27 **Short title:** Diversity of microsporidian *Nosema* spp. in freshwater gammarids (Amphipoda)

28 **Abstract**

29 The microsporidian genus *Nosema* is primarily known to infect insects of economic importance
30 stimulating high research interest, while other hosts remain understudied. *Nosema granulosis* is
31 one of the formally described *Nosema* species infecting amphipod crustaceans, being known to
32 infect only two host species.

33 Our first aim was to characterize *Nosema* spp. infections in different amphipod species from
34 various European localities using the small subunit ribosomal DNA (SSU) marker. Second, we
35 aimed to assess the phylogenetic diversity, host specificity and to explore the evolutionary history
36 that may explain the diversity of gammarid-infecting *Nosema* lineages by performing a
37 phylogenetic reconstruction based on RNA polymerase II subunit B1 (RPB1) gene sequences. For
38 the host species *Gammarus balcanicus*, we also analyzed sex ratios of progenies to test for sex
39 ratio distortion in relation with *Nosema* infection.

40 We identified *Nosema* spp. in 316 individuals from nine amphipod species being widespread in
41 Europe. The RPB1-based phylogenetic reconstruction using newly reported sequences and
42 available data from other invertebrates identified 39 haplogroups being associated with
43 amphipods. These haplogroups clustered into five clades (A-E) that did not form a single
44 amphipod-infecting monophyletic group. Closely related sister clades C and D correspond to
45 *Nosema granulosis*. Clades A, B and E might represent unknown *Nosema* species infecting
46 amphipods. Host specificity seemed to be variable with some clades being restricted to single
47 hosts, and some that could be found in several host species. We show that *Nosema* parasite richness
48 in gammarid hosts is much higher than expected, illustrating the advantage of the use of RPB1
49 marker over SSU. Finally, we found no hint of sex ratio distortion in *Nosema* clade A infecting *G.*
50 *balcanicus*. This study shows that *Nosema* spp. are abundant, widespread and diverse in European
51 gammarids. Thus, *Nosema* is as diverse in aquatic as in terrestrial hosts.

53 **Author Summary**

54 The intracellular microsporidian parasites of the genus *Nosema* are important pathogens as they
55 infect insects of economic importance such as pollinators or domestic silk moths. However, they
56 have been overlooked in other groups of invertebrates such as crustaceans, where only few *Nosema*
57 spp. were detected, including *Nosema granulosis* in two gammarid amphipod hosts. Here, using
58 molecular tools, we detected infections by *Nosema* spp. in nine freshwater amphipod species from
59 various European localities. These infections are common, widespread, and the phylogenetic
60 analysis revealed that some *Nosema* lineages are specific to certain host species, while the others
61 are not restricted to single hosts. We also confirm that there are several *Nosema* lineages infecting
62 gammarid crustaceans, not only *N. granulosis*, that can be new candidate species of *Nosema*. We
63 conclude that *Nosema* is as diverse in aquatic as in terrestrial hosts.

64 **Keywords:** Host-parasite relationships, co-diversification, phylogeny, RPB1, SSU rDNA,
65 *Gammarus*

66 Introduction

67 Since the mid-19th century, Microsporidia, a large group of obligate intracellular eukaryotic
68 microparasites related to fungi, has aroused interest in both basic and applied studies [1–3]. In this
69 context, the microsporidian genus *Nosema* (Nosematida) holds in a seminal place. The first
70 formally described microsporidium was *Nosema bombycis* [4]. Since then, 16 *Nosema* spp. or
71 closely-related species have been described infecting insects [5]. All are pathogenic to some
72 extent, with some species having a negative economic impact and some have been used for insect
73 pest control [6,7]. There are strains of *Nosema* that are horizontally transmitted (HT) [8], while
74 others are known to also use vertical transmission (VT) in their life cycle [9].

75 Few *Nosema* spp. are known to infect freshwater decapod or amphipod crustaceans based on
76 morphological and molecular data [10–18]. Many amphipod species are known to serve as hosts
77 for many other microsporidian parasites, such as *Dictyocoela* spp. and *Cucumispora* spp.
78 [summarised in 18], and one *Nosema* species, *N. granulosis*, which has been reported from only
79 two amphipod species. This parasite, unlike *Nosema* of insects, has not been recognized as a
80 pathogen so far, while in other crustaceans the impact on host fitness is unknown. *Nosema*
81 *granulosis* was first described in the amphipod *Gammarus duebeni* [10]. Infected *G. duebeni*
82 females transmit *N. granulosis* directly to their offspring through infected eggs [19–21]. Vertical
83 transmission occurs only via female hosts because eggs contain enough cytoplasm in which *N.*
84 *granulosis* can live and be transmitted [22]. Under the selective pressure of this transmission
85 asymmetry, traits increasing the proportion of female hosts is selectively advantageous for the
86 parasites. Therefore, the parasite's ability for turning genetic males into functional females
87 (feminization) was selected [10,23–26]. As a consequence of this feminization, female-biased sex
88 ratios can be found in populations of *G. duebeni* and *Gammarus roeselii* [20,21,23,27] and only a
89 few males were found to be infected by *N. granulosis* in *G. roeselii* (presumably resulting from
90 failed feminisation) [23]. These vertically-transmitted infections cause little pathogenicity to their

hosts [10,23,28,29], even having beneficial effects in *G. roeselii* [23]. Because of female excess and positive effect on fitness-related traits, host populations infected with the feminizing *N. granulosis* strains are predicted to have higher growth rate and may help the invasive host *G. roeselii* in colonizing new territories [30]. Supporting this hypothesis, Quiles *et al.* [31] found that the feminizing *N. granulosis* strain of *G. roeselii* is associated with the only host mitochondrial genotype that invaded Western Europe after the last glaciation [32]. However, as feminizing *Dictyocoela* microsporidians vary in their feminizing ability [21], it is likewise possible that the feminization capacity of *N. granulosis* infecting *G. duebeni* and *G. roeselii* varies between parasite strains and/or host species. The recent detection of *Nosema* spp. in populations of different amphipod species with highly variable prevalence fuels this hypothesis [33,34], but more data are necessary to understand *N. granulosis* diversity in amphipods. Studying microsporidian infections in amphipods is facilitated by the fact that some hosts are subjected to intensive phylogenetic and biogeographical research. For example, a study on New Zealand amphipods suggested that amphipod-*Dictyocoela* associations could have preceded the split of Pangea some 180 million years ago (MYA) and that these parasites co-differentiated with their hosts [35]. Similarly, the resolution of the evolutionary histories of morphospecies *Gammarus balcanicus* and *G. roeselii* [32,36,-38] allowed the study of co-differentiation between these hosts and some of their microsporidian parasites, especially those belonging to the genus *Dictyocoela* [31,39,40]. However, data on *Nosema* infections remain too scarce in European gammarids to allow a general analysis of their diversification. *Gammarus balcanicus* is a potential host of particular interest, having begun its diversification in the early Miocene (c. 17 MYA) in the central Balkans, and for which cryptic lineages are locally endemic due to paleo-habitat fragmentation and a complex phylogeographic history [36,38]. Furthermore, the recent biogeographical study of the pan-European morphospecies *Gammarus pulex* [41-43] and *Gammarus fossarum* [44] show high levels of cryptic lineages diversity, with diversification starting some >10 MYA. The crown age of the genus *Gammarus* itself has been estimated at 65 MYA [45]. All this offers the opportunity to

117 extend the analysis of *Nosema* diversity to a wider set of European gammarid species and to
118 decipher the age of infection in this group of hosts.

119 Besides the aforementioned advantages, the study of the phylogenetic diversity of microsporidian
120 parasites faces some problems with the resolution of available genetic markers. The small subunit
121 ribosomal DNA marker (SSU) is routinely used to PCR-screen hosts for microsporidian infections.

122 SSU sequencing data proved to be very useful for phylogenetic reconstructions at higher
123 taxonomic levels and for distinguishing major microsporidian clades (e.g. genera) [46], and
124 sometimes also for resolving phylogenetic relationships at lower taxonomic levels [40,47].

125 However, the use of SSU showed some unresolved phylogenetic relationships [e.g. *Dictyocoela*
126 *duebenum* / *muelleri*] [47], and generated ambiguous results for the *Nosema* genus. On the one
127 hand, it enabled formal redefinition of the two genera *Nosema* and *Vairimorpha* within the family
128 Nosematidae [5]. On the other hand, phylogeography of *N. granulosis* in *G. roeselii* based on SSU

129 showed a low level of genetic variation despite a pan-European sampling [31]. Therefore, a more
130 variable marker is needed to unravel the phylogeography of *N. granulosis* and the evolution of
131 *Nosema*-amphipod associations. The genomes of the few economically relevant insect-infecting
132 *Nosema* spp. have been sequenced [48–50], as well as, recently, the genome of *N. granulosis* [51].

133 Based on these available genome data, the large subunit of the RNA polymerase II (RPB1) gene
134 has been shown to be a suitable marker to unravel microsporidian phylogenetic relationships in
135 cases where SSU was of limited value [5,52–54]. RPB1 is used for all mRNA synthesis in
136 eukaryotes [55], displaying a high level of synonymous variation. Its higher level of genetic
137 variation compared to SSU was already emphasized in a previous study on Microsporidia [52].

138 The aim of the present study was to deepen our understanding of the evolutionary history of
139 *Nosema* lineages infecting amphipod crustaceans, focusing mainly on *Gammarus* species, by using
140 both SSU and RPB1 markers. Specifically, we first aimed at elucidating the extent of molecular
141 variation associated with *Nosema* infections in amphipods (i.e., could all lineages identified as
142 *Nosema* based on SSU be considered as *Nosema granulosis sensu stricto*, or are they divergent

143 enough to be considered as different species?). Second, we wanted to infer host specificity and
144 explore evolutionary history scenarios that may explain the diversity of gammarid-infecting
145 *Nosema*. Finally, as new divergent lineages of *Nosema* were detected over the entire distribution
146 area of a new host, *Gammarus balcanicus*, the possible existence of sex ratio distortion associated
147 with vertical transmission was tested, using the crude proxy of an infection bias in females (as
148 already used in [20]). Such a test allowed us to explore whether sex ratio distortion is a trait that
149 appeared more than once in the evolution of amphipod *Nosema*.

150

151 **Materials and methods**

152 **Overview of dataset composition for *Nosema* infecting amphipods**

153 Our dataset combined information on 316 *Nosema*-infected amphipod individuals gathered from
154 three sources. The first source was data from the literature for which both SSU and RPB1
155 sequences were available. The second source was data for which SSU information is available
156 from the literature or GenBank and for which RPB1 information was tentatively gained from the
157 original DNA samples as part of this study. The third source was *de novo* sequencing data of
158 parasite SSU and RPB1 from individuals detected as infected by *Nosema* by SSU PCR screenings
159 (Table S1 and S2).

160 The first source is very limited, comprising of only two pairs of sequences, one associated with
161 infection of *G. duebeni* [56] and one associated with *G. roeselii* [51]. The second source included
162 samples of *G. fossarum*, *Niphargus schellenbergi* from Luxembourg and *Niphargellus arndti* from
163 Poland [34,57], *G. pulex* from Poland (Wroblewski unpublished), *G. pulex* and *G. fossarum* from
164 Germany [58], *G. duebeni* from Ireland [59] and *G. roeselii* from France [23]. A large number of
165 amphipod individuals from different countries were available for three taxa: *Dikerogammarus*
166 *villosus* [60], *G. roeselii* [31] and *G. balcanicus* [61] from 34, 94 and 88 sites, located in 8, 19 and
167 13 countries, with 1436, 1904 and 2225 host individuals tested, respectively. The third source was

168 associated with three host taxa we sampled during three local-scale surveys: *G. duebeni* (sites KER
169 and ROS in Brittany, France), *G. balcanicus* (site SK in Slovakia), and *G. pulex* (5 sites in France,
170 one in Germany and one in Poland). In addition, host individuals from two large-scale surveys we
171 conducted on *G. fossarum* and *G. balcanicus* were included (S1 Table). In *G. balcanicus* (unlike
172 other species), the sex of individuals was noted during dissection (S1 Table). This allowed us to
173 test if females are more often infected than males, which is an indication of sex-biased infection
174 by the parasites and suggestive of VT mode and sex ratio distortion, as previously shown in *G.*
175 *duebeni* and *G. roeselii* [20,23].

176

177 ***Nosema* infection status based on SSU ribosomal DNA sequencing**

178 All host individuals without previous information on microsporidian infection were first screened
179 to assess possible infection with *N. granulosis* based on the SSU marker. SSU was used for both
180 molecular screening for microsporidian infection based on specific PCR primers for Microsporidia
181 and assignment to *Nosema* based on BlastN searches [62] of sequenced PCR products against the
182 sequences available in GenBank. All molecular lab work conditions were as described in [31].

183

184 **Amplification and sequencing of *Nosema* RPB1**

185 All *Nosema*-infected individuals (based on SSU) were selected for RPB1 amplification (276
186 individuals). As all published primers tested [52,53,63,64] failed to produce reliable PCR products
187 of our samples, we designed new primers. Five RPB1 sequences were manually aligned, including
188 three *N. granulosis* sequences (associated with infection of *G. duebeni*: DQ996233 and EF119339
189 [52], and *G. roeselii*: SBJO01000442 [51]), and two sequences from *Nosema* infecting insects: *N.*
190 *bombycis* (DQ996231 [52]) and *Nosema empoascae* (DQ996232 [52]). Variable regions of interest
191 for phylogenetic reconstruction and conserved regions suitable for primer design were identified

192 from the alignment. Two sets of degenerated primers were designed using Geneious 10.2.2 [65],
193 targeting two non-overlapping fragments, named F2 and F4, starting at positions 386 and 1161 on
194 the RPB1 gene of the genome SBJO01000442, respectively (S1 Fig). The F2 primers were 5'-
195 GKT GTG GRA ATA AAC AGC-3' (forward, F2f) and 5'-TCT ACT CTC TTM CCC ATA AG-
196 3' (reverse, F2r), generating a 520 bp-long amplicon. The F4 primers were 5'-GAA AGA CAC
197 ATG CAG RAT G-3' (forward, F4f) and 5'-TTC CWG ACA TGA TYT CTC C-3' (reverse, F4r),
198 generating a 640 bp-long amplicon.

199 PCRs were performed in a volume of 30 µl, containing 2.5 mM MgCl₂, 0.5 units of 5 PRIME
200 HotMaster Taq DNA polymerase (Qiagen, Hilden, Germany), 0.2 µM dNTPs (MP Biomedicals
201 Europe, Illkirch, France), 0.2 µM of forward and reverse primers each (Eurofins Genomics,
202 Ebersberg, Germany) and 2 ng DNA template. Amplification conditions were as follows: an initial
203 denaturing phase at 94°C for 2 min, 35 cycles at 94°C for 20s, annealing temperature was 50°C
204 for each fragment for 20 s and extension was at 65°C for 30 s, with a final extension step at 65°C
205 for 5 min. PCR products were purified and sequenced directly with the BigDye technology
206 (Genewiz, Leipzig, Germany) using the forward PCR primers. The chromatograms showed no
207 ambiguity in sequences and all the detected double peaks were of high quality. Nevertheless, seven
208 PCR products were bi-directionally sequenced to test for uncertain nucleotide position associated
209 with double peaks in chromatograms, and 17 products (from populations AL56, BF05, GR11,
210 H05, NIT, PA and PL8 (S1 Table), were sequenced twice with the forward primer to confirm
211 double peaks.

212 Using Geneious 10.2.2 [65], raw sequences were checked for microsporidian RPB1 specificity via
213 BlastN search [62] against sequences available in GenBank. Each sequence was manually edited,
214 and double peaks were called following the International Union of Pure and Applied Chemistry
215 (IUPAC) degenerate nucleotide code. The RPB1 gene is known to be a nuclear single-copy gene
216 in *Vairimorpha necatrix*, a close relative of *Nosema* [63], thus excluding paralogy as an
217 explanation for the observed double peaks. Instead, they could result from double infections with

218 *Nosema* individuals harbouring different haplogroups or from single infections by heterozygous
219 individuals. The F2 and F4 sequences were trimmed to the final size ranges of 282 to 455 bp and
220 280 to 562 bp, respectively, based on the quality level of the sequences. The RPB1 sequences were
221 translated into amino acids to confirm the absence of stop codons (S1A Fig). Sequences were
222 aligned after concatenation using MAFFT7.388 software [66,67] with the E-IONS-I algorithm
223 using the legacy gap penalty option, incorporated in Geneious 10.2.2 [65]. To eliminate introns,
224 translated amino acid versions were also used as a backbone based on the reference the RPB1
225 sequence AF060234 from *Vairimorpha necatrix*.

226

227 **Haplotype definition and phylogeny reconstruction for microsporidians**

228 As SSU and RPB1 sequence length was heterogeneous among individuals, definition of
229 haplotypes *sensu stricto* was not possible. Following the approach described in [31], sequences of
230 each marker were assigned to haplogroups as follows: two sequences were clustered in one
231 haplogroup based on 100% pairwise nucleotide identity in their shared part, each haplogroup being
232 defined by diagnostic SNPs [31]. Only few sequences could not be assigned to haplogroups, due
233 to reduced sequence length and lack of diagnostic features (S2 Table). Some RPB1 haplogroups
234 showed three short deletions in the F4 fragment (S1B Fig). Finally, the F2 or F4 fragments were
235 missing for some individuals, because amplification failed, and were coded as missing data (“N”).
236 The longest sequences of each haplogroup, were used for Bayesian phylogeny reconstruction (S2
237 Table). Haplotype alignments used for building trees are provided in the Supplementary Data S1.
238 Compared to SSU, nucleotide variation for the RPB1 marker was high, although mostly
239 synonymous. Consequently, all codon positions were used for phylogenetic analyses.

240 For phylogenetic analyses, sequences of *Nosema* spp. infecting amphipods were complemented
241 by a set of 11 species of *Nosema/Vairimorpha* spp. infecting insects, according to the taxonomic
242 revision of [5], for which both SSU and RPB1 markers are available. We further included the two

243 following *Nosema* species (both infecting crayfish) in our analysis: *Nosema cheracis*, infecting the
244 Australian crayfish species *Cherax destructor* introduced in Europe and *Nosema austropotamobii*,
245 infecting *Austropotamobius pallipes*, a western European freshwater crayfish. *Ordospora*
246 *colligata* served as the outgroup [68]. All details are given in S2 Table.

247 Phylogenetic reconstructions were performed separately for SSU and RPB1 using Bayesian
248 inference implemented in MrBayes [69] integrated in Geneious 10.2.2. The best-fitting model of
249 nucleotide substitution was determined with JModelTest-2.1.10. [70]. For both SSU and RPB1 we
250 used the General Time Reversible (GTR) model with gamma-distributed rate heterogeneity (+G)
251 and a proportion of invariable sites (+I). For each marker, four heated chains, each 1,100,000
252 iterations long, sampled every 100 iterations, were run. Runs reached satisfactory effective
253 sampling sizes (ESS > 200). Fifty percent majority-rule consensus trees were constructed after
254 removal of 10% ‘burn-in’ trees. For the RPB1 phylogeny reconstruction, a maximum likelihood-
255 tree was also constructed in MEGA version 11 [71] using the GTR+G+I model and node support
256 was assessed with 1,000 bootstrap replicates.

257

258 **Molecular species delimitation**

259 To explore the number of molecular operational taxonomic units (MOTUs) that may represent
260 potential species within the *Nosema* clade, we applied two methods: Assemble Species by
261 Automatic Partitioning (ASAP) [72] and the Poisson tree processes (PTP) model [73]. ASAP was
262 conducted using the ASAP webserver (<https://bioinfo.mnhn.fr/abi/public/asap/> accessed on June
263 2, 2023) based on the distance matrix generated through IQ-TREE analysis [72]. ASAP divides
264 species partitions based on pairwise genetic distances, and that was why the dataset for this
265 analysis included only the sequences covering both fragments of RPB1 (F2 and F4). ASAP also
266 computes a probability of panmixia (p-val), a relative gap width metric (W), and ranks results by
267 the ASAP score: the lower the score, the better the partitioning [72].

268 PTP modelling was performed using the PTP web server (<https://species.h-its.org/>; accessed on
269 June 1, 2023) with the Bayesian implementation (bPTP), which adds Bayesian support (pp) values
270 for putative species to branches in the input tree. The PTP method infers speciation events based
271 on a shift in the number of substitutions between internal nodes [73]. Analysis was run with
272 500 000 iterations, the run was examined and showed convergence. The sites reported on Figs 1
273 and S2 were plotted on a map from Natural Earth resources in QGIS 3.32.0-Lima [74].

274

275 **Testing sex-biased infection pattern**

276 In *G. balcanicus*, 334 males and 310 females from 16 populations were tested for estimating the
277 prevalence of *Nosema* (after removing the two populations in which no females were tested, S1
278 Table). A General Linearized Model (binomial distribution using a Logit transition function) was
279 executed, analyzing the effect of sex and population as factors, and their interactions, on the
280 infection rate by *Nosema*. A bias of infection towards females should be associated with sex ratio
281 distortion [20,23].

282

283 **Results**

284 Based on SSU sequences, 316 individuals from nine amphipod species were found to be infected
285 by *Nosema* spp. (S1 and S2 Table). Our new census yielded 181 new *Nosema* sequences: 89 from
286 *G. balcanicus*, 39 from *G. duebeni*, 47 from *G. fossarum*, five from *G. pulex* (S1 Table). They
287 extend a set of 136 sequences previously determined as *Nosema* (99 from *G. roeselii*, 18 from *G.*
288 *pulex*, 7 from *G. duebeni*, 6 from *G. fossarum*, two from *D. villosus*, two from *Eulimnogammarus*
289 *verrucosus*, one from *N. arndti* and one from *N. schellenbergi*) (S1 and S2 Tables).

290 The phylogenetic reconstruction inferred from the SSU marker was to a large extent in line with
291 previously published phylogenetic reconstructions (e.g. [31]), except that the clade containing the

292 *Nosema* spp. found in amphipods also included a crayfish-infecting species (Fig 2). Most
293 haplogroups (18/24) were found specifically infecting a single host species, while six were found
294 in two to four host species.

295 Amplification success of the F2 and F4 fragments of RPB1 gene was variable, including no success
296 (113 ind., 41%), single fragment amplified (57 ind., 21%) or both fragments amplified (105 ind.,
297 38%). Therefore, we newly obtained RPB1 sequence information for 163 individuals (depending
298 on DNA availability and sequencing success), including 60 from *G. roeselii*, 45 from *G.*
299 *balcanicus*, 38 from *G. fossarum*, 15 from *G. duebeni* and 4 from *G. pulex*. To this set, two RPB1
300 sequences of VT, feminizing, *N. granulosis* infecting *G. duebeni* from Scotland, Wales and
301 Sweden [48,53] were added which matched the F2 and F4 regions of RPB1 (GenBank accession
302 numbers, DQ996233 and JX213747). The geographic distribution of the parasites for which the
303 RPB1 sequences were obtained is shown in Fig 1.

304 Alignment of RPB1 sequences from *Nosema* infecting amphipods revealed 39 haplogroups (Fig
305 3) showing a higher variability compared to the phylogenetic relationships among haplogroups
306 based on SSU sequences (Fig 3). The amphipod-infecting *Nosema* spp. were all within a well-
307 defined and supported clade, which was the sister to a clade of insect-infecting *Nosema* spp. (*sensu*
308 [5]). Based on the available sequences, the amphipod-*Nosema* clade also contained three
309 sequences from non-amphipod hosts (Fig 3). All but one sequence of amphipod-infecting *Nosema*
310 spp. could be assigned to five well-supported clades (named A to E, Fig 3). The single remaining
311 sequence is associated with a branch (termed F) of uncertain phylogenetic position (highlighted in
312 grey in Fig 3).

313 Parasites from clade A were found only in *G. balcanicus* (Fig 3), despite extensive sampling. These
314 *Nosema* strains, particularly F2A2-3F4A2-3 and F2A2F4A2-3, were found in numerous
315 populations, exhibiting high prevalence in some of the populations (see S1 Table), and their
316 geographic distribution covered the entire geographic range of their host (Fig 1). However, they

were not found in other *Gammarus* species from the close area, and were particularly absent in *G. roeselii*, the other abundant host species overlapping *G. balcanicus* distribution (Fig 1). We found no clear pattern for co-diversification between *G. balcanicus* and these *Nosema* parasites. We were not able to run a formal co-diversification analysis, because the asymmetry of amplification of F2 and F4 fragments among some hosts (S2 Fig) prevented the construction of a complete matrix of genetic distance among parasite haplogroups of this relatively small clade. We nevertheless observed only little congruence of phylogenies between hosts and parasites (S2 Fig). We tested whether, with our dataset, we could provide clues suggesting the presence of VT/sex ratio distortion in *Nosema* clade A infecting *G. balcanicus*. A General Linearized Model analysis showed that the interaction sex*population was non-significant and the corrected Akaike Information Criterion (AICc) of the whole model was quite high ($\text{LR } \chi^2 = 18.03$, 15 df., $P = 0.26$, $\text{AICc} = 553.19$), so the interaction was removed from the model. The non-significance of this interaction means that globally there was no difference in the infection rate between sexes among the different populations. The model including sex and population was globally significant ($\text{LR } \chi^2 = 124.59$, 16 df., $P < 0.0001$, $\text{AICc} = 538.60$). The infection rate significantly differed among populations, ranging from 4.2% (in populations AL57 and AL69) to 64.6% (in population UA03) (S1 Table). In total, males were more infected than females (26.9% vs. 14.8%, respectively, $\text{LR } \chi^2 = 17.67$, 1 df., $P < 0.0001$). In most populations, there was no significant difference between sexes (12 populations), but in four populations, males were significantly more infected than females (populations AL56, H07, H09, H11).

Parasites from clade B were found in *G. pulex* and *G. roeselii* hosts. *Gammarus roeselii* parasites were restricted to south-eastern Europe (Greece and Albania), while the single haplogroup from *G. pulex* was recorded in France (Fig 1). Clades A and B were more distantly related to clades C, D and E.

341 Clade C included the parasites infecting *G. duebeni*, i.e. the host in which *Nosema granulosis* was
342 first described as a vertically-transmitted, feminizing sex ratio distorter [10]. Interestingly, clade
343 C also included *Nosema* infecting *G. roeselii*, in which vertical transmission and feminization has
344 also been demonstrated [23,24]. Overall, clade C haplogroups were widespread all over Europe,
345 and it must be noticed that a single haplogroup (F2C3F4C3) was frequent (52 occurrence) and
346 detected in various populations of *G. roeselii* from six countries and in one French population of
347 *G. fossarum* (Fig 2,3, S2 Table). Clade D, which appears to be closely related to clade C, consisted
348 of highly similar haplogroups of *Nosema* that were solely found in *G. fossarum* (Fig 3, S3 Table).
349 Clade D was restricted to France and Austria, and these parasites infected nine individuals from
350 four populations. All haplogroups from clades C and D shared two short deletions in the F4
351 fragment (deletions of 27 and 15 bp) (S1 Fig) and they were not distinguishable using the SSU
352 marker (Fig 2). Haplogroups of clade C included a supplementary 15 bp-long deletion.

353 Finally, clade E consisted of parasites infecting three host species (*G. fossarum*, *G. pulex* and *G.*
354 *duebeni*) sampled at French and Swiss sites (Fig 1).

355 In summary, our sequences grouped within clades A, B, C, D, E, with C and D being sister groups,
356 and a single sequence identified as lineage F. The ASAP molecular delimitation analysis revealed
357 four putative species within *Nosema* infecting amphipod crustaceans (excluding lineage F), mostly
358 overlapping with the aforementioned clades, but C and D grouped as one species, here interpreted
359 as *Nosema granulosis sensu stricto* (Fig 3). On the other hand, bPTP overall suggested from 19 to
360 29 putative species, with partitioning to 25 species with the highest support (lowest posterior
361 probability 0.50) (S2 Appendix), and 13 species within *Nosema* found in amphipods (Fig 3).

362
363 **Discussion**

364 Our results indicate that various microsporidian lineages of the genus *Nosema*, not only *N.*
365 *granulosis*, are abundant, widespread and diverse in European gammarid amphipods. Thus, we

366 deepen our knowledge of host range for this parasitic genus beyond the already well-known insects
367 and terrestrial hosts (e.g. [75,76,77]). Indeed, our phylogenetic reconstructions unambiguously
368 grouped freshwater amphipod parasites as a sister group to Lepidoptera and Hymenoptera-
369 infecting *Nosema* (*sensu* [5]). However, we cannot formally conclude that amphipod *Nosema* are
370 monophyletic. The phylogenetic tree reconstruction based on the RPB1 marker suggests that
371 *Nosema* spp. found in freshwater crustaceans are not limited to amphipod hosts and include one
372 terrestrial species, *Nosema empoascae*. Furthermore, *Nosema* isolates infecting crayfish are nested
373 within those infecting amphipods. This could suggest either that there has been an ancient *Nosema*
374 infection in Malacostraca (the crustacean group to which amphipods and decapods belong), or a
375 freshwater origin of this *Nosema* clade, with horizontal transfers between host species. The
376 divergence among crustacean *Nosema* strains reported here could appear low compared to host
377 divergence (Malacostraca diversified around 300 MYA [78]). Crustaceans colonized freshwater
378 at diverse times independently [79]. If so, the most likely explanation would be horizontal transfer
379 of parasites. However, the molecular phylogenetic reconstructions of the hosts and the parasites
380 could not be compared directly since different genetic markers were used. For example, the New-
381 Zealand amphipod hosts and their microsporidian parasites (*Dictyocoela*) seemed to have initiated
382 their diversification simultaneously several MYA, but their genetic divergence appears to have
383 reached different levels [35]. The presence of the insect-infecting *N. empoascae* within the *Nosema*
384 lineage infecting crustaceans is more puzzling and may reflect horizontal transfer between
385 crustaceans and insects. Consistently, horizontal transfer of *Wolbachia* intracellular
386 microorganisms between insects and crustaceans has previously been suggested [80]. However,
387 owing to the strict terrestrial life cycle of the insect host of *N. empoascae* (*Empoasca fabae*, a
388 small leafhopper of the Cicadellidae family [81]) a recent host shift is ecologically difficult to
389 conceive in the present state of knowledge. In addition, this parasite seems to be vertically
390 transmitted in its host [82], which may further reduce the likelihood of horizontal transfer between
391 hosts. However, the existence of additional vector/intermediate hosts such as water insects or

392 terrestrial insects drowning in water cannot be excluded, as suggested for *Nosema cheracis* [11],
393 even if no data is available up to now. Besides, microsporidian samples presently available for
394 insect hosts are far from representative of the global diversity of *Nosema* infecting these hosts.
395 Thus, future studies are necessary to address the problem of the potential transfer of *Nosema*
396 between aquatic and terrestrial ecosystems.

397 The improved phylogenetic resolution of the RPB1 marker compared to SSU allowed us to
398 distinguish five *Nosema* clades infecting amphipods [31,51]. Clade A was found only associated
399 with *G. balcanicus*, whose biogeographical history is well documented for both host and other
400 microsporidian parasites [36,39,40]. In this case, host specificity may be proposed. Indeed, clade
401 A parasites infected individuals in several locations throughout the entire host range. In addition,
402 they colonized diverse host cryptic lineages (S2 Fig.) but they were not found in other *Gammarus*
403 spp., conversely to most other *Nosema* parasites revealed in this study. An infection by *Nosema*
404 clade A therefore possibly occurred anciently in *G. balcanicus* and subsequently spread further
405 during host radiation. However, unlike other microsporidian parasites [40], no clear co-
406 diversification pattern was found between *Nosema* clade A and *G. balcanicus* (S2 Fig). Therefore,
407 ancient infection followed by several horizontal transfers may explain the present distribution of
408 *Nosema* in *G. balcanicus*. Parasites belonging to clade D were restricted to a few lineages of the
409 *G. fossarum* species complex [44]. However, the range of the host *G. fossarum* is pan-European,
410 and since we did not have access to the whole geographic range for our survey, we cannot firmly
411 conclude that the parasites of clade D are specific to this host. Because of the low diversity within
412 this clade, it is likely that these infections were recently acquired by the host species.

413 Prior to this study, microsporidians from gammarids showing high score values by BlastNN with
414 *Nosema granulosis* isolated from *G. duebeni* based on SSU sequences were generally assigned
415 either to *N. granulosis* [31,34], to *Nosema* sp. or to *Vairimorpha* sp. [83]. Here we found that the
416 vertically-transmitted (VT) and feminizing *N. granulosis* described from *G. duebeni* [10,19–21]
417 correspond to clade C, also includes the closely related *Nosema* from *G. roeselii*, which likely is a

418 VT sex ratio distorting parasite [23,24]. These infections are characterized by a high number of
419 infected individuals in each host species, numerous infected populations, and few haplogroups in
420 each species (e.g., in *G. roeselii*, 77 individuals from 12 populations share the same RPB1 variant).
421 As noted in [31], all these traits are compatible with the dynamics of VT-feminizing
422 microsporidians. Their spread in host populations is enhanced by parasite-induced female-biased
423 sex ratios of host progenies, which provides a selective advantage for infected vs. uninfected
424 females [30]. Theoretical models suggest that female-biased sex ratios result in populations with
425 high numbers of individuals and high demographic dynamics that may outcompete non-infected
426 populations [30]. Thus, the presence of this VT *N. granulosis* infection might have facilitated the
427 recent spread of the host species, *G. roeselii*, in western Europe [32,37], by directly enhancing
428 host invasion success through increased rates of population growth, as suggested for another
429 amphipod *Crangonyx pseudogracilis* and its VT-parasite, *Fibrillanosema crangonycis* [84,85].
430 Because all *Nosema* belonging to clade C are genetically very similar to the originally described
431 *N. granulosis* (0.02 ± 0.003 average genetic divergence over all RPB1 sequence pairs), we propose
432 that all parasites clustering into clade C should be referred to as *N. granulosis*. Furthermore,
433 because i) clades C and D are in a close sister group relationship, ii) clade C contains sequences
434 linked to type material used for *N. granulosis* description [10], iii) the monophyly of clades C +D
435 is statistically supported, and iv) clade C + D is also supported by the ASAP analysis, we propose
436 that clades C and D should be seen as *Nosema granulosis sensu stricto*. By contrast, we suggest
437 that parasites grouped into clades A, B and E and lineage F may be candidates to the status of new
438 *Nosema* species, based on their genetic divergence supported by the species delimitation analysis.
439 Remarkably, this divergence is larger than the range of divergence observed for *Nosema* taxa from
440 insects. It may be explained by the differences in mutation rate and evolutionary dynamics
441 between *Nosema* spp. infecting gammarids and insects. In our interpretation of the number of
442 putative *Nosema* species infecting gammarids, we followed a more conservative approach: we
443 based our outcomes on the ASAP results assuming fewer putative species than the bPTP analysis.

444 There are many studies demonstrating that ASAP is often in congruence with
445 morphological/biological species delimitation while bPTP method tends to overestimate the
446 species number [e.g. 47,86,87]. However, more studies including ultrastructural analysis are
447 needed to formally describe those clades as putative species. We also cannot exclude that our new
448 lineages can be *Nosema* spp. already described from different amphipods, including *G. pulex*,
449 based solely on morphology (light microscopy for older observations) [13–17,88]. However,
450 morphological descriptions of *Nosema* can be misleading [5], and using an integrative approach is
451 advisable and ultimately could lead to taxonomic revisions [89].

452 Interestingly, most haplogroups involving *Nosema* from clades B, D and E are present in a single
453 or few individuals within the same population. Because of the sharp contrast of this infection
454 pattern compared to clade C, it does not seem reasonable to us to propose that parasites of clades
455 B, D, and E are feminizing and VT microsporidia. Contrastingly, infections in *G. balcanicus* hosts
456 belonging to clade A show an infection pattern similar to those of clade C. For example, sequences
457 in populations from Slovakia, Hungary and Romania show closely-related or similar RPB1
458 haplogroups infecting numerous individuals (> 70) in a dozen of populations all over the host
459 geographic range. This pattern therefore resembles the VT-feminizing *N. granulosis* infection
460 patterns in *G. roeselii* (Fig 2, 3). However, the analysis of infection patterns relative to sexes
461 showed that there were no significant differences in prevalence between sexes in most populations.
462 Yet, parasites that have been shown to be sex ratio distorters - such as *N. granulosis* in *G. duebeni*
463 and *G. roeselii* or *Wolbachia pipiensis* in the isopod *Armadillidium vulgare* - are always more
464 frequent in females than in males (which makes sense given that the parasites convert infected
465 males into females) [20,23,90]. The high prevalence and above all the homogeneity of *Nosema*
466 haplogroups across the geographic range of *G. balcanicus* is therefore puzzling. Based on this
467 survey and previous evidence, VT and feminization in *Nosema* infecting amphipods therefore
468 currently appear to be limited to *N. granulosis* belonging to clade C. It is noteworthy that clade C

469 also contains parasites infecting *G. fossarum* individuals, which opens the possibility that VT-
470 feminization might be found in a larger spectrum of amphipod species than previously thought.

471 In conclusion, our study illustrates the interest of using the RPB1 marker for the study of *Nosema*
472 parasites, allowing elucidating the parasitic richness in their gammarid hosts. We found that
473 *Nosema* diversity is much higher in amphipods than previously thought, and that the association
474 appears to be ancient in this host group. Furthermore, the new host species found to be infected by
475 *N. granulosis sensu stricto* opens the possibility that VT-feminization may be present in a larger
476 spectrum of amphipod species. Finally, given that gammarids are keystone species in the
477 functioning of freshwater environments, with their functions being affected by microsporidian
478 infections [91-94–], it is of crucial importance to correctly identify host-parasite relationships by
479 means of reliable markers.

480

481 **Acknowledgments**

482 We acknowledge the French National Research Agency (ANR) (Grant # ANR-15-CE32-0006) for
483 paying AQ salary, for contribution in designing the study, molecular analyses, statistical analyses,
484 writing the manuscript; as well as the ‘Polonium’ exchange program (PPN/BIL/2018/1/00138),
485 for funding travel between France and Poland in terms of analysing the results and writing the
486 manuscript by the authors. The sampling was performed during a series of scientific expeditions
487 in the years 2004–2021 supported by internal funds of the University of Lodz and partially by the
488 Polish Ministry of Science and Higher Education, grant number N N303 579439, as well as the

782

783

784 **Figure captions:**

785 **Figure 1.** Geographic distribution of *Nosema* spp. infecting a range of amphipod hosts based on
786 data listed in S1 and S2 Table. Assignment to clades or lineages is based on RPB1 (see Fig 3). The
787 infection of *Nosema* sp. in *Eulimnogammarus verrucosus* from the Lake Baikal, Russia is not
788 shown. The sites were plotted on a map from Natural Earth resources in QGIS 3.32.0-Lima [74].
789

790 **Figure 2.** Bayesian phylogenetic reconstruction of *Nosema* spp. based on small ribosomal subunit
791 (SSU) rDNA, and their association to different host species. *Ordospora colligata* (AF394529) was
792 used as an outgroup (not shown). Labels include: Genbank accession number (for previously
793 published sequences), microsporidian species name as given in [5] and for the newly produced
794 sequences the haplogroup name is given as in S1 and S2 Table. An X denotes an association and
795 a figure denotes the number of individuals infected, each amphipod species being represented by
796 a given geometric symbol (see also Fig 1). Colour code refers to lineages identified by the RPB1
797 marker (see Fig 3). PP: Bayesian Posterior Probability.
798

799 **Figure 3.** Bayesian phylogenetic reconstruction of *Nosema* spp. based on fragments F2 and F4 of
800 the RPB1 gene. For parasite sequences found in amphipods labels include: the GenBank accession
801 number in case of published sequences, the host species name (abbreviated for gammarids, see
802 below), the abbreviated SSU haplogroup name (as in S2 Table and Fig2), the RPB1 haplogroup
803 name, population name and the number of host individuals infected. Other sequences from
804 Genbank are representatives of further *Nosema* and *Vairimorpha* species (see S2 Table). PP =
805 Bayesian Posterior Probability, nodes supported by the Maximum Likelihood tree by bootstrap
806 values higher than 0.7 are indicated by red dots. Bars annotated on the right represent results of
807 the molecular species delimitation ASAP and bPTP methods. * – ASAP analysis was performed
808 using only the sequences covering both F2 and F4 RPB1 fragments; ? – haplogroup excluded from
809 the ASAP analysis because of lack of F2 or F4 fragment. Abbreviations for gammarid species
810 names: Gbal – *Gammarus balcanicus*, Gdue – *Gammarus duebeni*, Gfos – *Gammarus fossarum*,
811 Gpul – *Gammarus pulex*, Groe – *Gammarus roeselii*.

812 **Supporting information captions:**

813 **S1 Figure.** A. Overview of the amino-acid alignment for the RNA polymerase II largest subunit
814 (RPB1) gene haplogroups identified in amphipods. Grey colour stands for absence of amino acids.
815 B. Overview of the nucleotide alignment for the RPB1 gene haplogroups, for two fragments (F2
816 and F4). Grey colour stands for either absence of PCR product or shorter sequences for a given
817 fragment.

818

819 **S2 Figure. A.** Details of Clade A of *Nosema* phylogenetic reconstruction. Names in black are
820 *Nosema* haplogroups, names in red or blue are names of host clades to which they are associated.
821 Legends are similar to Fig 3 in the paper. Host clade names are given from the *Gammarus*
822 *balcanicus* phylogenetic tree simplified from [36] presented in **(B)**. N and S represent the two
823 major *G. balcanicus* groups that differentiated around 18 MYA. **C.** Map showing sites where host
824 and parasites are coming from, where the limit between N and S host groups were redrawn after
825 [1]. Lines between A and B trees indicates the position of host individuals infected by *Nosema*
826 haplogroups on host phylogenetic tree. The sites were plotted on a map from Natural Earth
827 resources in QGIS 3.32.0-Lima [2].

828

829 **S1 Table.** A list of 85 sites where *Nosema* spp. were recorded in amphipod crustaceans. The names
830 of the SSU haplogroups are as in Fig 2 and for RPB1 clades/lineages as in Fig 1 and 3.

831

832 **S2 Table.** A list of samples used in the study, with host, site and country name, as well as GenBank
833 Accession numbers given. Sequences in blue are samples of *Nosema* infections outside the
834 amphipod hosts, used for the phylogenetic reconstructions. **sequences too short to be deposited
835 in GenBank (see S2 Appendix). References: Refence list is provided in the spread-sheet
836 REFERENCES. DS : Direct submission to Genbank, no published article associated.

837

838 **S3 Table.** Estimates of Average Evolutionary Divergence over Sequence Pairs within Groups. The
839 number of base substitutions per site from averaging over all sequence pairs within each group are
840 shown. Analyses were conducted using the Kimura 2-parameter model [1]. This analysis involved
841 36 nucleotide sequences. Codon positions included were 1st+2nd+3rd+noncoding. All ambiguous
842 positions were removed for each sequence pair (pairwise deletion option). There were 1025
843 positions in the final dataset. Evolutionary analyses were conducted in MEGA11 [2] The presence

844 of n/c in the results denotes cases in which it was not possible to estimate evolutionary distances.

845 SE - standard error.

846

847 **S1 Appendix:** Alignment of F2 and F4 RPB1 fragments of *Nosema* spp., *Vairimorpha* spp. and

848 outgroup used for the Bayesian and Maximum Likelihood phylogeny reconstructions.

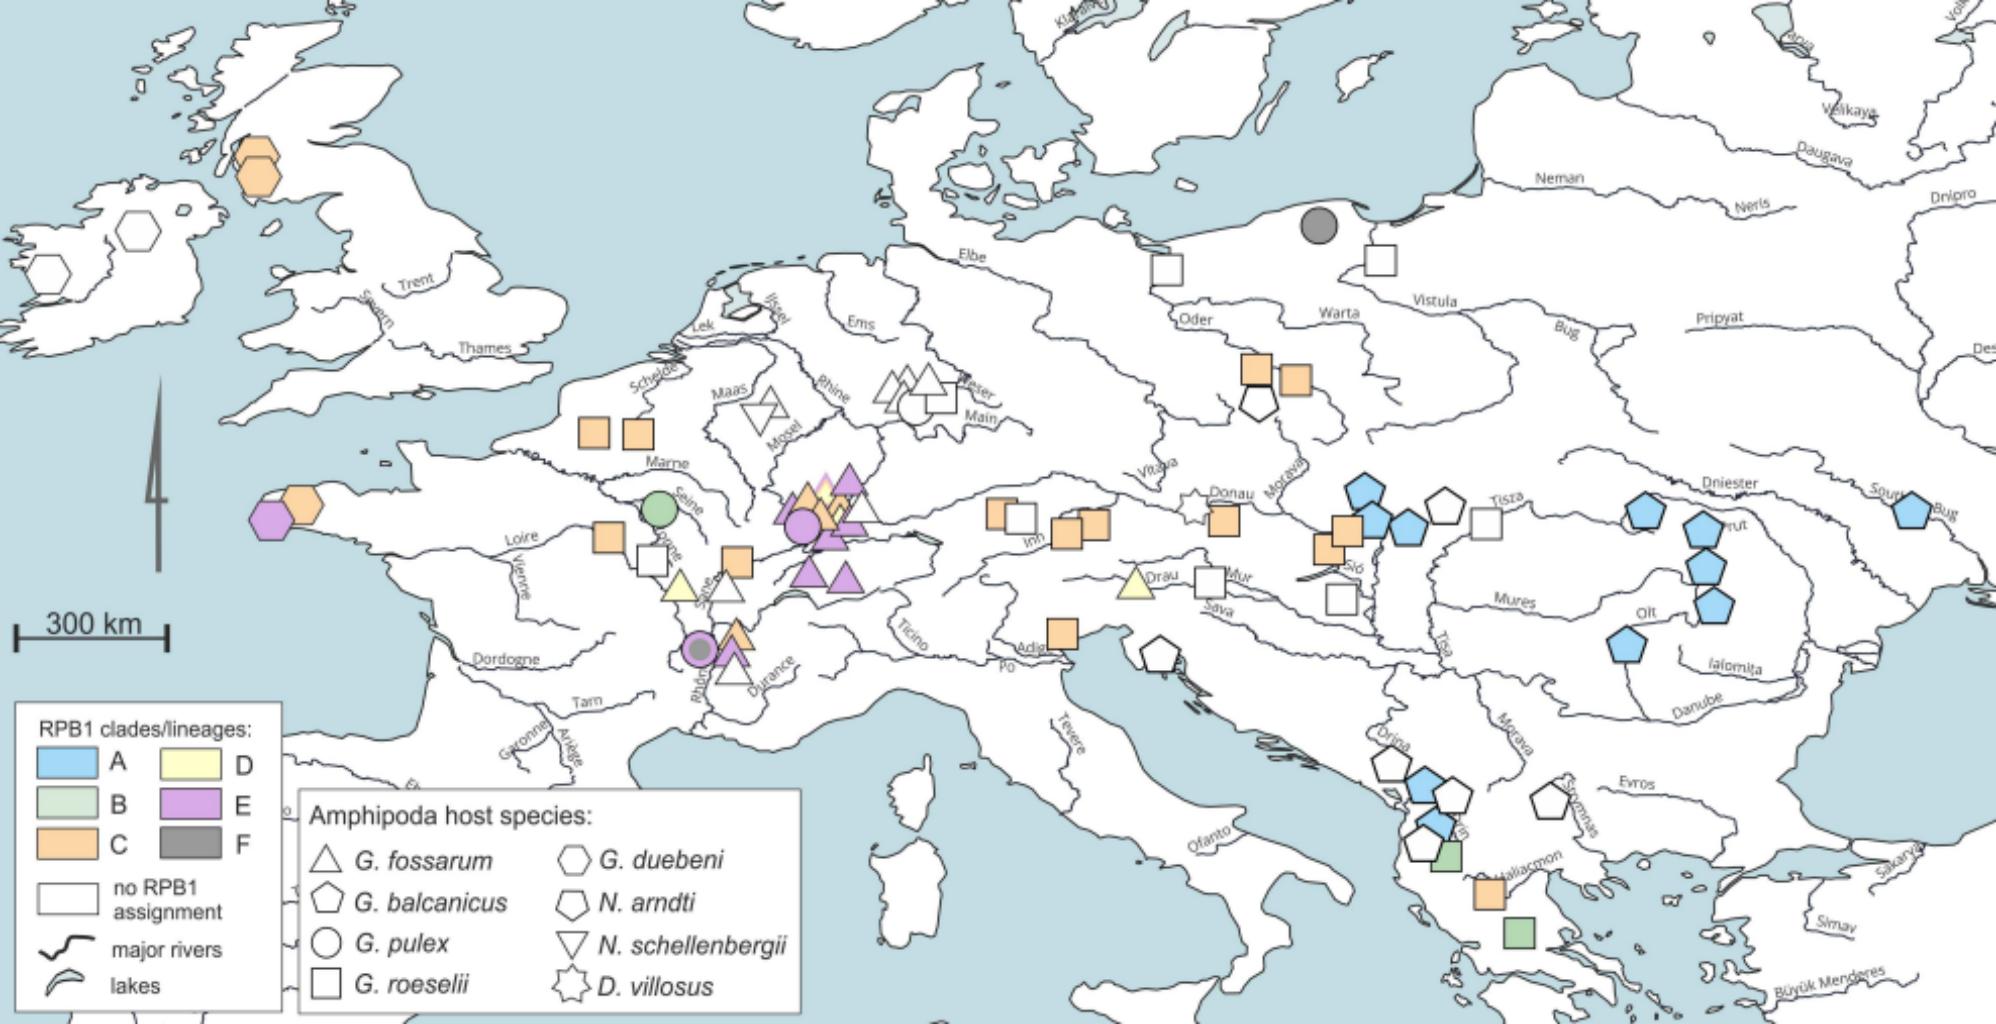

849

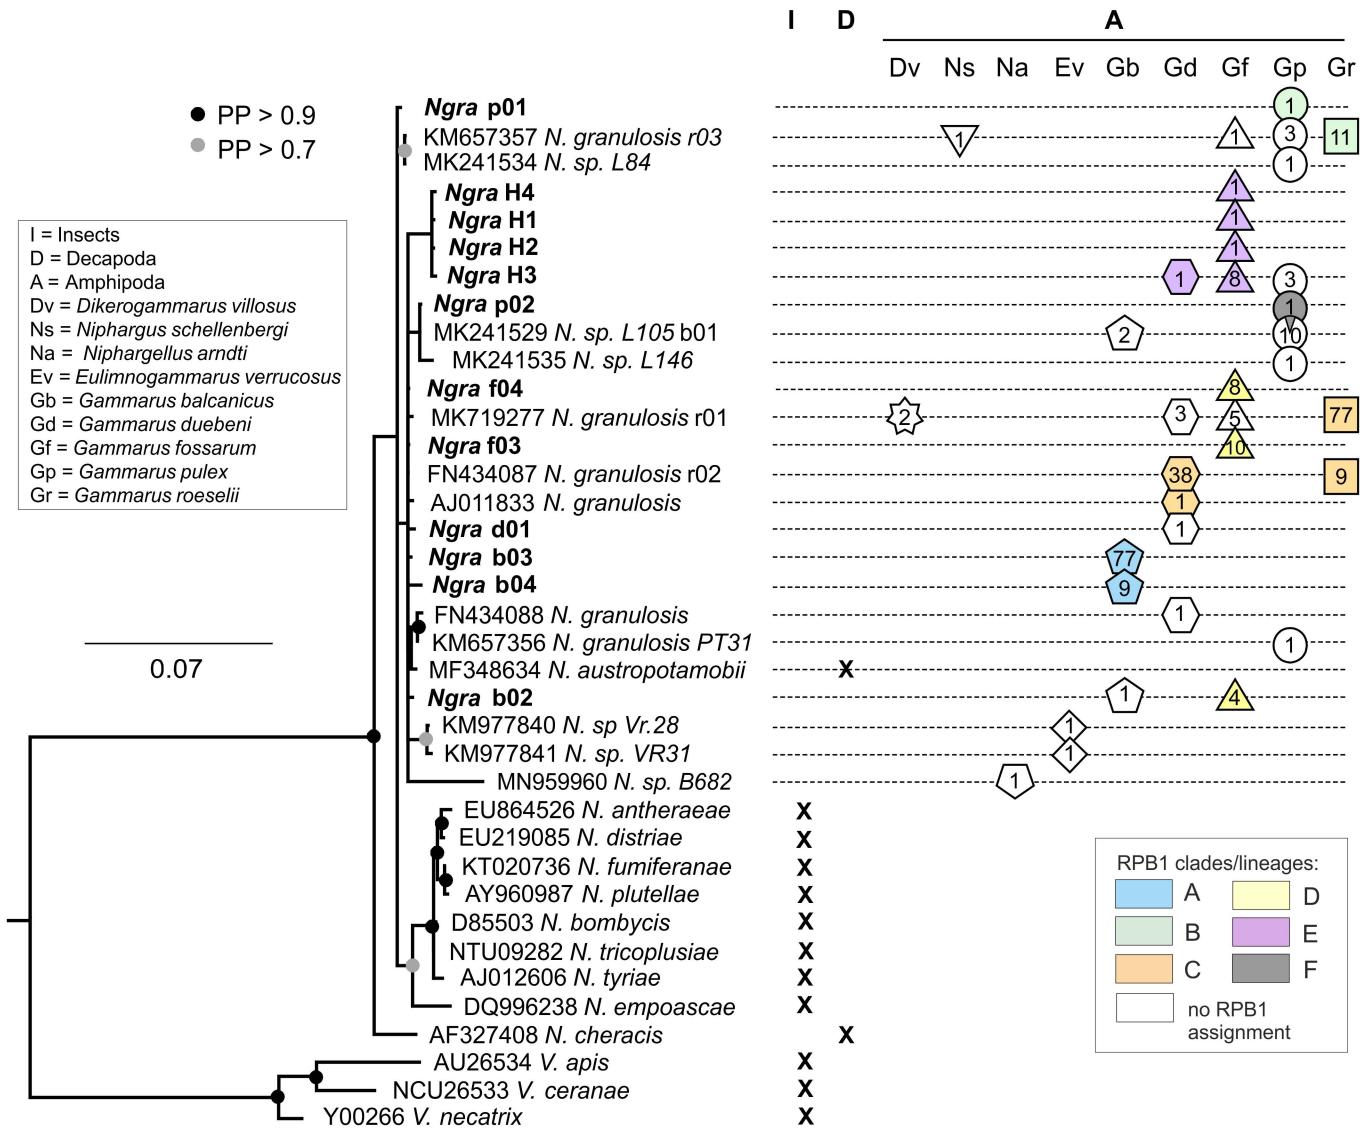

850 **S2 Appendix:** Small ribosomal subunit (SSU) rDNA sequences too short (<200bp) to be

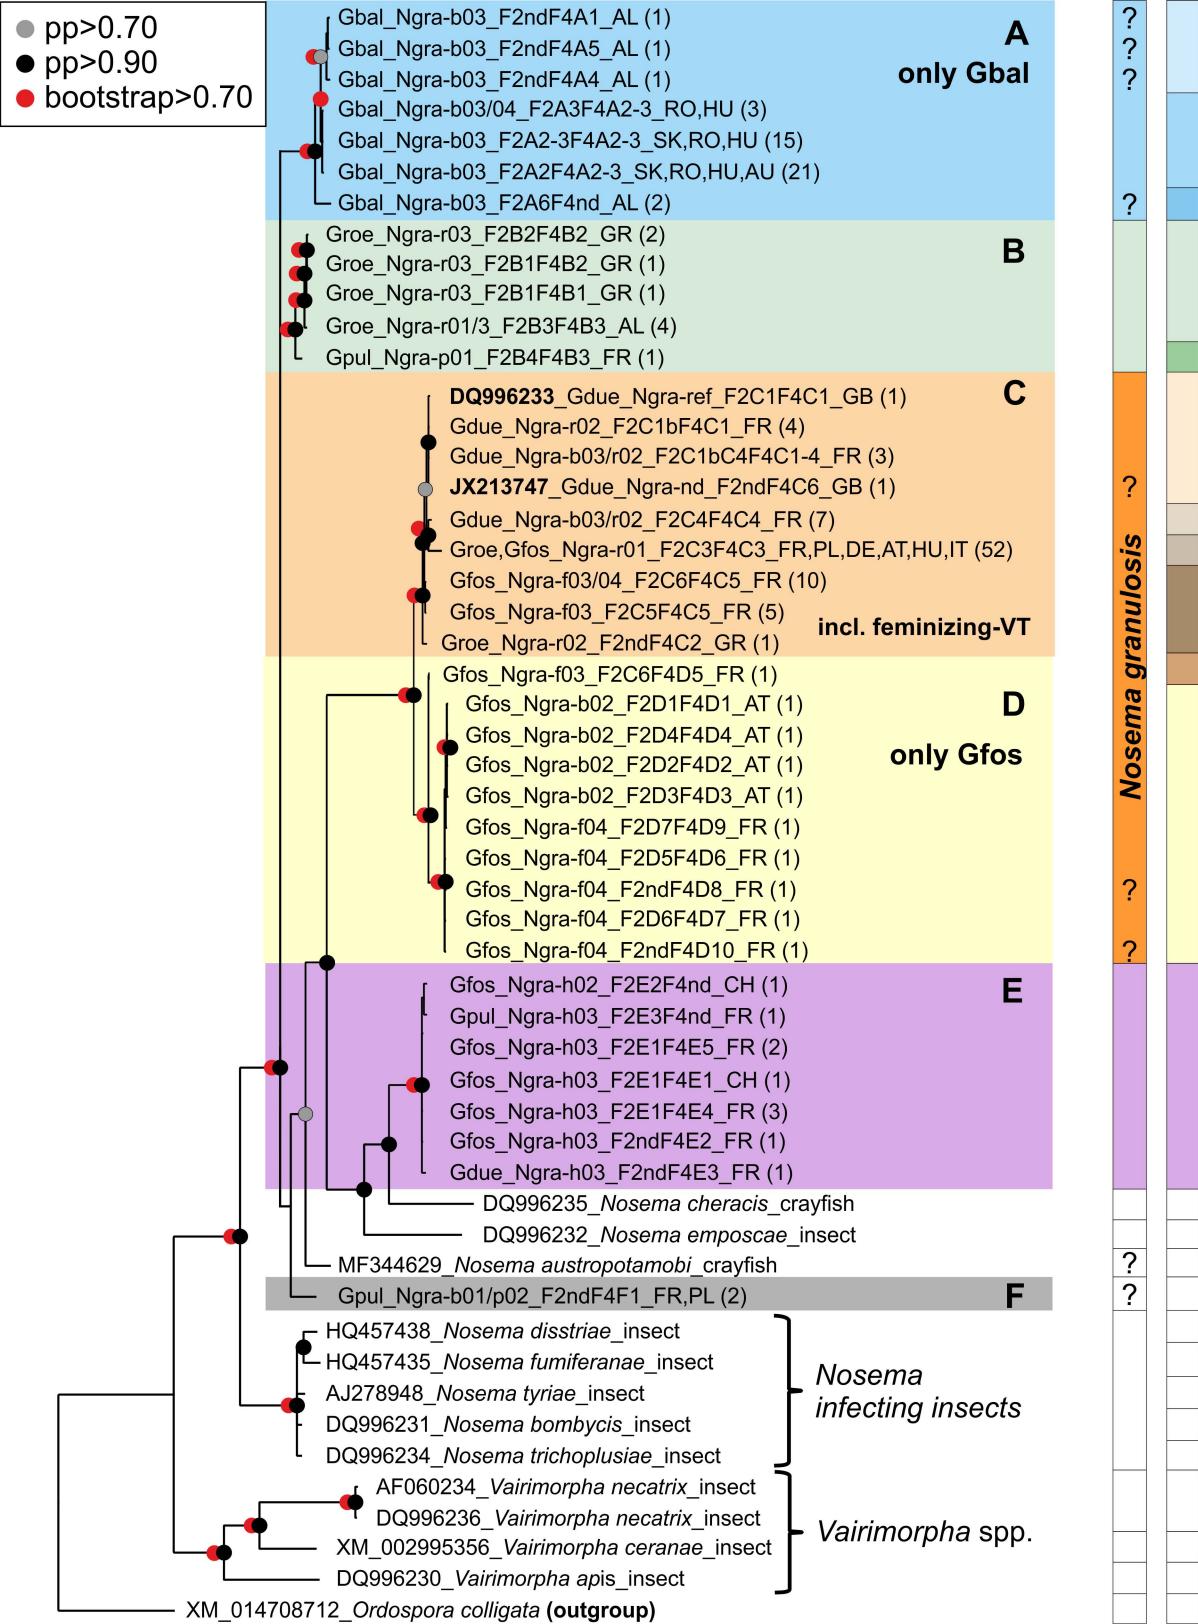

851 deposited in GenBank.

852

853 **S3 Appendix:** Results of the ASAP and bPTP species delimitations.

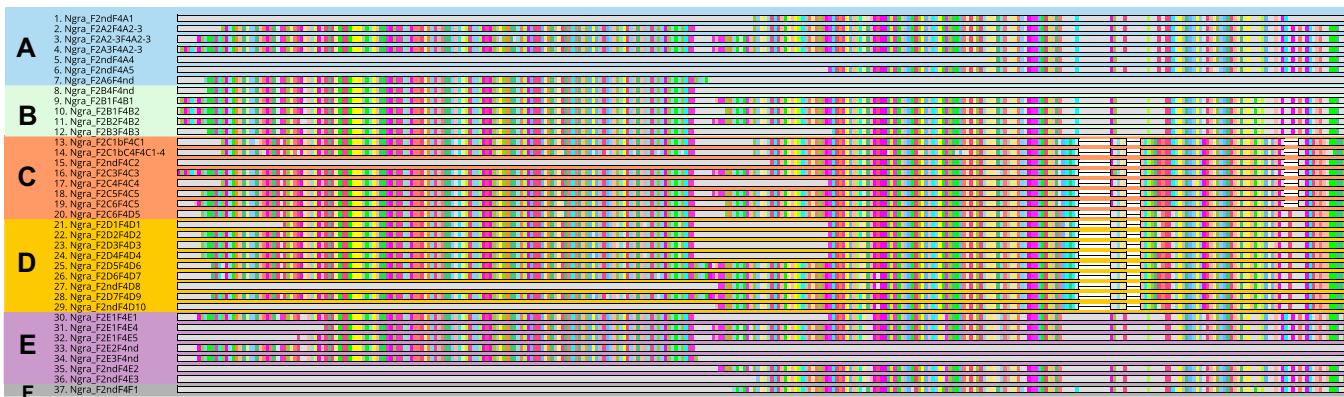

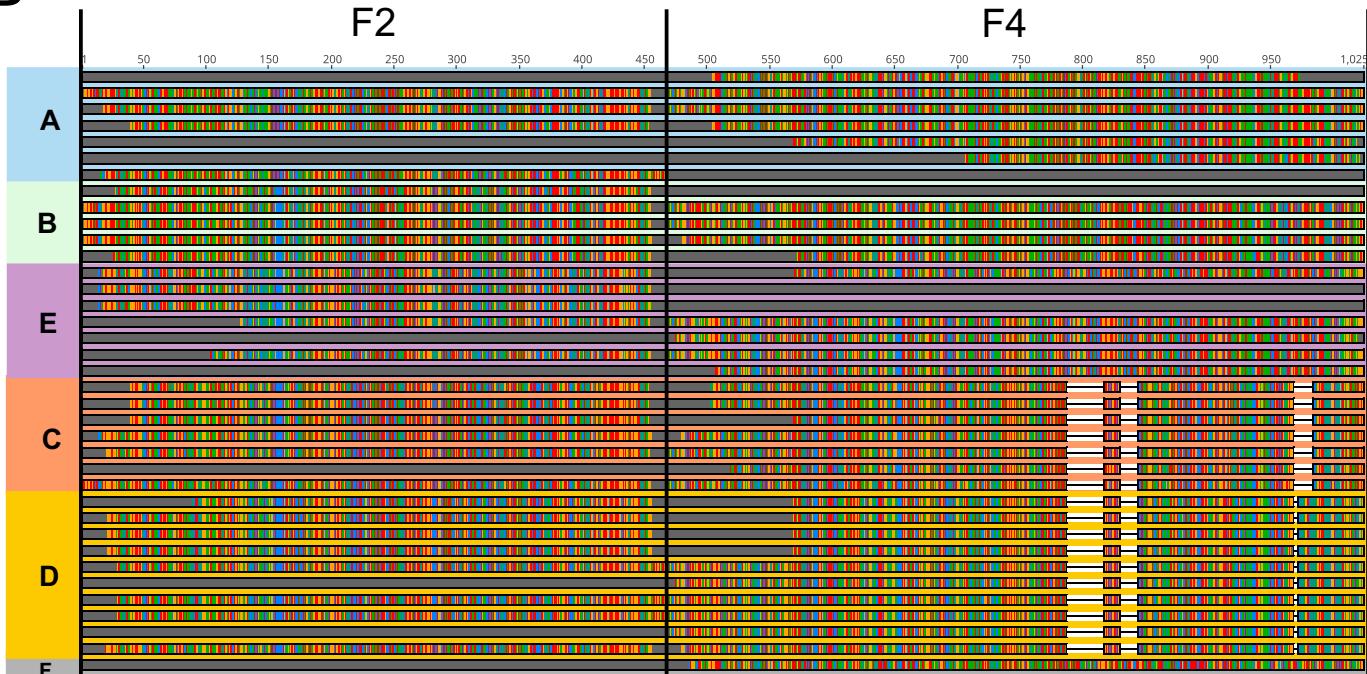

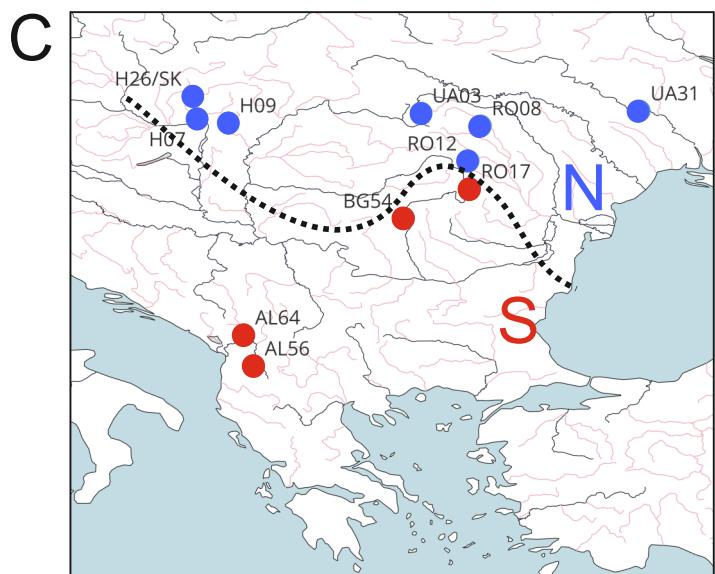

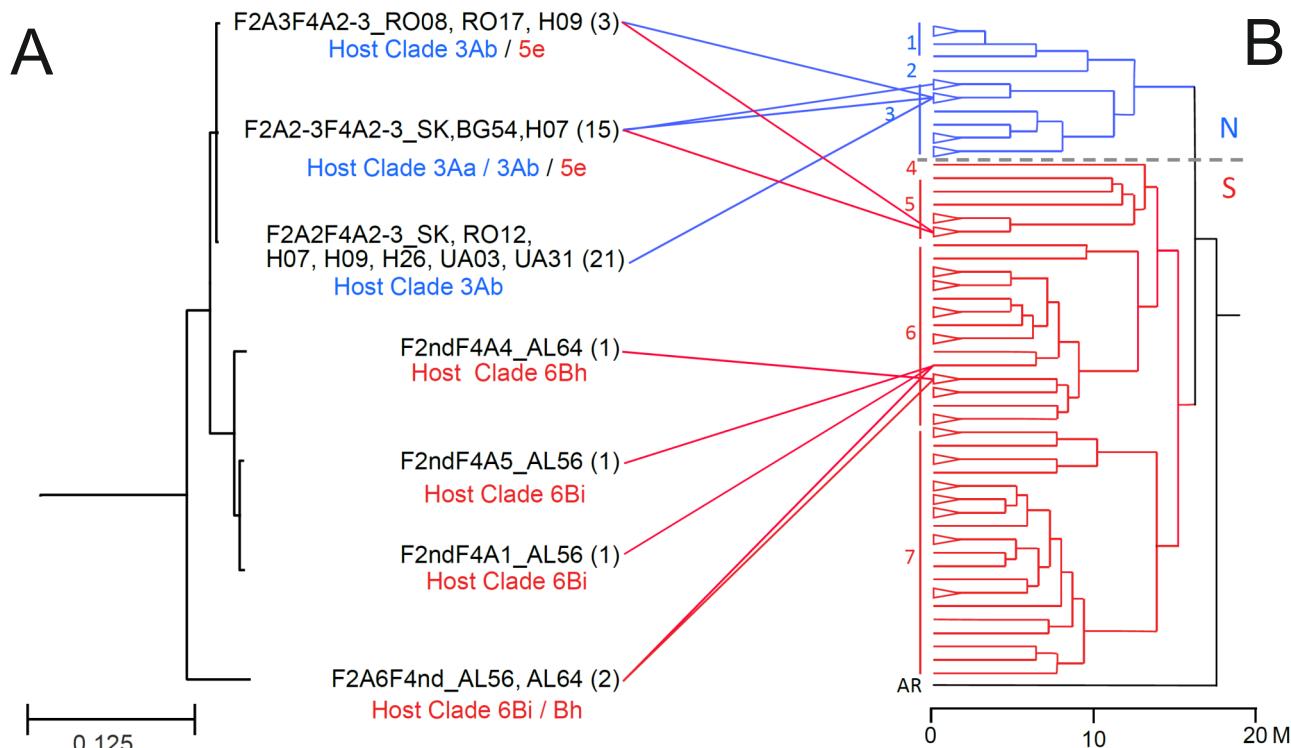

A**B**

Figure S1.

A. Overview of the amino-acid alignment for the RNA polymerase II largest subunit (RPB1) gene haplogroups identified in amphipods. Grey color stands for absence of amino acids.

B. Overview of the nucleotide alignment for the RPB1 gene haplogroups, for two fragments (F2 and F4). Grey color stands for either absence of PCR product or shorter sequences for a given fragment.

S2 Figure. A. Details of Clade A of *Nosema* phylogenetic reconstruction. Names in black are *Nosema* haplogroups, names in red or blue are names of host clades to which they are associated. Legends are similar to Fig 3 in the paper. Host clade names are given from the *Gammarus balcanicus* phylogenetic tree simplified from [1] presented in (B). N and S represent the two major *G. balcanicus* groups that differentiated around 18 MYA. **C.** Map showing sites where host and parasites are coming from, where the limit between N and S host groups were redrawn after [1]. Lines between A and B trees indicates the position of host individuals infected by *Nosema* haplogroups on host phylogenetic tree. The sites were plotted on a map from Natural Earth resources in QGIS 3.32.0-Lima [2].

Table S3. Estimates of Average Evolutionary Divergence over Sequence Pairs within Groups

The number of base substitutions per site from averaging over all sequence pairs within each group are shown.

Analyses were conducted using the Kimura 2-parameter model [1]. This analysis involved 36 nucleotide sequences.

Codon positions included were 1st+2nd+3rd+Noncoding. All ambiguous positions were removed for each sequence pair (pairwise deletion option).

There were a total of 1025 positions in the final dataset.

Evolutionary analyses were conducted in MEGA11 [2] The presence of n/c in the results denotes cases in which it was not possible to estimate evolutionary distances.
