression equivalent of Equation 1.
Thus in the following sections, we use the general notations of equation 1 with $I(g) \equiv M S E(g)$ when the target variable is numerical.

### 2.1.2 Stopping rules

Stopping rules can be specified. In that case, the growing phase continues until one of them is met. First of all, a node will not split any further if all observations it contains have the same target variable value. Other commonly used stopping rules are: a minimum improvement in the splitting criterion, a maximum depth of the tree (parameter: maxdepth), a minimum number of observations in a node (parameter: minsplit), or a minimum number of observations in the hypothetical child nodes that would result from a new split.

### 2.1.3 Tree pruning

The stopping rules affect the size of the maximal tree. No or weak stopping rules will generate a high-variance/low-bias over-fitted tree whereas constraining ones will lead to smaller, more interpretable low-variance/high-bias under-fitted trees. The idea of cost-complexity pruning developed by Breiman emerged from the need to find a compromise between the two extremes.

The main idea behind cost-complexity pruning is to consider sub-trees of the maximal tree and evaluate them with a cost function that increases as the error rate rises and decreases as the number of leaves drops. When a tree is pruned at a node, the weighted summed error of the leaves increases while the number of leaves reduces, thus a pruned sub-tree is selected only if the error gain is counter-balanced by the complexity loss. The cost of a tree $\mathcal{T}$ is given by:

$$
\begin{equation*}
C_{\alpha}(\mathcal{T})=R(\mathcal{T})+\alpha \psi\left(n_{L}\right), \quad \alpha \geq 0 \tag{4}
\end{equation*}
$$

where $R(\mathcal{T})$ is the sum of all errors or impurities of the leaves of $\mathcal{T}$, weighted by the number of individuals they represent. The function $\psi$ is an increasing function of $n_{L}$, it is originally
set to $\psi\left(n_{L}\right)=n_{L}$ in Breiman's work [5], but as demonstrated relevant properties when set to $\psi\left(n_{L}\right)=\sqrt{n_{L}}$ in classification settings (see Appendix A. 1 for more details and references). The penalty $\alpha$ is the complexity parameter: the higher it is, the smaller the pruned tree. With a reasonable choice of $\psi$, the interest of $\alpha$ is that for a fixed complexity parameter value, there exists a unique smallest subtree $\mathcal{T}$ of the maximal tree $\mathcal{T}_{\text {max }}$ that minimizes $C_{\alpha}(\mathcal{T})$. Thus by decreasing $\alpha$, we can construct a sequence of pruned optimal subtrees $\left[\mathcal{T}_{1}, \mathcal{T}_{2}, \ldots, \mathcal{T}_{\text {max }}\right]$ of different sizes. This tree sequence is such that $\mathcal{T}_{1}$ is the root node, $\mathcal{T}_{2}$ a sub-tree of $\mathcal{T}$ with more leaves and accuracy than $\mathcal{T}_{1}$ and so on until $\mathcal{T}_{\max }$, the unpruned maximal tree. With Breiman's notation, we have

$$
\mathcal{T}_{\text {max }} \supseteq \cdots \supseteq \mathcal{T}_{2} \supseteq \mathcal{T}_{1} .
$$

The optimal complexity parameter value, hence the best tree in the sequence is usually selected using cross-validation.

### 2.2 Longitudinal notations

This paper aims to enrich the growing process of decision trees in the presence of time-varying covariates. To do so, let us introduce some notations borrowed from the existing longitudinal literature including works of Rizopoulos or Yao et al [35, 46]. Let us assume a very general setting where we want to build a dataset $\mathcal{D}_{\text {long }}$, encompassing the time-varying features of $N$ subjects, which are repeatedly measured over time. In all generality, let us assume that among the $p$ covariates, $p_{T V}$ of them are time-varying and $p_{T I}$ others are time-invariant. At time $t$, the set of covariates is given by $\boldsymbol{x}(t)=\left(x_{1}, x_{2}, \ldots, x_{p_{T I}}, x_{p_{T I}+1}(t), \ldots, x_{p}(t)\right)$. In order to simplify the notations, we consider all constant features as a special case of time-varying covariates, with $\boldsymbol{x}(t)=\left(x_{1}(t), x_{2}(t), \ldots, x_{p}(t)\right)$ with $x_{k}(t)=x_{k}, \forall t$ and $\forall k \in\left[1, \ldots, p_{T I}\right]$. Let $n^{(i)}$ be the number of distinct times $t_{j}^{(i)}, j=0,1, \ldots, n^{(i)}-1$ at which subject $i$ has been observed. At time $t_{j}^{(i)}$, subject $i$ has a vector of covariates denoted $\boldsymbol{x}_{j}^{(i)}=\left(x_{j, 1}^{(i)}, \ldots, x_{j, p}^{(i)}\right)$.

Classical longitudinal setting: For a given subject $i$, covariates are stored in rows, one row per observation window $\left[t_{j}^{(i)}, t_{j+1}^{(i)}\right)$. Each row contains the unique $\left(t_{j}^{(i)}, t_{j+1}^{(i)}, \boldsymbol{x}_{j}^{(i)}, y_{j}^{(i)}\right)$ elements, with $y_{j}^{(i)}$ the target variable observed at time $t_{j}^{(i)}$. They are completed by the subject unique identifier $i$. Each row represents what we will now call an observation. We build $\mathcal{D}_{\text {long }}$ as the collection of all observations structured longitudinally :

$$
\mathcal{D}_{\text {long }}=\left\{\left(i,\left\{t_{j}^{(i)}, t_{j+1}^{(i)}, \boldsymbol{x}_{j}^{(i)}, y_{j}^{(i)}\right\}_{j=0}^{n^{(i)}-1}\right)\right\}_{i=1}^{N}
$$

Or, if displayed in a table:

### 2.3 Existing longitudinal tree-based algorithms

The problem when splitting time-varying covariates: Whether they are designed for survival analysis or not, longitudinal tree-based models exist and propose various methods to include time-varying covariates that cannot naturally fit in the tree-growing algorithm described in Algorithm 1. As an illustrative example, let $x_{1}(t)$ be a numerical time-varying covariate. At each node, a splitting rule of the form " $x_{1}(t) \leq d^{" 3}$ should be able to split subjects into two child nodes. A subject for which this rule is true at all observed times

[^2]| Table 1 A longitudinally structured dataset |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| ID | Time window Start | Time window End | Covariate 1 | $\ldots$ | Covariate $p$ | Target variable |
| 1 | $t_{0}^{(1)}$ | $t_{1}^{(1)}$ | $x_{0,1}^{(1)}$ | $\ldots$ | $x_{0, p}^{(1)}$ | $y_{0}^{(1)}$ |
| 1 | $t_{1}^{(1)}$ | $t_{2}^{(1)}$ | $x_{1,1}^{(1)}$ | $\ldots$ | $x_{1, p}^{(1)}$ | $y_{1}^{(1)}$ |
| 1 | $t_{2}^{(1)}$ | $t_{3}^{(1)}$ | $x_{2,1}^{(1)}$ | $\ldots$ | $x_{2, p}^{(1)}$ | $y_{2}^{(1)}$ |
| 1 | $t_{3}^{(1)}$ | $t_{4}^{(1)}$ | $x_{3,1}^{(1)}$ | $\ldots$ | $x_{3, p}^{(1)}$ | $y_{3}^{(1)}$ |
| 2 | $t_{0}^{(2)}$ | $t_{1}^{(2)}$ | $x_{0,1}^{(2)}$ | $\ldots$ | $x_{0, p}^{(2)}$ | $y_{0}^{(2)}$ |
| 3 | $t_{0}^{(3)}$ | $t_{1}^{(3)}$ | $x_{0,1}^{(3)}$ | $\ldots$ | $x_{0, p}^{(3)}$ | $y_{0}^{(3)}$ |
| 3 | $t_{1}^{(3)}$ | $t_{2}^{(3)}$ | $x_{1,1}^{(3)}$ | $\ldots$ | $x_{1, p}^{3)}$ | $y_{1}^{(3)}$ |
| 3 | $t_{2}^{(3)}$ | $t_{3}^{(3)}$ | $x_{2,1}^{(3)}$ | $\ldots$ | $x_{2, p}^{(3)}$ | $y_{2}^{(3)}$ |
| $\ldots$ | $\ldots$ | $\ldots$ | $\ldots$ | $\ldots$ | $\ldots$ | $\ldots$ |

will go in one child node without any ambiguity. On the other hand, the general case where the rule is true for some periods but false for anywhere else is unclear and needs to be addressed.

The "eventually not longitudinal" methods: The most naïve model would be a regular CART, trained on all observations in the longitudinal dataset without taking the correlation between observations of the same subject into account. As stated by Segal [38], this would simply ignore the capital aspect of dealing with longitudinal data: "The covariation induced by making several observations of some continuous response on the same unit, as occurs with repeated measures designs, cluster designs, and longitudinal studies, poses data analytic problems. Analysis of such designs that ignore the covariance structure are known to produce incorrect variance estimate.". Other naïve attempts consist of summarising the longitudinal trajectories of time-varying covariates with a small number of parameters. For instance, one could think of only keeping the mean value of every trajectory, the median, its final slope, the baseline value, or the most recent one, ignoring all the remaining information. This leads to a loss of precious information. A similar idea is to regress every longitudinal covariate against time and possibly other features, within-subjects to include the parameters of the regression intercept and slope - as baseline covariates. It can be argued that if the longitudinal covariates are all strongly linearly associated with time, which is rarely the case in practice, this kind of alternative solution can be relevant. Eo and Cho [13] proposed a model called mixed-effects longitudinal tree (MELT) able to handle a longitudinal response by fitting a mixed-effect model at each node of the tree. Subjects are then split based on the heterogeneity of their slopes. Kundu [23] extended this idea of resuming information contained in the longitudinal covariates by a combination of splits on baseline covariates and implemented it in the R package LongCART. Other approaches (such as [34] and more recently [31]) designed longitudinal trees that use lagged response values as potential predictors, but still do not treat either the outcome or the covariates as inherently dynamic with time. Overall, in these methods, information is lost during the process, and the number of measurements per subject in real datasets can be too small to obtain consistent time-invariant surrogates to the time-varying covariates.

The "CART-extended" methods: Segal and De'Ath [38, 11] independently proposed the first applications that clearly define an extension to the CART method and directly account for correlation in the response variable. They both suffered limitations as they were designed for a longitudinal response but time-fixed covariates where all the subjects were measured at
the same observation times, with the same interval between them. On the one hand, Segal's regression tree consisted of imputing a covariance structure in the split procedure. This led to many theoretical questions about defining that covariance structure as well as practical ones regarding the complexity of the computations. On the other hand, De'Ath procedure simply modified the CART algorithm by allowing it to consider an entire matrix containing all the observations for one subject as a single observation. Allowing that was done by using the gain of MSE as a splitting criterion, and replacing the 1-dimensional mean in the MSE with a multi-dimensional mean modified with a covariance structure; the prediction given by the tree would then be the multi-dimensional mean of the observation in the terminal nodes. In both cases, those methods can be seen as fitting a model to the longitudinal outcome at every node as part of the splitting criterion. More recent works by Larsen and Speckman [24] as well as Hsiao et al. [22] followed and improved the idea of De'Ath, by redefining the node impurity measure with the Mahalanobis distance and estimating the covariance matrix from the whole data set. It is worth mentioning that other articles extended the idea of Segal, to binary responses and classification trees (see [47]), in a clustering context using deviance as a goodness-of-fit criterion for partitioning (see [1]) and then to every type of longitudinal response - not only continuous or binary - using Generalized estimating equations (see the works of Lee [25, 27, 26]). Such models show advantages in terms of predictive ability and interpretability but do not handle time-varying covariates.

The "state-of-the-art" methods: In the work of Hajjem et al. [18], Sela et al. [39] and their respective extensions (see $[20,10]^{4}$ and $[15]$ ), a general mixed-effect model is assumed for the longitudinal outcome. The tree-based part only predicts fixed effects whereas individual estimated parameters account for all the time-varying effects. Such approaches can estimate longitudinal outcomes but the inclusion of time-varying covariates is handled via the pseudosubject workaround detailed in the next paragraph. It relies on the assumption that all the dependency between several observations of the same subject is captured by the random effect of the mixed model. In a survival setting, Du et al. [16] and its extensions (see [45]) proposed a model based on those ideas: they allowed subjects to be divided into pseudo-subjects and used an adjusted log-rank test in the splitting procedure to accommodate for left truncation and ensure that the independence implicit assumption does not lead to biased results. We refer the astute reader to the works mentioned in this paragraph as we consider they are the most advantageous approaches today. The algorithms corresponding to their respective work are the R packages REEMtree, LongituRF, LTRCtrees and LTRCforests, the R function REEMctree and the Python library MERF.

Pseudo-subjects LTRC and mixed-effect tree-based models (at least their tree-based part) consider the unmodified $\mathcal{D}_{\text {long }}$ as an input and run through a CART-like growing process, finding optimal binary decision rules at each node of the tree. Whenever a split produces an ambiguity as described in Section 2.3, the periods $\left[t_{j}^{(i)}, t_{j+1}^{(i)}\right)$ where their splitting rule " $x_{1}(t) \leq d$ " is true would go to the left node, and the other would go to the right node, thus dividing one subject into several pseudo-subjects. It cleverly addresses the time-handling issue when the bias that comes with correlated right-censored and left-truncated (LTRC) observations is neutralized otherwise. In such models, any individual can be spread in many different tree leaves - even if, at any fixed time, any individual will have a single observation that will fall into a unique one. Treating one subject's observations, not as an indivisible block of information but rather as multiple pseudo

[^3]subject's data leads to a loss of interpretability. In our opinion, none of these procedures can inherently handle time-varying covariates, while maintaining CART's interpretability. A unique trajectory per subject would ensure a clear visualization of the data: the algorithm should be designed to separate individuals whose features are significantly diverging regarding the target variable rather than pseudo-subjects.

## 3 Time penalized trees

We present here the building blocks of a new way to think about decision trees in the presence of time-varying covariates: time-penalized trees or TpT. Let $\mathcal{D}_{\text {long }}$ be a longitudinal dataset, and $\mathrm{T}=\left[0 ; \max \left(t_{j}^{(i)}\right)\right]$ be the continuous observation interval of time. We define $\mathcal{D}(t)$ as the dataset contaỉning, for every subject $i$, her unique observation with the maximal observation time $t_{j}^{(i)}$ such that $t_{j}^{(i)} \leq t$ and $t_{n^{(i)}-1}^{(i)} \geq t$, where $\boldsymbol{x}^{(i)}(t) \in \mathcal{X}(t)$ is the vector of covariates and $y^{(i)}(t) \in \mathcal{Y}(t)$ the target variable at time $t$. Eventually, $\mathcal{N}(t)=|\mathcal{D}(t)|$ is the total number of subjects under study at time $t$. Let $g$ be a node, which is also identified with a subregion of $\mathcal{X} \otimes \mathrm{T}$ it represents. We thus define $\mathcal{D}(g)$, the set of observations in the node $g$ and $\mathcal{N}(g)=|\mathcal{D}(g)|$ the number of subjects it contains.

The idea behind TpT is to build a tree that benefits from all the longitudinal information available and where the concept of time is central: at each node, we chose to split along covariates and time. As stated in Section 2.1, a tree-growing algorithm is defined by its splitting criterion, stopping rule(s), and pruning process. This applies to TpT and the algorithm we propose can be described as:

```
Algorithm 2 Growing a maximal TpT
    Input: Training longitudinal dataset \(\mathcal{D}_{\text {long }}\)
    Output: Maximal TpT \(\max\)
    Initialize the root node \(g_{p}\) with the entire dataset at time \(t=0, \mathcal{D}_{\text {long }}(0)\)
    \(\operatorname{Grow}\left(g_{p}, 0\right)\)
    Function \(\operatorname{Grow}\left(g_{p}, t_{p}\right)\) :
    if Stopping criteria met (e.g., maximum depth, minimum samples) then
        Let \(g_{p}\) be a "terminal leaf".
    else
        For all possible covariates \(x_{k}\), thresholds \(d\) and time points \(t_{c}>=t_{p}\) find the triplet
        \(\left(x_{k}, d, t_{c}\right)\) such that a partitioning of \(\mathcal{D}_{\text {long }}\left(t_{c}\right)\) along \(x_{k}\), at threshold \(d\) obtains the best
        splitting criterion.
        Split the node \(g_{p}\) : all subjects with \(t_{n^{(i)}-1}^{(i)}<t_{c}\) go to a "duration leaf" \(g_{t}\). All other
        subjects - with \(t_{n^{(i)}-1}^{(i)} \geq t_{c}\) - are split along covariate \(x_{k}\) at threshold \(d\) into two child
        nodes \(g_{r}\) and \(g_{l}\).
        \(\operatorname{Grow}\left(g_{r}, t_{c}\right)\)
        \(\operatorname{Grow}\left(g_{l}, t_{c}\right)\)
    end if
```

In the end, a final Time-penalized Tree would look like that:

Figure 3: Illustration of a TpT

Let us detail how to understand the TpT depicted in Figure 3. The root node appears in blue, and leaf nodes appear in green. The root node contains all subjects of $\mathcal{D}\left(t_{0}\right)$ and is then split into three nodes:

- a left child node containing all subjects from the root node for whom the covariate $x_{1}$ is inferior or equal to the threshold $d_{1}$, at time $t_{1}$,
- a right child node containing all subjects from the root node for whom the covariate $x_{1}$ is greater than $d_{1}$, at time $t_{1}$,
- a third node (depicted horizontally from the root node in Figure 3) containing all subjects from the root node without any observation at time $t_{1}$ or later. Without any information about the value of $x_{1}$ at time $t_{1}$, such subjects cannot be spread into one of the child nodes. As this third node cannot be split any further, constitutes a duration leaves.

The right and left child nodes, thus, each contain non-overlapping subsets of $\mathcal{D}\left(t_{1}\right)$ and are themselves split further, along optimal covariate, threshold, and at a time $\geq t_{1}$. The iterative splitting process continues until a stopping criterion is met and the nodes cannot be partitioned any further. The final nodes obtained at the very end of every branch constitute terminal leaves.

## Remark 1

The time points figuring along the vertical axis on the left of Figure 3 can be understood as the time of all subjects arriving to the node: the last time that was used to split the subjects in the previous node. Conversely, the time points mentioned inside the nodes indicate the decision rule: the optimal times at which the node is split. For instance, all subjects from $\mathcal{D}\left(t_{0}\right)$ arrive to the root node (hence the " $t_{0}$ " on the left axis) and the root node is then split based on the value of covariate $x_{1}$, at time $t_{1} \geq t_{0}$ (hence the " $t_{1}$ " inside the root node).

Defining TpT stopping rules is exactly similar to CART (see Section 2.1.2). Its splitting criterion to be optimized at each node, as well as its pruning process, meanwhile, are modified and discussed in the sections below.

### 3.1 TpT splitting criterion

The split function for Tp T is rather straightforward. We want to select the split on a covariate, at a threshold and a time that will maximize a time-penalized split criterion. The division of a node into two child nodes and a duration leaf has been detailed for the root node of Figure 3, and in all generality, a single split of a parent node $g_{p}$ into the three nodes $g_{l}$ (the left child node), $g_{r}$ (the right child node), and $g_{t}$ (the duration leaf), is illustrated in Figure 4.

Figure 4: Single split of a TpT

To obtain such a split, we have to define a time-penalized split criterion, as

$$
\begin{equation*}
G_{\gamma}\left(g_{p} ; g_{l}, g_{r}, g_{t}\right)=\left[I\left(g_{p}\right)-\left(\frac{\mathcal{N}\left(g_{l}\right)}{\mathcal{N}\left(g_{p}\right)} I\left(g_{l}\right)+\frac{\mathcal{N}\left(g_{r}\right)}{\mathcal{N}\left(g_{p}\right)} I\left(g_{r}\right)+\frac{\mathcal{N}\left(g_{t}\right)}{\mathcal{N}\left(g_{p}\right)} I\left(g_{t}\right)\right)\right] \cdot e^{-\gamma \cdot\left(t_{c}-t_{p}\right)} \tag{5}
\end{equation*}
$$

with $\gamma \in \mathbb{R}^{+}, I(g)$ an impurity or MSE function as described in Section 2.1.1, $t_{p}$ and $t_{c}$ the respective times of the parent node and child nodes and $\gamma$ the penalty parameter. We can immediately see that this is simply the classical CART splitting criterion with an additional exponential penalty term, depending on how distant in time the considered split is. The exponential penalty that we propose induces that the more time distance there is between a
parent node and its potential child node, the more penalized the split. Without that penalty term, a TpT would have early splits at advanced times, and much information contained in early observations would be lost. It ensures that early observations are explored and exploited and that distant splits are selected early in the tree if and only if they are greatly informative. In other words, splits are chosen where covariates AND time points are informative about the target variable; we first try to find close splits if they can detect heterogeneity but distant splits will be considered if they are very informative. We can find examples of this type of exponential consideration of time in time series analysis with exponential smoothing (see $[7,21]$ ), where exponential functions are used to assign exponentially decreasing weights over time. As far as our knowledge extends, instances of tree-based modified splitting criteria where exponential weights were introduced are very rare. A first reference can be found in Section 5.5 of Bremner's PhD thesis [6] that used localized splitting criteria that are based on local averaging in regression trees or local proportions in classification trees, weighted by exponential weights. The weights have no link to time or a measure of distance from the previous node. Goldstein [17] also suggested using exponential weights in tree-based algorithms to promote splits on covariates that were already used in previous splits over others.

The partitioning procedure of TpT can also be visualized similarly to Figure 1, the only difference is that the iterative splits occur on different versions of the longitudinal dataset. Instead of partitioning the feature space alone, we need to illustrate how TpT partitions the feature space at different times.

Consider two time-varying covariates $x_{1}(t)$ and $x_{2}(t)$ et let us assume that $t_{0}=0$ : at depth 0 and $t=0$, the tree is only a root and $\mathcal{D}(0)$ is not partitioned (as it can be seen on the left side of Figure 5). We can see that on the first iteration of the algorithm, a first split, at $t=0$ creates a division of $\mathcal{D}\left(t_{1}\right)^{5}$ such as illustrated on the right side of Figure 5.

Figure 5: TpT 1-depth recursive partitioning
If we go on with the iterative partitioning, at depth 2 and $t=t_{1}$, all subjects that have been

[^4]observed up to $t=t_{2}$ within each partition, are once again split into two subgroups. This creates a division of $\mathcal{D}\left(t_{2}\right)$ such as depicted in Figure 6.

Figure 6: TpT 2-depth recursive partitioning

Eventually, a few more steps of the iterative partitioning procedure can be visualized as in Figure 7. It is the representation of a classical binary split procedure, with the inclusion of a time dimension. The routes of all subjects can be displayed in that representation: the red, blue and green paths in Figure 7 are examples of such individual trajectories.

Figure 7: TpT recursive partitioning and individual trajectories

## Remark 2

Several things need to be noted regarding the partitioning illustration depicted in Figure 7.

First, duration leaves are not represented here: the red trajectory for instance, does not split after time $t=t_{1}$ because the subject it represents has not been observed at time $t_{2}$ or later. Its course at time $t_{2}$ being unknown, it stops in the region of $\mathcal{D}\left(t_{1}\right)$, which is then a duration leaf for similar subjects.

Secondly, this illustration shows that divisions of early steps transpose into continuous partitions in further steps: this is not true in general. The two groups formed by the partition of $\mathcal{D}\left(t_{1}\right)$ may not be represented by a unique region of $\mathcal{D}\left(t_{2}\right)$, split at a constant threshold over one covariate.
To illustrate that point with a concrete example, let us assume that one of the covariates in $\mathcal{D}$ is the subject's salary. The set of all individuals with a salary $\leq 1,000$ at time $t_{1}$ is composed
of individuals without any observation at time $t_{2}$, of subjects with a salary that increased by $t_{2}$ and is $>1,000$ and of others still earning $\leq 1,000$. A set of subjects within a unique connected region of the feature space at time $t_{1}$ generally lies within disconnected subregions of the feature space at time $t_{2}$.

Eventually, it is also to be noted that not every disjoint region splits at every time step of the partitioning. There are times when several splits occur, others where only one region is partitioned, and others where none. All those points are not depicted in Figure 7 for simplicity's sake.

We can already foresee that higher values of $\gamma$ ensure that the next optimal split is more likely to be close in time to the previous node (a distant split is to be chosen only if it is very interesting). The produced TpT will be close to a CART with all longitudinal covariates values blocked at $t=t_{0}$. And it can be easily proven that

$$
\begin{equation*}
T p T\left(\mathcal{D}_{\text {long }}\right) \underset{\gamma \rightarrow+\infty}{\longrightarrow} C A R T\left(\mathcal{D}_{\text {long }}\left(t_{0}\right)\right) . \tag{6}
\end{equation*}
$$

It allows a TpT to explore the covariates space but prevents it from exploring the time dimension. On the contrary, lower values of $\gamma$ are more likely to produce distant splits and the constructed TpT will show similarities with a CART where all longitudinal covariates values rapidly approach their final value. It allows a TpT to split along the time dimension quickly but prevents it from exploring the covariates space at any given time.

## Remark 3

Because the impurities of the parent and child nodes can be computed at different time points, it can happen that $G_{\gamma}<0$. Such cases imply that a specific stopping rule must be enforced for TpT: $G_{\gamma}$ must be positive for a node to split. Otherwise, it would allow ineffective splits.

### 3.2 TpT pruning process

For a TpT , the penalty parameter $\gamma$ affects the tree's dimensions (depth and number of leaves, see Section 4 for an analysis on the matter). An optimal $\gamma$ that minimizes the impurity of the tree (the weighted sum of all leaves impurities) can be chosen but it is not a pruning process comparable to cost-complexity pruning. For a given $\gamma$, a maximal TpT can be grown and may overfit the data. To control for bias and overfitting, various pruning strategies can be considered. First, Breiman's cost-complexity pruning is still well-defined under the TpT framework, for a given $\gamma$, and can be applied as long as all term nodes - denoted as $g_{t}$ in previous illustrations and algorithm - are considered as leaves. We suggest a slightly different adaptation of this pruning strategy to select both $\alpha$ and $\gamma$ simultaneously. It consists of selecting the pair $(\alpha, \gamma)$ that minimizes $C_{\alpha}(\mathcal{T})$, the cost of the tree. Simpler pruning strategies such as Reduced Error Pruning (see [33]) can also be used. Their advantages and flaws are notably discussed in Esposito's article [14] as well as their tendency to over/under-prune.

### 3.3 Time-to-event

Survival analysis can also be carried out directly under the TpT framework. Indeed, for data mining purposes, subjects are distributed in the final tree considering their last observed time $T^{(i)}$. Censorship and event occurrences are visible in the term nodes $g_{t}$. Adapting TpT for prediction tasks would require additional work to account for censorship (see [43]), but this specific topic is not in the scope of our paper.

## 4 Applications

Such a longitudinal data mining algorithm can prove useful in various fields (medicine, sports analytics, taxonomy, biology), here we applied it to a life insurance customer segmentation analysis. For that purpose, we use a real-world dataset of 983 policyholders (PHs), a subset of the dataset used in [41], and we investigate the link between the PH's characteristics through time and the final outcome of their policies, a categorical response variable. Throughout the lifetime of such insurance policies, a series of events can occur. Firstly, one policyholder's coverage can be increased with premium payments that are highly flexible, both in terms of amount and frequency, and are adjusted according to the policyholder's financial circumstances and preferences. Additionally, policyholders may decide to reduce their coverage by withdrawing a portion of their policy. We refer to these events as partial lapses, enabling PHs to adjust their coverage to better align with their changing needs. Other financial operations can occur, such as the payment of interest or profit sharing from the insurer to the PH , and the payment of fees from the PH to the insurer. Insurance companies' information systems are usually designed to keep track of those operations at the policy level, thus actuaries and life insurers often have access to the complete history of their policyholders as the information system is updated in real-time. Eventually, one's insurance plan ends whenever the PH dies or decides to terminate it by lapsing. In the end, the timeline of such insurance policies can be illustrated below: ${ }^{6}$

Figure 8: Example of policyholders timelines
At any given time a policy is either active, has been lapsed by the policyholder, or has ended because of her death. Among all insurance plans subscribed between 1998 and 2019, in our dataset, $57.4 \%$ are active, $22.8 \%$ ended with the death of the policyholders, and $19.8 \%$ lapsed. We only consider uncensored observations here, we thus have $46 \%$ of churned policies and $54 \%$ that ended with death. For this application, our data mining goal is to gain insights into the PH's pathways that lead to these different outcomes. We want to find time-dependent clusters of individuals with similar timelines and outcomes at a given time. This is thus a time-dependent classification problem, where the target variable is the final outcome of the policies, the tree grows with the survival time and splits on potentially time-varying covariates such as age, rate, Customer Lifetime Value (CLV), face amount (FA) or gender. More detailed descriptions of the dataset used can be found in Valla et al. and in Valla's works [42, 41]. In all visualizations of the following sections, all leaves or regions that contain a majority of policies that ended

[^5]with the PH's death are labeled "D", and all those that contain a majority of policies that ended with lapse (or churn) are labeled "C". In terms of colors, the proportion of each class is represented by a nuance between (for a $100 \%$ proportion of "D") and $\quad$ (for a $100 \%$ proportion of "C"). For example, a leaf or region with $50 \%$ of churners is represented by the color . Since we only consider PHs that were observed until the termination of their policy, there are no censored observations to consider.

### 4.1 Properties of TpT for the maximal tree

First of all, Table 3 in Appendix A. 3 displays the results obtained by TpT with various choices for the time penalty parameter $\gamma$. It shows the dimensions of TpTs (depth and number of leaves), their global impurities and costs, the highest time point when a split occurred, and the average time at which any subject is split. Graphs of those results can be found in Figure 17. Here we considered unpruned trees using the time-penalized version of the Gini impurity measure as a splitting rule (Equation 5) and without any stopping_criterion. For this application, we computed the cost of the tree with a choice of $\alpha=\sqrt{\frac{3 \log 2}{2 N}}$, suggested by Scott [36]. The pruning process then only consist of selecting $\gamma$ as the solution of $\operatorname{argmin} C_{\alpha}(\mathcal{T})$.

We can observe that the depth and number of leaves grow with $\gamma$. This was to be expected, as a TpT that does not penalize time-distant splits will quickly find high impurity-gain splits at distant times thus preventing the exploration of less distant time periods. Conversely, the same phenomenon explains that the average time when splits occur is a decreasing function of $\gamma$. As the penalty parameters get high values, any future split is heavily penalized and can not compete with splits at time $t_{0}$, regardless of their potential unpenalized gain. Eventually and very interestingly, we observe that the unpenalized TpT , as well as the heavily penalized one, are not optimal in terms of global impurity. There exists an optimal choice of $\gamma$ that generates a TpT minimizing the sum of its leaves impurities. This tree has a penalty parameter of 0.2725 , a depth of 17 and a number of leaves of 190-173 terminal leaves and 17 duration leaves and is displayed in Appendix A. 3 as long with more results and graphs obtained with diverse settings, with various impurity measures.

Such trees, without stopping criterion and post-pruning are useful to discuss the properties of TpTs but do not yield immediate insights on our dataset. Nevertheless, there is one statistic that proves to be insightful: the distribution of times when splits occur. Obviously, with an exponentially penalized splitting criterion, the more distant from its parent time $t_{p}$ a split time $t_{c}$ is, the more penalized it is and the less likely it is to be selected. The a priori probability for time to be selected as a split time is $\propto e^{-\gamma \cdot\left(t_{p}-t_{c}\right)}$ Thus, by weighting the frequency of times when splits occur with an exponential factor, we balance this bias and retrieve the importance of the time periods. In the optimal unpruned and unstopped tree, the splitting time points are distributed as such:

Figure 9: Split times distribution for the optimal unstopped and unpruned TpT

In the weighted histogram, we can clearly see that some periods seem to be critical split points that differentiate active policies from lapsers or policies that are likely to end with the policyholder's death. Interestingly, we see that $t=0$ and $t=8$ are particularly important in terms of differentiation between policies' outcomes. For $t=0$, the insight is clear: most of the information that separates the churners from policies that end with the PH's death can be retrieved from the baseline covariates: for instance, it can be seen in the early splits of Figure 10 that the age at subscription seems to be very informative - older PHs are more exposed to the mortality risk - and thus is selected at baseline. Regarding the important splits at $t=8$, we see in Figure 10 that they correspond to splits on age, CLV, or FA. CLV is highly dependent on both age and FA, thus we could argue that age and FA are the most informative covariates at $t=8$. By law, French life insurance plans ensure that when a given policy is at least eight years old, the policyholder can lapse without any surrender penalty. This is a clear incentive not to churn before one's policy reaches 8 years of seniority. It seems consistent to observe that this threshold is pointed out in our analysis. The third year of seniority comes right after $t=0$ and $t=8$ in terms of temporal importance, which does not have any obvious business justification. However, every split at $t=3$ (see Figure 10) is either a split on CLV or the FA of the policy, thus we can argue that the final outcome of a policy seems dependent on its FA 3 years after subscription. Similarly, the unpenalized suboptimal TpT with $\gamma=0$, depicted in Figure 12 only splits at times $t=0, t=3$ or $t \geq 8$, with respectively 1, 1 and 24 splits.

This application has also been tried on a larger longitudinal dataset, containing 119,431 observations of 9,873 PHs. Characteristics of TpTs grown with various $\gamma$ are described in Figure 10 It gives the split times distribution in Figure 11. Due to the heavy computation time, all other analyses are carried out on the smaller dataset.

Figure 10: Characteritics of unstopped and un-Figure 11: Split times distribution for the optimal pruned TpT, trained on $9,873 \mathrm{PHs}$ with various time penalties unstopped and unpruned TpT , trained on $9,873 \mathrm{PHs}$

Figure 12: Overfitted unpenalized, unstopped and unpruned $\mathrm{Tp} T$

### 4.2 Use-case with minsplit

A clear strength of decision trees is their interpretability. Obviously, trees with hundreds of leaves each containing a handful of subjects can not be interpreted. Here we decided to investigate the results obtained by TpTs with various $\gamma$, using the time-penalized version of the Gini impurity measure as a splitting rule and including a stopping criterion: any leaf must contain at least 50 individuals otherwise it does not split. This choice of stopping rule is not really close to the default value for the minsplit parameter in most CART implementations, but it will generate shorter, less overfitted TpTs, better suited for direct interpretability and data analysis. Here are the results for TpT on our longitudinal dataset, with minsplit= 50 . Graphs of those results can be found in Figure 13.

Table 2 Characteritics of TpT (minsplit: 50) depending on the time penalty

| Time penalty $\gamma$ | Runtime | Depth | \# of terminal leaves | \# of duration leaves | Total \# of leaves | Tree cost | Max of split times | Mean of split times |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 0.0000 | 587.03 | 4 | 9 | 7 | 16 | 0.319 | 15.0 | 4.309 |
| 0.0025 | 736.31 | 6 | 11 | 6 | 17 | 0.306 | 15.0 | 2.134 |
| 0.0075 | 730.35 | 6 | 11 | 5 | 16 | 0.306 | 15.0 | 2.102 |
| 0.0200 | 726.84 | 6 | 11 | 4 | 15 | 0.306 | 15.0 | 1.97 |
| 0.0275 | 789.2 | 6 | 13 | 6 | 19 | 0.300 | 8.0 | 2.203 |
| 0.0325 | 784.67 | 6 | 13 | 5 | 18 | 0.300 | 8.0 | 2.131 |

| 0.0650 | 840.38 | 7 | 15 | 3 | 18 | 0.297 | 9.0 | 1.129 |
| 0.0925 | 841.11 | 7 | 15 | 2 | 17 | 0.299 | 8.0 | 0.88 |
| 0.1100 | 850.24 | 7 | 15 | 1 | 16 | 0.300 | 8.0 | 0.564 |
| 0.1250 | 873.15 | 7 | 16 | 1 | 17 | 0.298 | 5.0 | 0.423 |
| 0.1375 | 873.64 | 6 | 15 | 2 | 17 | 0.297 | 5.0 | 0.303 |
| 0.1900 | 899.41 | 6 | 15 | 1 | 16 | 0.297 | 3.0 | 0.157 |
| 0.2050 | 886.07 | 6 | 15 | 1 | 16 | 0.298 | 3.0 | 0.125 |
| 0.7000 | 752.84 | 6 | 15 | 0 | 15 | 0.299 | 1.0 | 0.032 |
| 0.8000 | 743.89 | 6 | 15 | 0 | 15 | 0.300 | 0.0 | 0.0 |

Figure 13: Characteritics of TpT (minsplit: 50) depending on the time penalty

Among all the different TpTs in table 2, we can discuss which one minimizes the tree cost. First of all, we see here that the trees with $\gamma=0$ and $\gamma \rightarrow \infty$ are not the best in terms of global
cost. This is a critical result: $\gamma=0$ is the case where the last observed observation points are quickly considered whereas early periods are not really considered, and high $\gamma$ represents the case where a tree is grown only on the baseline values of all time-varying covariates. Thus, Tp T shows that considering time in the splitting process improves the global purity of the tree, it better differentiates between individuals with different outcomes and trajectories. In terms of interpretability, Figure 14 shows that the optimal TpT is a compromise between small TpTs with time-distant splits and a large baseline tree without any temporal information. Whole-page versions of those trees can be found in Appendix A.3.3.

Figure 14: TpTs with $\gamma=0, \gamma=0.035$ and $\gamma \rightarrow \infty$, respectively
An important temporal dependence that can be learnt from the tree is the fact that there exists an incentive not to lapse before eight years of seniority. It is clearly depicted in the optimal $\mathrm{TpT}-\gamma=0.035-$ as the duration leaves generated by splits occurring at times $\geq 8$ contain a majority of policyholders that did not lapse. It means that regardless of their age, subjects with a seniority $\leq 8$ years do not lapse. The TpT with no time penalty $-\gamma=0$ - can capture the same temporal dependence for splits that occur immediately after 8 years for older PH but fails to do so for younger ones. This is explained by the fact that for the latter, the unpenalized TpT quickly finds an excellent split at time $t=15$, which prevents splits around 8 years from being found. This is a compelling argument in favor of a time penalty. Furthermore, the TpT with a very high time penalty produces a tree that only splits at time $t=0$, thus no temporal insights can be found with it. If we were to conclude from such a tree, we could say that Age is the most important covariate, and allow for a good partitionning of $\mathcal{D}$ but we cannot have any temporal analysis. This is an argument in favor of TpT and the suggested $\gamma$ selection process.

### 4.3 Pathways vizualizations

In terms of data mining and clustering, let us focus on the optimal TpT obtained in the previous section and depicted in Figure 15. In the same way a decision tree is a representation of all observations in a cross-sectional dataset, a TpT is a complete representation of a longitudinal one and we can highlight the pathway of any given policyholder in the tree. Unlike any other longitudinal tree-based model, any individual has a unique continuous trajectory in the tree.

The pathways of five policyholders selected at random from our dataset are represented in the following TpT.

Figure 15: Individual longitudinal trajectories in the optimal TpT (minsplit $=50$ )

Thus, the longitudinal dataset and all individual timelines can be easily represented as a partitioning. All PH are represented on the y-axis and the region of the covariate space where they belong changes as a function of time, on the x-axis. In this example, the 18 leaves of Figure 15 correspond to the 18 final regions of Figure 16, as $t \rightarrow \infty$.

Figure 16: Global timeline and individual longitudinal trajectories

The numbers in each region of Figure 16, as well as their heights, are the number of PH they contain, and the five individual trajectories represented as pathways in the tree correspond to the five horizontal lines within the global timeline. Let us take a few examples to understand this Figure. In the TpT displayed in Figure 15, there are 520 policyholders that are older than 62.5 years old, at subscription, they all go from the root to the first right node of the tree. At that point, we see the trajectories of three policyholders (depicted in light blue, red and brown dashed lines) taking that path to the right. Their trajectories spread after the next split at $t=1$. Similarly, those 520 PHs can be found in the lower region of Figure 16 , with $t \in[0,1]$ on the y-axis. The light blue, red, and brown dashed paths can be found in that region. After that, when $t>1$, these PHs' trajectories are never in the same region again, the same way they can never be found in the same node of the corresponding TpT. This type of visualization allows to better interpret the periods where changes in the outcome can occur.

## 5 Conclusion, limitations and future work

### 5.1 Conclusion

This paper exhibits TpT , a new tree-based data-mining algorithm that accounts for time-varying covariates through time-penalized splitting criteria. Our methods handle time-varying covariates as well as longitudinal target variables inherently. Contrary to existing approaches, it does not need workaround strategies such as the pseudo-subject method and provides a tree that separates "complete individuals", as each subject covariates trajectory corresponds to a single unique trajectory in the final tree. Pruning strategies were proposed and tested with real
datasets and illustrative examples. The algorithm proves to have appealing data-mining and visualization potential in various fields that could be explored more deeply in the future.

### 5.2 Limitations and future work

Right away, it is crucial to acknowledge the general limitations of this work, before going into more technical details. First of all, the need for a thorough investigation into the statistical properties and theoretical underpinnings of the developed tools is evident to ensure their reliability and robustness. Such theoretical work is critical and constitutes forthcoming research. Secondly, conducting comprehensive comparisons of TpT with existing longitudinal techniques, employing well-studied datasets and consistent indicators is pivotal for a more rigorous evaluation of the proposed methods. These identified gaps in the current work underscore the necessity for subsequent research on Tp T.

Besides those points, and with the algorithm as it is defined for data-mining purposes, many improvement paths can be considered.

Firstly, the introduction of a penalized splitting criterion, and thus a penalty parameter could be discussed more thoroughly. The current multiplicative exponential form of penalization has been duely justified but one could explore the effects of different approaches. Other distributions of the future time cut-off penalties such as Gamma (with parameters $\alpha<1, \beta \geq 1$ or $\alpha=1, \beta>2$ ), Pareto, Weibull (with parameter $k<1$ ) or Log-logistic ( $\beta \leq 1$ ) could be justified on concrete examples. Moreover, in the algorithm as it stands, every point in time can be considered for a potential cut-off; some time-horizon limit where distant splits would simply be ignored would have an impact on the shape of the final tree. Eventually, the possibility of a penalty parameter that changes along the growth of the tree is yet to be explored. In all those scenarios, the penalty parameter affects the width and length of the final tree and can even be interpreted as a pre-pruning parameter. The properties of that pre-pruning as well as the choice of an optimal $\gamma$ are yet to be discussed. On a final note, we do not know if any technical properties (see [4, 8]) of the penalized splitting criterion still hold. That knowledge will certainly not affect the concrete applications of TpT but is more of a theoretical interest.

Secondly, we showed in illustrative applications that time-outliers can be easily miscategorized as the TpT can send them early in one direction of the tree from which they will not escape. In addition to that, those observations are likely to end up being isolated in a leaf if the stopping rules allow it. On the one hand, it forces observation into an early path that may not be consistent with later observations. On the other hand, this behavior is linked to an abrupt change of the covariates and target variable trajectories in time, which is a discriminating feature that can justify that such subjects end up in a specific leaf. We see two ways to handle this specific property:

- A first idea would be to modify the TpT algorithm to make it less greedy. Instead of choosing the best split at each node, we could consider finding the best sequence of several consecutive splits. This multi-step ahead strategy would ensure that abrupt changes in covariates in the future are anticipated in early splits. In cases where the penalty parameter is low, this approach also ensures that the TpT does not grow too fast with time.
- Another innovative solution is to introduce the possibility for an outlier in a node to teleport into another one, at a similar depth/split time in the tree. For instance, if it so
happens that a subject trajectory suddenly becomes significantly different from the other ones in the same node, it can be clever to acknowledge that it is no longer consistent to keep it in the said node. This solution has drawbacks: it requires testing for outliers in every node, at every step. If one is found, it can only be teleported if another node within which the subject would not be an outlier is found. Moreover, it is a straightforward solution for data mining but other adaptations are necessary if TpT is to be used for predictive tasks. Despite this, it would still ensure individual trajectories for every subject in the tree and it would consolidate the global within-node homogeneity.

Then, our last point raises another capital question: the applications shown in Section 4 only exhibit the potential of Tp T for clustering tasks; can it be adapted to prediction ones? In our context, a prediction is an estimation of a subject's target variable $y^{(i)}$ at a time $t$, given its covariate history up to $t$. An obvious research path in that direction is to mimic the example of CART. For a subject in node $g$, predicting the mean of the target variable at time $t$ of all subjects emerging from node $g$ is to be tried. If the target variable is a time-to-event and the observations are censored, it could be weighted by the inverse probabilities of censoring weights (IPCW). It perfectly translates in terms of interpretability: the prediction of an outcome at time $t$ for individual $i$ is the mean of the outcomes at time $t$ of all subjects taking the same trajectory in the tree. There are several obvious drawbacks to this approach: there needs to exist observations of other subjects at time $t$. And even if some exist, the variance of the prediction is directly linked to the number of such subjects. Exploring the properties and predictive performance of this approach is left as future work and other methods such as fitting a longitudinal model ${ }^{7}$ at every node, not for splitting but for prediction purposes are also studied.

Eventually, if prediction is made possible in the future, exploring the performance of ensemble methods for TpT looks like a reasonable next step. Such approaches are in contradiction with the research of interpretability that motivated TpT , but competitive predictive performance could justify them.

In conclusion, we are sincerely aware of all limitations and future theoretical and applied work to be done on the subject and simply wanted to rigorously lay the foundations of TpT to allow forthcoming studies to start from an existing base. This paper can also prove to be useful if any collaboration and improvements on the subject - whether is it on a more efficient implementation, different applied examples, or new theoretical insights - are to result from it.

## A Appendix

## A. 1 About cost-complexity pruning

Even thougt the original cost function of the CART algorithm described by [5] is penalized proportionnaly to its number of leaves $n_{L}$, several works on the matter suggest other types of penalty. [2] shows that applying risk bounds to CART imply a penalty with $\psi\left(n_{L}\right)=\sqrt{n_{L}}$. In later works, [28], [32], then [37] also showed that risk bounds with a penalty using $\psi\left(n_{L}\right)=\sqrt{n_{L}}$ can be derived for classification trees whereas penalties proportionnal to $n_{L}$ can only be derived in specific cases discusse by [3]. In summary, square-root penalties appear to have a much stronger theoretical foundation than $n_{L}$ proportionnal ones in various context, notably for classification tasks.

## A. 2 Frechet trees

Another very interesting and general approach is Fréchet trees - and Fréchet forest - by [9]. It is a tree-building procedure that allow handling data for which input covariates and the outcome take values in general metric spaces. Concretely, it is designed to handle covariates and outcomes that can be any functions and can be, in particular, functions of time. In this article, they illustrate the prediction ability of Fréchet forests on longitudinal data and the robustness of their method to missing data and time shifts. Several limitations can be pointed out: firstly the mathematical assumption of the existence of the Fréchet mean in the output space must be verified and that mean must be approximated as precisely as possible. Another limitation is the interpretability, as it is always the case with bagging techniques, but here it is also true for individual Fréchet trees: if covariates' importance can be analyzed, relevant threshold and time points can not be easily observed. Eventually, the computational burden of this algorithm is also important. This method has been implemented in the R package FrechForest.

## A. 3 More results

## A.3.1 Results without stopping criterion

The maximal unpruned and unstopped TpT , obtained with the time-penalized Gini splitting criterion and an optimal time penalty achieves a depth of 17 , has 190 leaves - 173 terminal leaves, 17 duration leaves - and is too large to be fully displayed as a tree here. However, we can still represent it as a list of decisions describing how the dataset is partitionned:

```
The maximum depth achieved is 17
The number of leaves is 190
173 terminal leaves and 17 duration leaves
The tree impurity is : 0.06270710057403012
The penalized tree impurity is : 0.3556124586066797
The maximum time where a split occured is 10.0
The average split time is 0.9805922147055561
The tree is:
    depth = 0 if Age <= 65.5 at t = 0.0, samples: 983
    and no duration leaf
    then depth = 1 if Ag
        then depth =2 if GENDER }<=1.5\mathrm{ at t = 0.0, samples: }11
            and no duration leaf
                then depth = 3 if Age }<=30.5\mathrm{ at t = 0.0, samples: 58
                    and no duration leaf
                            then depth = 4{value: CHURNED, samples: 29}
                                    else depth =4 if CLV <=9.16 at t =0.0, samples: 29
```

```
    and no duration leaf
    then depth = 5{value: CHURNED, samples: 9}
    else depth = 5 if FACE_AMOUNT <= 7197.19 at t = 2.0, samples: }2
    and no duration leaf
        then depth =6 if FACE_AMOUNT <= 3654.22 at t = 2.0, samples: 9
            and no duration leaf

## A.3.2 Results with minsplit $=\mathbf{2 5}$

The maximal unpruned and unstopped TpTs, obtained with the time-penalized entropy splitting criterion, minsplit $=25$, and various time penalties yields the following results:

Table 5 Characteritics of Entropy TpTs (minsplit=25) depending on the time penalty

| Time penalty $\gamma$ | Runtime | Depth | \# of terminal leaves | \# of duration leaves | Total \# of leaves | Tree cost | Max of split times | Mean of split times |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 0.0000 | 668.38 | 5 | 14 | 8 | 22 | 0.664 | 15.0 | 5.722 |
| 0.0025 | 690.38 | 5 | 14 | 7 | 21 | 0.664 | 15.0 | 5.172 |
