Abstract – This paper presents a numerical study of thermoacoustic heat pumping along a stack of solid plates placed inside a compact cavity submitted to an oscillating flow. Velocity and pressure fields are controlled by two acoustic sources: a main "pressure" source monitoring the fluid compression and expansion phases, and a secondary "velocity" source generating the oscillating fluid motion. Numerical simulations are performed with an "in-house" code solving Navier–Stokes equations under a Low Mach number approximation in a two-dimensional geometry. In the linear regime, thermoacoustic heat pumping is correctly described with this model for different sets of parameters such as thermo-physical properties of the stack plates, amplitude of pressure oscillation or of the velocity source, phase shift between both sources. Numerical results on the normalized temperature difference established between the ends of stack plates are in excellent agreement with analytical estimates and experimental results published in the literature. Several configurations corresponding to different thermal conditions applied on the outside wall and an inside separation plate are then considered. If the separation plate is adiabatic, temperature varies linearly along the stack, recovering classical linear theory's results. If the separation plate is thermally conductive, the model, providing detailed description of local heat and mass transfer, shows that the temperature field becomes fully two-dimensional and thermoacoustic heat pumping is less efficient. The model is well adapted to explore the influence of local heat transfer constraints on the heat pump efficiency and thus well suited for detailed analyses of more complex mechanisms such as buoyancy effects.

1 Introduction 32

33 Thermoacoustic effect is a phenomenon of heat trans-34 port driven by acoustic oscillations. It occurs in the gas 35 oscillating in the vicinity of a conducting solid, within 36 viscous and thermal boundary layers. Thermoacoustic 37 devices are used to generate either heat pumping for refrig-38 erating purposes or mechanical work for engine operating 39 purposes. The energy conversion takes place in a thermoa-40 coustic core consisting of a stack of solid plates or a porous 41 medium made of mesh grids or another geometry, placed 42 between two heat exchangers. The thermoacoustic core is 43 usually placed inside a closed resonator in which the gas 44 is working at the fundamental resonant frequency associ-45 ated with the geometry of the resonator [1-3].

46 Thermoacoustic engines and refrigerators are interesting 47 for industrial applications because they are an ecological 48 alternative of classical thermal machines, since they have 49 very few moving parts, use inert gas and are simple to build. They are however less competitive because of a much lower 50 51 efficiency, which is limited by acoustics. For more than 30 52 years, different configurations have been studied for various types of resonators and thermoacoustic cores and coupling 53 54 methods between engines and refrigerators. A wide variety 55 of thermoacoustic devices were constructed in order to improve the overall performance for each application: 56 cryogenics [4], air conditioning [5], domestic refrigeration, 57 solar powered thermoacoustic engines [6], electric energy 58 59 generators [7], waste heat recovery systems [8].

60 In the last 20 years efforts have focused on reducing the dimensions of the systems, especially for applications in 61 cooling microelectronic components [9]. The present study 62 deals with thermoacoustic refrigerating systems. When 63 reducing the size of a device with a classical configuration, 64 the resonance working frequency is significantly increased, 65 and it is difficult to construct thermoacoustic cores well 66 adapted to high frequencies, so that the resulting systems 67 have limited performances [10]. A different design based 68

1 on a co-axial travelling wave refrigerator [11] allowed to 2 reduce the resonator's length and to obtain a more compact 3 device with better performances than previously developed 4 standing-wave refrigerators (COP equal to 25% of the 5 Carnot COP, representing improvement by a factor of 6 two). Smith et al. [12] developed a more compact travel-7 ling-wave system in which the resonator is replaced by a 8 hybrid acoustic-mechanical system.

9 Another solution was to eliminate completely the res-10 onator and create the acoustic field needed in the thermoa-11 coustic core with two acoustic sources inside a non resonant 12 compact cavity [13-15] (i.e. the cavity size is much smaller 13 than the wavelength associated to the frequency of the 14 acoustic sources). The main driver acts as a pressure source 15 and the second source is a loud-speaker acting as a velocity 16 source. The thermoacoustic core is a regenerator (mesh of 17 stainless steel screens) or a stack of solid plates placed 18 between heat exchangers. The overall geometry is coaxial 19 with a peripheral channel allowing a feedback flow. There-20 fore the fluid can oscillate in this closed cavity in a similar 21 way as in a travelling wave system. The acoustic sources 22 are working at the same frequency and their amplitudes 23 and phases are tuned independently. The device can be 24 directly optimized by controlling the magnitude and phase 25 shift of acoustic sources.

26 Following this idea a compact thermoacoustic refrigera-27 tor prototype for automobile air conditioning applications 28 was designed and built recently [16]. The prototype was 29 designed using the numerical code DeltaEC [17], based on 30 the linear theory of thermoacoustics (Rott's linear theory 31 [18, 19], later extended by Swift [2], Arnott et al. [20]). 32 The numerical implementation is based upon a lumped 33 element approximation, each element being a part of the 34 system: stack, heat exchanger, duct, etc. For each element, 35 the geometry of the transverse section and the characteris-36 tics of the solid are accounted for through mean values over 37 the element section, in the quasi-one dimensional set of 38 equations, written in the frequency domain. The code 39 provides an estimate of one-dimensional distributions of 40 pressure, velocity and temperature, for a given system 41 working in the periodic regime. Until now, this approach 42 has been widely used to design thermoacoustic devices, 43 despite observed discrepancies on the thermal quantities 44 [16, 21]. These could be associated with nonlinear phenom-45 ena such as streaming [22], end effects or natural convection 46 [23, 24], known to be responsible for reducing the efficiency 47 of thermoacoustic systems. Those phenomena are partially 48 taken into account or simply neglected in the context of 49 the linear thermoacoustic theory. Previous CFD studies of 50 thermoacoustic standing wave refrigerator have been based 51 upon a fully viscous, conductive, and compressible solu-52 tion [25] for high frequencies (20 KHz), simulating devices 53 of extremely small size (on the order of millimeters). 54 Although promising, this approach would lead to extremely 55 large simulations for the present application (cavity size on 56 the order of ten centimeters, and low frequency of 50 Hz). 57 Simulations based on the linearized Navier–Stokes 58 equations (LNSE) are commonly used to implement

multidimensional acoustic simulations, in which a back-
ground flow interacts with and modifies an acoustic field59

62[26]. This approach could be interesting but is restricted
to the linear regime.61
62

In the present work a numerical simulation of the flow 63 and heat transfer in a compact simplified thermoacoustic 64 heat pump is proposed. It consists in solving Navier–Stokes 65 equations under a low Mach number approximation (using 66 the numerical solver SUNFLUIDH [27]). The low Mach 67 68 number approximation has already been used to describe a thermoacoustic stack refrigerator in the years 1998–1999 69 70 [28, 29] and later by [30]. The simulation of the oscillation 71 flow and the heat pumping effect was performed in a region 72 restricted between two stack plates with boundary condi-73 tions that meant to represent the acoustic resonator. More 74 recently, the same approach was used to simulate idealized thermoacoustic engines, by coupling a numerical model of 75 nonlinear flow and heat exchange inside the stack with 76 77 linear acoustics in the resonator and a variable load 78 [31, 32]. In the present study the low Mach number 79 approach can be applied to describe finely the entire device since the frequency of the acoustic sources is such that the 80 associated wavelength is much greater than the cavity size. 81 As a consequence, pressure oscillations can be considered as 82 83 spatially uniform in a first approximation. This model is capable of simulating non-linear hydrodynamics interac-84 85 tions with lower numerical cost than CFD simulations.

86 The main objective of this work is to show the relevance and interest of such an approach for the simulation of 87 88 heat pumping in compact cavities. For the sake of simplic-89 ity a 2D geometry of the cavity is considered. The simula-90 tions provide a fine description of the flow fields and heat 91 transfer inside the cavity allowing to account for their two-dimensional features and to analyse their effect on 92 thermoacoustic heat pumping. Moreover, we point out that 93 thermoacoustic effects can be correctly represented by 94 95 coupling two mechanisms: a compression-relaxation cycle and an oscillating fluid motion. The former is related to a 96 97 homogeneous thermodynamic pressure component whose 98 time variation is governed by a first source acting as an "acoustic driver". The latter is sustained by a second source, 99 the "oscillating fluid generator" that imposes a sinusoidal 100 time-variation of the flow rate. This point of view is quite 101 different from the linear theory of thermoacoustics where 102 the main role of acoustic propagation and local pressure 103 104 gradients is emphasized. Part of this work was presented during the CFA 2022 [33]. The paper is organized as 105 follows: After a short presentation of the low Mach number 106 approach coupled with specific boundary conditions model-107 ing both acoustic sources, and of numerical methods, a 108 reference simulation setup is described (geometry, thermo-109 physical properties, ...). In the result section, thermoacous-110 tic heat pumping is first analyzed for different key parame-111 ters such as the stack thermal conductivity, the flow 112 113 velocity magnitude, the drive ratio, the relative phase between pressure oscillations and particle velocity oscilla-114 tions. Numerical results are compared with analytical esti-115 116 mates and experimental results presented by Poignand

et al. [13, 15]. Several configurations corresponding to differ ent thermal conditions applied on the outside wall and the
 separation plate are then considered and their impact on
 thermoacoustic heat pumping is discussed.

6 2.1 Governing equations in the low Mach number7 approach

8 For a perfect gas, the flow dynamics is commonly 9 described by the compressible, viscous, and heat-conductive 10 Navier–Stokes equations, namely the conservation laws of 12 mass, momentum, energy and the ideal state equation:

14
$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{V}) = 0, \qquad (1)$$

17
$$\rho\left(\frac{\partial \mathbf{V}}{\partial t} + \mathbf{V} \cdot \nabla \mathbf{V}\right) = -\nabla P + \nabla \cdot \mathbf{\tau} + \mathbf{f}_{\mathbf{V}}, \qquad (2)$$

20
$$\rho c_p \left(\frac{\partial T}{\partial t} + \mathbf{V} \cdot \nabla T \right) = \nabla \cdot \kappa \nabla T + \frac{\mathrm{d}P}{\mathrm{d}t} + \Phi, \qquad (3)$$
21

$$P = \rho \frac{R}{\mathcal{M}} T, \tag{4}$$

24 where ρ stands for the density, V for the velocity field, 25 $\mathbf{f}_{\mathbf{V}}$ for the volume forces (i.e. gravity force) and $\boldsymbol{\tau}$ for the 26 stress tensor, which is defined as $\tau = \mu(\nabla \mathbf{V} + T(\nabla \mathbf{V}) - T(\nabla \mathbf{V}))$ 27 $(\frac{2}{3}\nabla\cdot\mathbf{V})\mathbb{I}$, with μ the dynamic viscosity. In the energy 28 equation, T represents the temperature, c_p the specific 29 heat at constant pressure, κ the thermal conductiv-30 ity and $\Phi = \tau : \nabla \mathbf{V}$ the viscous dissipation rate. In the state equation, R is the universal gas constant $(R = 8.314 \text{ J.K}^{-1}.\text{kg}^{-1})$ and \mathcal{M} the molar mass of the 31 32 33 gas. The viscous dissipation rate is often negligible com-34 pared to the other terms for low speed flows and this 35 was checked in the present study. It will therefore no 36 longer be considered here.

Solving the fully compressible Navier–Stokes equations
can be too time consuming since it requires a numerical
time step very small in order to verify an acoustic Courant–
Friedrichs–Lewy condition, based on the speed of sound as
velocity scale.

42 As already mentioned in introduction, the dimensions of 43 the prototype under study are much smaller than the wave-44 length associated with the oscillation frequency of the two 45 sources, i.e. the Helmholtz number He defined as the ratio 46 of a reference length scale L of the cavity to the wavelength 47 λ_0 is small. Acoustic wave propagation can therefore be 48 neglected and the whole prototype considered as acousti-49 cally compact. Navier–Stokes equations can then be simpli-50 fied using asymptotic expansions in powers of Mach number $(M = \frac{V_0}{c_0})$ yielding the so-called low Mach number 51 model that filters acoustic waves, following the approach 52 53 proposed in [34, 35]. As a result, the pressure P is split 54 into two terms : the first order thermodynamic pressure component $P_{\rm th}$ and a much smaller dynamic pressure component $P_{\rm dyn}$ of order $\mathcal{O}(M^2)$. The first term $P_{\rm th}$ is homogeneous in space, depends only on time and is related to the global time-variation of the thermodynamic state of the system during an expansion/relaxation cycle. The second term, which depends on both space and time, represents the small variations of pressure that directly acts on the flow dynamics. The Navier–Stokes equations are rewritten as:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{V}) = 0, \qquad (5) \qquad \mathbf{66}$$

$$\rho\left(\frac{\partial \mathbf{V}}{\partial t} + \mathbf{V} \cdot \nabla \mathbf{V}\right) = -\nabla P_{\rm dyn} + \nabla \cdot \tau, \qquad (6) \qquad \mathbf{69}$$
70

$$\rho c_p \left(\frac{\partial T}{\partial t} + \mathbf{V} \cdot \nabla T \right) = \nabla \cdot \kappa \nabla T + \frac{\mathrm{d} P_{\mathrm{th}}}{\mathrm{d} t}, \qquad (7) \qquad \mathbf{72}$$

$$P_{\rm th} = \rho \frac{R}{\mathcal{M}} T. \tag{8}$$
⁷⁵

The low Mach number model allows to finely describe flow 77 78 dynamics and heat transfer for compact thermoacoustic 79 configurations, while being less time-consuming than a fully compressible model. In this study, the buoyancy effect is 80 not considered ($\mathbf{f}_{\mathbf{V}} = 0$). This point will be discussed in 81 Section 4. Since the pressure is split into two components 82 83 an added equation is required to close the system. The relation yielding $P_{\rm dyn}$ is described in the following Section 2.2. 84 The relation for $P_{\rm th}$ is obtained by integrating over the 85 whole domain the state Equation (8), yielding: 86

$$P_{\rm th} = \frac{R}{\mathcal{M}} \frac{\int_{\Omega} \rho \mathrm{d}\Omega}{\int_{\Omega} \frac{1}{T} \mathrm{d}\Omega},\tag{9}$$

taking into account that the entire mass of fluid is known 90at any time in the domain Ω . 91

In the solid parts of the stack, the following heat equation is solved, denoting with the subscript s the thermophysical properties of the stack plates:

$$\rho_s c_{ps} \frac{\partial T}{\partial t} = \nabla \cdot \kappa_s \nabla T. \tag{10} \qquad 97$$

Continuity of heat flux is applied at fluid-solid interfaces.99The main steps of the algorithm are outlined in the next100section.101

2.2 Numerical methods

The governing equations are solved following a finite103difference approach of second order in time and space.104Convective/advective fluxes and conductive/viscous terms105are discretized with a second order scheme on a staggered106grid. The time scheme is based on a Crank–Nicholson107method where the diffusive terms are implicit in order to108

increase the numerical stability of the method with respect 1 2 to the time step, which is based on the CFL criterion only. 3 The dynamic pressure component is solved by means of an 4 incremental projection method commonly used for the 5 simulation of incompressible flows [36] and adapted for the 6 low-Mach number approach. For that, the divergence-free 7 constraint is replaced by the mass conservation constraint 8 by using Equation (5). The projection method also allows 9 to update the velocity field estimated from the momentum 10 Equation (6) in such a way that mass conservation is satis-11 fied. More information can be found in [37], for example. To sum up, this leads to a Poisson's equation of the form: 12

$$\nabla^2 \cdot \Psi = \frac{\nabla \cdot \left(\rho^{n+1} \mathbf{V}^* - \frac{\partial \rho^{n+1}}{\partial t}\right)}{\Delta t},$$
 (11)

16 where $\Psi = P_{dyn}^{n+1} - P_{dyn}^{n}$ is the time increment of pressure, 17 the index *n* denotes the time iteration, \mathbf{V}^{*} is the velocity 18 field estimated from the momentum Equation (6), ρ the 19 mass density obtained from the state Equation (8), $\frac{\partial \rho}{\partial t}$ 20 its time derivative and Δt the numerical time step. In 21 order to satisfy the mass conservation Equation (5), the 22 velocity field is updated as:

$$\mathbf{V}^{n+1} = \mathbf{V}^* - \frac{\Delta t}{\rho^{n+1}} \nabla \Psi.$$
(12)

The main steps of the algorithm used for the time advance-ment of physical quantities can be summarized as:

29 1. Solve Equation (10) to update the temperature field.

- 30 2. Use the state equation in both forms (9) and (8) to 31 obtain the thermodynamic pressure component $P_{\rm th}$ 32 and the density ρ respectively/in that order. The 33 entire mass of fluid in the domain is known at each 34 time step from initial and boundary conditions (see 35 Sect. 2.3.2 below).
- 36 3. Solve Equation (6) to estimate the velocity field V^{*}
 37 (which does not satisfy mass conservation).

42 2.3 Boundary conditions

43 2.3.1 Wall boundary conditions

44 Wall boundary conditions considered in this numerical 45 study are classical. The usual impermeability and no-slip conditions ($\mathbf{V} = 0$ on the solid walls) are used for the veloc-46 47 ity. Since velocity values are fixed, the projection method 48 naturally imposes a zero normal derivative for the dynamic 49 pressure component $P_{\rm dyn}$. Several cases are considered 50 about heat transfer. Either walls are adiabatic, which 51 implies to impose a zero normal derivative for temperature, 52 or wall temperature is imposed and set to a constant value 53 T_w . For thermally conductive solids, continuity of tempera-54 ture and heat flux at the solid–fluid interface is ensured in 55 the model, since the enthalpy equation naturally reduces 56 to the heat equation within the solid.

2.3.2 Modeling the acoustic sources

The experimental technology used to monitor the governing pressure variation and oscillating fluid motion consists in various acoustic sources, like pistons and loud-speaker membranes. These complex elements are difficult to model in a CFD code. This would require specific methods managing moving objects in a fluid, like ALE or immersed body methods, as well as a finer mesh refinement in the zones of interest. As a consequence, numerical simulations would be particularly complex and time consuming. To overcome this difficulty, we have opted to model the acoustic sources by using oscillating flowrate inlets (see Fig. 1). For each acoustic source, the boundary conditions are defined as:

$$Q_{m}(i) = \rho_{0} U_{i} S_{i} \sin(2\pi f_{0} t - \phi_{i}), \qquad (13)$$

where $Q_m(i)$ is the mass flow rate at each inlet *i* with an amplitude $\rho_0 U_i S_i$ (reference values of fluid density, velocity and surface of the inlet *i*) and a time variation defined from the oscillation frequency of the device f_0 and the phase ϕ_i . This formulation ensures mass conservation over each thermoacoustic cycle and allows us to know the mass of fluid at any time. For others quantities (temperature, density, dynamic pressure component) a zero normal derivative is imposed.

For sake of clarity the inlets are reported in red color in 83 the sketch of the computational domain (see Fig. 1). The 84 oscillating fluid generator (OFG) is constructed as two 85 back-to-back inlets which have the same parameters ρ_0 , 86 $U_{\rm OFG},\,S_{\rm OFG},\,\phi_{\rm OFG}.$ The OFG model therefore produces a 87 zero mass balance at any time and plays a role in the 88 fluid motion only. The acoustic driver (AD), which governs 89 the the compression/relaxation cycle through the varia-90 tion of pressure, is modeled as a single inlet whose 91 parameters are ρ_0 , U_{AD} , S_{AD} , ϕ_{AD} . By considering the phase 92 of the acoustic driver as a reference $(\phi_{AD} = 0)$ and the 93 quadratic phase delay between the time variation of pres-94 sure and the acoustic driver velocity, the usual phase 95 shift between velocity and pressure can be expressed as 96 $\Phi_{u} - \Phi_{p} = \frac{\pi}{2} - \phi_{\text{OFG}} \pm m \cdot \pi \text{ (where } m \text{ is an integer).}$ The drive ratio (i.e. the ratio between the amplitude of 97

The drive ratio (i.e. the ratio between the amplitude of
pressure oscillation and the mean pressure) and the velocity98scale in the stack are directly related to the flow rates of the
acoustic driver and the oscillating fluid generator.100

2 3.1 Description of the thermoacoustic device

3 In this section, we describe the 2D configuration used in 4 our numerical simulations (in the context of this study, we 5 consider that any phenomenon associated with the third 6 direction can be neglected). It includes the main compo-7 nents of compact thermoacoustic refrigerators designed in 8 laboratory experiments [14, 16]: an acoustic driver (AD) 9 controling the compression and relaxation cycle, an oscillat-10 ing fluid generator (OFG), a peripheral channel (PC) allow-11 ing circulating fluid and a stack of 16 solid plates along 12 which is created the temperature gradient (see Fig. 1). 13 The geometry is cartesian and the computational domain 14 is restricted to the upper part of the device by assuming 15 symmetry of the flow behavior with respect to the med-16 ian-plane. The main geometrical features of the device are 17 summarized in Table 1.

18 The physical properties of the stack plates are chosen 19 to be representative of materials commonly used in 20 thermoacoustic devices. The mass density is fixed at $\rho_s =$ 2000 kg.m⁻³ and the thermal conductivity is set to $\kappa_s = 0.2 \text{ W.m}^{-1}.\text{K}^{-1}$ (except in Section 4.1.1 where dif-21 22 ferent values of κ_s are considered). The specific heat 23 capacity is however set to an artificially small value 24 25 $(c_{ps} = 10 \text{ J.K}^{-1} \text{ kg}^{-1})$. The objective is to shorten the tran-26 sition time before reaching a converged time-average state of 27 flow and heat transfer, and thus reduce the CPU time. The 28 value of c_{ns} has a negligible impact on the final temperature 29 gradient in the stack as will also be shown in Section 4.1.1.

30 The fluid is a gas mixture composed of 30% argon 31 and 70% helium as in the TACOT experiments [16]. This 32 choice is made in order to verify the ability of the numerical 33 model to supply a high temperature gradient of the same 34 order of magnitude as those obtained with experimental 35 prototypes [16]. The perfect gas state law is considered with 36 constant physical properties. The specific heat capacity, 37 thermal conductivity and dynamic viscosity are set to 38 Q1 $c_p = 1404.97 \text{ J.K}^{-1} \text{.kg}^{-1}, \ \kappa = 8.56 \cdot 10^{-2} \text{ W.m}^{-1} \text{.K}^{-1}$ and $\mu = 2.11 \cdot 10^{-5} \text{ kg.m}^{-1} \text{ s}^{-1}$ respectively. 39

40 The frequency of both the acoustic driver and the oscil-41 lating fluid generator is fixed at $f_0 = 50$ Hz. By considering a reference temperature of $T_0 = 298$ K and mass density of 42 $\rho_0 = 0.597 \text{ kg.m}^{-3}$ (corresponding pressure $P_0 = 10^5 \text{ Pa}$), 43

the thicknesses of the dynamic and thermal boundary layers 44 along the stack plates are estimated to be $\delta_{\nu} = 4.75 \cdot 10^{-4} \text{ m}$ 45 and $\delta_{\kappa} = 8.07 \cdot 10^{-4}$ m respectively. 46

The value of the resulting temperature difference along the stack plate and therefore of the heat pump efficiency is potentially dependent upon constraints on local heat transfer within the cavity. Several configurations corresponding to different thermal boundary conditions applied on the outside wall and the separation plate are thus considered:

- Case 1: All solid walls are adiabatic (except for the stack plates). This configuration corresponds to an ideal situation with no heat transfer through external walls or the separation plate between the stack region and the peripheral channel (locations are shown on the sketch of the device, Fig. 1).
- Case 2: All external walls are at fixed temperature T_w and the separation plate between the stack region and the peripheral channel is adiabatic. It is also a simplified configuration corresponding to isothermal outer walls, but it allows for heat loss to the ambient surroundings. In real situations there is also convective heat transfer with the surroundings and a fine determination of the overall heat loss would require complex numerical simulations which is beyond the scope of this study. The wall temperature T_w is arbitrarily set to 285 K.
- Case 3: All external walls are at fixed temperature $T_w = 285$ K and the separation plate between the stack region and the peripheral channel is conductive. For the sake of simplicity, the values of heat capacity and mass density are the same as for the stack. The thermal conductivity is set to either $\kappa_1 = 0.25 \text{ W.m}^{-1} \text{.K}^{-1}$ (case 3a : moderate conductivity specific to ceramics [15]) or $\kappa_2 = 14 \text{ W.m}^{-1}\text{.K}^{-1}$ (case 3b: large conductivity specific to stainless steel [16]) accounting for the variability of materials used in thermoacoustic devices.

3.2 Numerical parameters

The computational domain is discretized according to a 83 cartesian grid 384×320 in the longitudinal (x) and the 84 85 normal (y) directions respectively (with respect to the stack plates orientation). In the normal direction, the cell size dis-86 tribution is regular over the stack area. There are 16 cells 87 across the plate thickness as well as across the fluid inter-88 space between plates, the resulting cell size being 89 $\Delta y = 8 \cdot 10^{-5}$ m. This ensures a correct spatial resolution 90 of the boundary layers. 91

In the longitudinal direction, the cell size varies following a specific distribution law so that the minimum values

are positioned nearby the stack ends ($\Delta x_{\min} = 2.5 \cdot 10^{-4}$ m). The time step is fixed at $\Delta t = 2 \cdot 10^{-5}$ s. This choice 95 ensures that the CFL criterion is satisfied (maximum value 96 97 is about 0.5) and each period of the thermoacoustic cycle is 98 exactly described with 1000 time steps. Initially the fluid is at rest. Initial conditions for pressure and temperature are 99 set to $P_0 = 10^5$ Pa and $T_0 = 298$ K and the mass density 100 is equal to $\rho_0 = 0.597 \text{ kg.m}^{-3}$. 101

1 4 Numerical results

2 The numerical results presented below are obtained for 3 physical configurations adapted from experiments [14, 16] 4 so that the operating mode mainly corresponds to the linear 5 regime. The working gas and frequency were chosen to be 6 the same as in the TACOT prototype [16] in order to obtain 7 a thermoacoustic heat pumping effect large enough for 8 industrial applications. However, the mean thermodynamic 9 pressure was set to atmospheric pressure in order to keep 10 boundary layers large enough to be discretized without 11 excessive numerical cost. Here the ratio between the half-12 distance between plates and the thermal boundary layer 13 thickness is equal to 0.8 which means that the stack is 14 neither quasi-adiabatic nor quasi-isothermal, but in 15 between.

16 Numerical simulations are then compared with analyti-17 cal results obtained from linear theory [13] for various 18 sets of parameters as well as with experimental measure-19 ments of Poignand et al. [15], with either a quasi-adiabatic 20 stack (Exp. 1) or a quasi-isothermal regenerator (Exp. 2). 21 Equations for the linear theory are solved with parameter 22 values presented in Section 3.1, in order to describe the ideal 23 case 1. The main input parameters characterizing the differ-24 ent simulations are the drive ratio, the stack velocity scale 25 and the phase shift between the acoustic driver and the 26 oscillating fluid generator. The drive ratio is the commonly 27 used parameter to characterize the acoustic operating 28 regime. It is defined with respect to the thermodynamic $\frac{29}{30}$ pressure component as:

$$Dr = \frac{P_{\rm th}^{\rm max} - P_{\rm th}^{\rm min}}{P_{\rm th}^{\rm max} + P_{\rm th}^{\rm min}}$$

34 In the present study, the drive ratio is small enough 35 (Dr < 2.5%) so that Rott's linear theory should give the 36 correct value for the temperature difference between stack 37 ends (ΔT). The stack velocity scale u_s is commonly defined 38 as the mean velocity amplitude over the stack channels. It can be simply estimated as $u_s = \frac{U_{\text{OFG}}}{R_b}$ (the density variation in space being neglected as a first approximation), where 39 40 41 U_{OFG} is the velocity amplitude of the OFG, and R_b is the 42 stack porosity (ratio between the fluid part and entire stack 43 volumes).

44 In the following sections, results obtained on the three 45 configurations presented in Section 3.1 are detailed. These 46 results mainly focus on the mean value of ΔT computed 47 from time series recorded at locations reported in Figure 1. 48 This quantity is normalized in order to compare numerical 49 results with experimental measurements whose operating 50 regimes are not the same as those used for computations. 51 Temperature fields are also presented to point out how 52 thermoacoustic heat pumping can be influenced by the 53 previously described thermal configurations. In order to 54 smooth the time variations related to each thermoacoustic 55 cycle, all physical variables are averaged over 100 oscillation 56 cycles. Time series show the evolution of the averaged quan-57 tities. Simulations are run until convergence is obtained for

the mean value of ΔT (or quasi-convergence, see discussion 58 in Sect. 4.2). 59

4.1 Parametric analysis of thermoacoustic heat 60 pumping 61

In this section, the sensitivity of the thermoacoustic 62 heat pumping effect, given by ΔT , with respect to some 63 input parameters (driver ratio, stack-velocity scale, ...) is 64 shown. The main objective is to validate the model in the 65 linear regime by comparison with experimental measure-66 ments and analytical results obtained from the linear 67 theory. Results corresponding to the configuration case 1 68 only were already described in CFA 2022 [33]. In the follow-69 ing discussion the reference operating conditions correspond 70 to a drive ratio equal to Dr = 0.0236, a velocity scale in the stack on the order of $u_s = 0.5 \text{ m.s}^{-1}$ ($U_{\rm OFG} = 0.25 \text{ m.s}^{-1}$ 71 72 and $R_b = 0.5$), and the mass flow rates associated with 73 74 the AD and OFG sources are adjusted in such a way that the phase shift between the velocity and the pressure in 75 the stack is equal to $\Phi_u - \Phi_p = 5\pi/6$, as explained in the 76 77 end of Section 2.3.2. These reference values were chosen in order to obtain a significant thermoacoustic effect for 78 all configuration cases. All other input parameters are 79 described in Section 3. The sensitivity to each parameter 80 is analysed separately. 81

4.1.1 Influence of stack thermo-physical properties

82

Results shown in this paragraph were obtained for the 83 configuration case 1. The considered thermo-physical 84 properties are the heat capacity $\rho_s c_{ps}$ and the thermal con-85 ductivity κ , since the heat flux is essentially determined by 86 these parameters. The time evolution of the temperature 87 88 difference ΔT is plotted in Figure 2 for several values of the stack plates specific heat capacity c_{ps} (the actual param-89 90 eter should be $\rho_s c_{ps}$ but it is obvious that considering only 91 the variation of c_{ps} is sufficient, ρ_s being fixed). There is a transient phase before reaching an asymptotic regime giving 92 $\Delta T \simeq 51.5$ K, which, as expected, is longer as the value of 93 the heat capacity is larger (see Fig. 2). The low sensitivity 94 of ΔT in the asymptotic regime to the heat capacity of 95 the stack allows us to consider a small value in order to 96 97 reduce drastically the computation time and justifies our choice to set $c_{ps} = 10 \text{ J.K}^{-1} \text{ kg}^{-1}$. Similar observations were 98 made for the other configurations (cases 2 and 3). Therefore 99 the same value of c_{ps} was kept for all simulations. 100

Figure 3 shows the value of ΔT between stack ends for 101 six values of the thermal conductivity κ_s of the solid stack 102 plates (case 1). The solid line shows the corresponding 103 prediction of the linear theory of thermoacoustics. The 104 agreement is excellent. As expected, when κ_s is very large, 105 ΔT becomes negligible because of enhanced heat conduction 106 in the solid: thermoacoustic heat pumping becomes ineffec-107 tive. For $\kappa_s = 0$ (adiabatic stack) the thermoacoustic effect 108 is canceled, as predicted by Swift [1]. Note that for very 109 small (non-zero) values of κ_s the numerical prediction 110 departs for the linear theory, suggesting that the evolution 111

as $\kappa_s \to 0$ is sharp but continuous and that there is an optimum κ_s value for which ΔT is maximum. Again similar observations were made for the other configurations (cases 2 and 3).

5 4.1.2 Influence of the Drive ratio

12

4

In this paragraph, the used relative velocities and phase 6 shift are fixed at their reference values $u_s = 0.5 \text{ m.s}^{-1}$ and 7 $\phi_u - \phi_p = 5\pi/6$. Figure 4 shows the variation of the 8 9 normalized temperature difference along the stack as a 10 function of the drive ratio for all considered configurations 11 (cases 1 to 3). Numerical points are plotted as well as the 12 linear theory prediction and experimental results from 13 [15]. In order to compare our results with those of Poignand 14 et al. [15], which are performed in very different physical 15 conditions, the reference scale $\Delta T_{\rm ref}$ used to normalize ΔT 16 is chosen at Dr = 0.01. Both sets of experimental points

Figure 4. Normalized mean temperature difference $\Delta T / \Delta T_{\rm ref}$ between stack ends as a function of the Drive ratio Dr. Numerical results (cases 1, 2, 3), linear theory (black solid line), Exp. 1 (green crosses) and Exp. 2 (red triangles) from [15].

(Exp. 1) and (Exp. 2) are shown on the figure, and the evolutions are consistent with the numerical simulation results which fall in between as expected, since in the numerical configuration the stack is neither fully adiabatic nor isothermal. Very good agreement with the linear theory is observed (see Fig. 4). We notice the numerical results are very similar independently from the considered configuration.

4.1.3 Influence of the stack velocity-scale

Another important parameter of the thermoacoustic 26 27 heat pumping effect is the characteristic velocity scale within the stack. The variation of this parameter is 28 29 obtained by changing the input velocity U_{OFG} of the oscillating fluid generator. The other relevant parameters, the 30 drive ratio and the phase shift, are fixed at their respective 31 reference value (Dr = 0.0236 and $\phi_u - \phi_p = 5\pi/6$). In order 32 33 to compare numerical, theoretical and experimental results, 34 the stack velocity scale corresponding to each data set is 35 normalized with respect to its own optimum value u_{opt} providing the maximum value of the ΔT in each case. 36

Figure 5 shows the evolution of ΔT between stack ends 37 as a function of the normalized stack velocity scale 38 $u_s^* = u_s/u_{opt}$ for all considered configurations. Again a simi-39 lar behavior is observed in numerical or experimental 40 results and in the linear theory. The value of ΔT resulting 41 42 from the different approaches increases with u_s^* , up to u_s^* 43 about 0.85, then reaches the same plateau. There are however some quantitative discrepancies for $u_s^* < 0.6$. While the 44 experiment 1 fits well with the linear theory, the experiment 45 2 yields lower values of ΔT . The numerical results present 46 47 larger values which are similar for the three considered 48 cases. The scattering of experiment 2 and numerical results around the linear theory curve is of the same order and is 49 50 more noticeable as u_s^* decreases. However the normalization 51 allows to obtain analogous behavior for all these physically 52 very different configurations.

4.1.4 Influence of the phase shift between velocity and pressure.

3 In this paragraph, the used relative velocities and drive ratio are fixed at their reference values ($u_s = 0.5 \text{ m.s}^{-1}$, 4 5 Dr = 0.0236). The influence of the phase shift between 6 velocity and pressure is studied and results are plotted in 7 Figure 6 for the three numerical configurations. Here again 8 a similar evolution is observed in numerical simulations. 9 experimental results and the linear theory. In the $[-\pi, 0]$ 10 interval, numerical results are bounded by linear theory 11 and experimental results, while in the $[0, \pi]$ interval all 12 curves are in close agreement. Numerical simulations, for 13 every cases, confirm the experiment results in that the 14 phase shift has a major influence on the thermoacoustic 15 heat pumping effect. Indeed it is possible to control the 16 orientation of heat pumping (and invert ΔT between the 17 stack ends) with the phase shift. The observed asymmetry 18 of the curve (for example on extreme values) is probably 19 correlated to the device geometry with respect to the stack

Figure 7. Time evolution of the temperature difference between stack ends for the different configurations.

middle cross-section. Note that the model deduced from the linear theory does not predict this asymmetry. It is observed that for all considered configurations, the numerical value of the phase shift Φ leading to the maximum value of ΔT varies between $5\pi/6$ and π which is slightly larger than the value found in the linear model $(3\pi/4)$ and close to the experimental results reported in [15].

27

28

4.2 Influence of heat transfer constraints (choice of configuration)

29 In addition to the very good agreement between the 30 numerical results, experimental measurements and linear 31 theory, we found that the relative variation of the thermoa-32 coustic heat pumping effect with respect to parameters defining the operating regime (drive ratio, stack velocity 33 scale or phase shift) does not depend significantly on the 34 considered configuration (i.e. on the heat transfer con-35 straints). In other words, the normalized temperature dif-36 ference across the stack plates follows the same scaling laws. 37

We now analyse how the heat loss through external 38 walls and the thermal conductivity of the separation plate 39 act on the magnitude of the thermoacoustic heat pumping 40 effect. We use the reference operating conditions described 41 in Section 4.1 for the three considered configurations. 42 Figure 7 describes the time evolution of ΔT for these difference operations 44

45 In both configurations for which the separation plate is adiabatic (cases 1 and 2), the established values of ΔT are 46 47 close to each other. Moreover, the mean temperature fields for these two cases present very similar spatial distributions 48 over the computational domain (see Figs. 8a and 8b). The 49 temperature distribution is unidirectional and quasi linear 50 along the plates in the stack region with same gradient 51 value while it is rather uniform in other parts of the device. 52 From this observation we can deduce that the established 53 54 time-average heat flux transported by the flow along the peripheral channel is relatively small and the adiabatic 55 56 separation plate is sufficient to ensure an efficient thermal 57 insulation of the stack region, thereby strongly reducing

(a) Case 1 : External walls and separation plate are adiabatic

(b) Case 2 : External walls are at a fixed temperature $(T_w = 285 K)$ while the separation plate is adiabatic

(c) Case 3a : External walls are at a fixed temperature ($T_w = 285 \text{ K}$) while the separation plate is thermally conductive ($\kappa = 0.25 \text{ W.m}^{-1} \text{.K}^{-1}$)

Figure 8. Mean temperature field over the computational domain for cases 1, 2 and 3a.

the impact of the heat loss on the thermoacoustic heat pumping efficiency. Only the global temperature level is larger in the adiabatic external walls configuration (since no heat loss is permitted) than that obtained for fixed temperature outer walls, with heat losses in the latter configuration occurring mainly during the transient stage.

1 2

3

4

5

6

7 Note that the adiabatic external wall configuration 8 (case 1) induces a small but continuous variation of ΔT over 9 a long time range. As a consequence, perfectly converged 10 state of the system (in the sense of time average quantities) 11 cannot be obtained especially for operating regime close to 12 optimal conditions. This can be explained by the fact that 13 the adiabatic conditions coupled with the mechanism of 14 expansion-compression of the gas cannot maintain the 15 same thermodynamic state of the fluid from one thermoa-16 coustic cycle to another. In other words, ensuring time-aver-17 age equilibrium between the enthalpy variation of the fluid 18 over a thermoacoustic cycle and the heat exchange with the 19 stack over any thermoacoustic cycle is very difficult. This 20 small shortcoming however does not affect our results if 21 the simulation takes place over a limited time (for example, 22 400 s in configuration case 1, see Fig. 7).

What about the absolute magnitude of the temperaturedifference established between stack ends? The established

value of ΔT obtained numerically in case 2 is $\Delta T \simeq 56$ K. 25 Rott's linear theory developed in [13] yields $\Delta T_{\text{lin}} = 49$ K 26 with the numerical input data set (case 2), in accordance 27 with our numerical result. 28

29 We now examine the influence of the thermal conductivity of the separation plate, by comparing results obtained in 30 cases 2, 3a and 3b. As expected, the larger the thermal 31 conductivity of the plate, the smaller the thermoacoustic 32 heat pumping efficiency, as shown in Figure 7. ΔT is 33 reduced by a factor of about 2–2.5 between the adiabatic 34 case (case 2) and both thermally conductive cases (3a and 35 3b). Moreover, the time required to reach a converged state 36 is drastically shorter in cases 3a and 3b. When the separa-37 tion plate is thermally conductive, a significant heat flux 38 contribution appears in the normal direction which enables 39 heat loss through the peripheral channel and the external 40 walls and reduces the magnitude of the mean temperature 41 gradient along the stack plates. As a consequence, the 42 temperature distribution over the computational domain 43 is drastically modified. When the separation plate is adia-44 batic, it is organized following a linear distribution along 45 the plates inside the stack plates and a quasi-uniform 46 distribution elsewhere (as seen in Fig. 8b). When the sepa-47 ration plate is thermally conductive, the temperature field 48 4

9

1 presents a 2D pattern resulting from heat flux contributions 2 along each direction (see Fig. 8c).

3 If we consider devices with larger span, the vertical distribution of the temperature field in the stack region 5 could trigger buoyancy effects and in turn strongly modify 6 the thermoacoustic heat pumping effect along the stack. As 7 a consequence, thermal insulation of the stack region 8 appears to be a key point in the device optimization, minimizing the vertical mean temperature gradient.

10 These observations constitute a significant added con-11 tribution of numerical simulations compared with linear 12 theory and experiments.

5 Conclusion 13

14 A numerical model based on a Low Mach number 15 approximation was designed to simulate the thermoacoustic 16 heat pumping effect inside a compact cavity consisting of an 17 acoustic driver, an oscillating fluid generator and a stack of 18 solid plates. In this fluid mechanics approach, the physical 19 coupling between the oscillating fluid and homogeneous 20 compression-relaxation cycles results in thermoacoustic heat 21 pumping along the stack plates with no account of acoustic 22 propagation. The main characteristics of thermoacoustics 23 are recovered: the normalized temperature difference as a 24 function of a wide range of operating conditions is in very 25 good agreement with the linear theory predictions and 26 experimental measurements, at least in the linear regime.

27 The model was used to explore a wide range of input 28 parameters in the linear regime for several numerical config-29 urations, and results were compared with the linear theory 30 as well as experimental measurements. The main results 31 are: Firstly, the normalized temperature difference between 32 stack plate ends follows a scaling law with respect to the 33 main parameters used to determine the operating condi-34 tions (drive ratio, stack velocity scale or phase shift) inde-35 pendently from the configuration.

36 Secondly, the influence of heat loss through external 37 walls and of insulation characteristics of the stack region 38 (through the separation plate) is studied. It is shown that 39 the latter has a prevailing effect on the resulting thermoa-40 coustic heat pumping efficiency, since the temperature dis-41 tribution inside the stack is no longer unidirectional when the thermal conduction properties of the separation plate 42 43 become significant. This leads naturally to investigate the 44 relevance of gravity effects when the temperature field 45 inside the stack region becomes multidimensional, especially 46 for compact cavities with larger spans in which buoyancy 47 could arise. The present model is very well adapted for such 48 a study which is the object of our work in progress. In addi-49 tion the model is also well adapted to explore other nonlin-50 ear effects, which can be associated for example with jet 51 flow instabilities around stack ends.

EDP JOURNALS - AUTHOR QUERY FORM

Journal Code: aacus	Article DOI: 10.1051/aacus/2023008	
Article Number: aacus220091	First Author: Yann Fraigneau	
Article Title: A numerical model of thermoacoustic heat pumping inside a compact cavity		

AUTHOR QUERIES – TO BE ANSWERED BY THE CORRESPONDING AUTHOR

Dear Author,

During the preparation of your manuscript for typesetting, the queries listed below have arisen. Please answer these queries by marking the required corrections at the appropriate point in the text.

Queries and/or remarks

Location in article	Query/remark	Response
Q1	Please check and approve the middot has been inserted between the values throughout the main text.	OK
Q2	Please check and approve "Conflict of interest" statement.	OK
Q3	Please check and approve conference date of reference [5].	See below
Q4	Please provide conference date and location of reference [8].	ОК
Q5	Please provide title of reference [27].	See below
Q6	Please check and approve conference date and location of reference [33].	See below
Q7	Please check and approve the middot has been inserted between the values of Table 1.	See below

Q3 Add "Western" before "Australia"

- Q5 Ref 27 has been updated : title has been provided, and the link updated :
 27. Y. Fraigneau: SUNFLUIDH: A software for computational fluid dynamics, User guide, LIMSI 2013. https://sunfluidh.lisn.upsaclay.fr
- Q6 The date should be 11-15 April 2022 (instead of April 2002). The rest is correct
- Q7 One middot is missing on the second line of Table 1, between 1.28 and 10^{-3}
