ABSTRACT

Background: Mismatch repair deficient (dMMR) tumors displaying microsatellite instability (MSI) represent a paradigm for the success of immune checkpoint inhibitor (ICI)-based immunotherapy, particularly in patients with metastatic colorectal cancer (mCRC). However, a proportion of patients with dMMR/MSI mCRC exhibit resistance to ICI. Identification of tools predicting MSI mCRC patient response to ICI are required for the design of future strategies further improving this therapy.

Patients and Methods: Here we combined high-throughput DNA and RNA sequencing of tumors from 116 patients with MSI mCRC treated with anti-PD-1 +/- anti-CTLA-4 of the NIPICOL phase II trial (C1, NCT03350126, discovery set) and the IMMUNOMSI prospective cohort (C2, validation set). We clinically relevant the DNA/RNA predictors whose status was significantly associated with ICI response in both C1 and C2. Primary endpoint was iPFS (progression-free survival by iRECIST).

Results: Analyses failed to validate previously suggested DNA/RNA indicators of resistance to ICI, e.g. MSISensor score, tumor mutational burden, or specific cellular and molecular tumoral contingents. By contrast, iPFS under ICI was shown in C1 and C2 to depend both on a multiplex MSI signature involving the mutations of 19 microsatellites ($HR_{C2} = 13.1$; 95% CI [2.71-63.8] ; $p = 1.4 \times 10^{-3}$) and the expression of a set of 182 RNA markers with a non-epithelial TGFB-related desmoplastic orientation ($HR_{C2} = 4.12$; 95% CI [1.44-11.8] ; $p = 4.19 \times 10^{-3}$). Both DNA ($HR_{C2} = 6.05$; 95% CI [1.68-21.8] ; $p = 5.92 \times 10^{-3}$) and RNA ($HR_{C2} = 8.38$; 95% CI [2.44-28.7] ; $p = 7.22 \times 10^{-4}$) signatures were independently predictive of iPFS.

Conclusions: iPFS in patients with MSI mCRC can be predicted by simply analyzing the mutational status of DNA microsatellite-containing genes in epithelial tumor cells together with nonepithelial TGFB-related desmoplastic RNA markers. These DNA/RNA signatures are readily available to be used in clinics.

INTRODUCTION

Mismatch repair deficient (dMMR) tumors display a molecular phenotype characterized by the genetic instability of numerous microsatellite repeated sequences throughout the genome (Microsatellite Instability, MSI) ¹⁻³. MSI was first observed in inherited tumors associated with Lynch syndrome and later in a large spectrum of primary tumors, in particular sporadic colorectal cancers (CRC) (for review see ⁴⁻⁶). Being highly genetically unstable, MSI cancers are highly immunogenic and generally show a strong infiltration with cytotoxic T-cell lymphocytes ⁴. Recently, it was reported that MSI tumors resist this hostile immune microenvironment by overexpressing immune checkpoint (ICK)-related proteins to allow immune-escape ⁷. Consistently, MSI status was shown to predict clinical benefit from ICK inhibitors (ICI) in patients with metastatic cancer including CRC (mCRC) ^{8, 9}. In patients pretreated with fluoropyrimidines, oxaliplatin and irinotecan prior to ICI for dMMR/MSI mCRC, the objective response rate ranges from 33% to 65% and the 1-year overall survival rate ranges from 34% to 71%. First-line pembrolizumab (anti-PD-1) has been associated with significant improvement of progression-free survival compared with standard of care chemotherapy ± cetuximab or bevacizumab ¹⁰. However, up to 15-46% of patients with dMMR/MSI mCRC exhibit primary resistance to ICI while 5%-25% of responders develop acquired resistance to these treatments, although this estimation might increase with longer follow-up ¹¹⁻¹⁴.

Several DNA and RNA-based markers predicting the efficacy of ICIs have been previously proposed in metastatic dMMR/MSI cancer settings ^{9, 15-21}. However, it is fair to say that these results lack independent validation, being based on the analysis of only limited series of dMMR/MSI tumor samples with heterogeneous tumor origins. At the DNA level, markers include quantitative genomic indexes measuring the level of MSI within the tumor bulk such as the MSIsensor score or the tumor mutation burden (TMB). Previous studies have considered the selection of specific somatic variants occurring in dMMR cancers due to MSI as specific predictive markers such as *BRAF*^{V600E} mutational status, *KRAS/NRAS* mutations, or the *B2M* truncating mutation resulting in loss of function of the resultant protein associated with the MHC class I complex ^{17, 20}. However, it was recently reported that B2M inactivation was unlikely to

1
2
3 blunt the efficacy of ICI in dMMR/MSI tumors in human ²² and using multiple murine
4 dMMR B2m null cancer models ²³, raising the question of the real impact of these
5 somatic mutations in the MSI cancer setting. At the RNA level, it was hypothesized
6 that the estimated abundance of specific cell populations in the tumor
7 microenvironment could be of clinical relevance, e.g., immune cell populations such as
8 antigen-presenting macrophages interacting with T-cells ²⁰. Logically, deregulated
9 activity of some cancer-related pathways associated with antitumor immunity were also
10 proposed, e.g., the reduced activity of *Wnt/Wingless* signaling, deregulation of the
11 interferon gamma pathway and/or of several immune escape processes ²⁰. Finally, a
12 study published by our team showed that the leading cause for association of primary
13 resistance to ICI in mCRC was the misdiagnosis of their MSI or dMMR status ²⁴,
14 emphasizing that the first and foremost criteria to be validated before the prescription
15 of ICI in metastatic dMMR/MSI cancer patients, and particularly in mCRC, is the
16 guarantee of a quality diagnosis with appropriate methods to identify genuine
17 dMMR/MSI.
18
19

20
21 In this study, we hypothesized that the response to ICI could be predicted by both
22 leveraging on the MSI-specific mutational patterns in epithelial cells (by DNA sequencing)
23 and by considering the modifications of the cancer stroma (by RNA sequencing) on
24 the other hand. We addressed the issue of response to ICI based on the investigation
25 of two independent prospective cohorts of 44 and 72 patients with dMMR/MSI mCRC,
26 respectively the multicentric NIPICOL clinical trial (NCT03350126) ¹⁴ and the
27 prospective ImmunoMSI cohort ²⁵.

ImmunoMSI prospective cohort (C2) ²⁵, all consecutive MSI/dMMR mCRC patients treated with ICI (anti-PD-1 monotherapy or anti-PD-1 plus anti-CTLA-4 combination) at Saint-Antoine Hospital, Medical Oncology department (Prof. Thierry André) from February 2015 to December 2019, were included. This research was approved by the ethics committee (N°2020 – CER 2020-6). The identification numbers of the ethic committees are the following, i.e., CPP N°2017/45 (ANSM reference: 170508A-12; EudraCT N°2017-002442-72) for C1 NIPICOL clinical trial and CPP N°2020 CER 2020-6C2 for ImmunoMSI. The Nipicol trial NCT03350126 has been completed and its primary endpoint published ¹⁴.

Assessment of microsatellite status

All CRC samples from C1, C2 and other cohorts used in this post-hoc study were centrally reassessed for MSI and dMMR status using immunohistochemistry (IHC) and for MSI using polymerase chain reaction (PCR) as described ^{26, 27}. Next, MSIsensor (version 0.6) and MSICare were used by default on paired normal-tumor exome data, to evaluate the mutation status of microsatellites using considering the whole exome data. MSIsensor score threshold of 10% or more was used to classify the MSI-H tumor (MSI-High) and a MSICare threshold of 20% was used to define MSI status as previously described ²⁸.

Radiological analyses

Tumors were assessed ≤ 28 days before the first dose (baseline) and every 6 to 10 weeks, thereafter, according to different protocols. The decision to pursue treatment beyond iuPD was at the discretion of the treating physician. Treatment beyond iuPD was conditional to a confirmatory imaging 4 to 8 weeks after the first evidence of progression. Imaging was retrospectively and centrally reviewed by an experienced radiologist according to RECIST1.1 and iRECIST. ²⁹. Radiological progression was defined as confirmed PD (cPD) according to iRECIST 1.1. All cases of PD and pseudo progression were reviewed by a second experienced radiologist unaware of the target and non-target lesions chosen by the first radiologist. In case of discrepancy, a final decision was reached by consensus.

Survival analysis of ICI treated patients

Survival analysis on ICI patients was performed from the date of first infusion of any ICI. iPFS by iRECIST²⁹ was calculated from the first dose to the first documented cPD, or death resulting from any cause, whichever occurred first. Kaplan Meier curves were used to visualize difference in progression free survival (iPFS) between patients' groups diverging on genomic instability (e.g., TMB-High or MSISensor-High or MSICare-High, >20th percentile; TMB-Low or MSISensor-Low or MSICare-low ≤20th percentile) or to show at the selected cutoff values a clinical effect of our DNA or RNA signatures. The cutoff values were selected to optimize the clinical effect of our DNA or RNA signatures on ICI response in patients. Nevertheless, the validity of same signatures was also tested without using cutoff values with Cox models, similarly showing a clinical relevance, as indicated in the corresponding figures. The use of the cutoffs has been envisioned more to illustrate the findings but there is no dependence on these cutoffs for the demonstration of the clinical impact of both the DNA and RNA signatures. Two-sided Log-rank test was performed using the R package Survival (version 3.2.3).

P-value levels and Correction of *p*-values

In all statistical analyses, *p*-value ≤ 0.05 (risk alpha) was used as a threshold of significance. As an exception, for the selection of DNA variants following WES in C1, *p*-value ≤ 0.1 has been applied in order to provide pre-selection of a larger number of DNA variants prior to validation of their putative clinical significance in C2 by targeted sequencing (reduction of the risk of false negatives).

We systematically applied multi-test correction using Benjamini-Hochberg's method to control the false discovery rate when multiple tests of the same hypotheses were performed. However, we chose to highlight either one or the other either for clarity or fairness of comparison. We systematically presented uncorrected and corrected *p*-values when relevant in each of the corresponding figures and supplementary figures.

Data availability

The processed datasets used in the current study are now available in the github repository, https://github.com/CRSA-MSI/R-ICI_MNB_Survival. Reasonable request for sharing biologic materials or raw data files will be reviewed by the corresponding author (ADu). Patient- related data not included in the paper were generated as part of clinical trials and may be subject to patient confidentiality. Any data and materials that can be shared will be released via a material transfer agreement.

Code availability

The scripts and the Naive Bayes model can be accessed at GitHub https://github.com/CRSA-MSI/R-ICI_MNB_Survival. Scripts for ICA of RNA can be assessed at GitHub <https://github.com/GeNeHetX/NipicolICA>.

Concerning Sample preparation and sequencing, Exome Analysis and Mutational load, MHC class-I neoepitopes prediction, Feature selection and data pre-processing, DNA signatures (mutation count and Multinomial Naives Bayes), and Transcriptome profile generation and analysis, see **SUPPLEMENTARY MATERIALS AND METHODS**.

RESULTS

Patient population and study design

A total of 129 prospectively collected mCRC patients were assessed for eligibility, including 57 patients from the NIPICOL clinical trial (C1, NCT03350126) and 72 patients from the prospective ImmunoMSI cohort (C2) ²⁵. Clinical and disease characteristics of patients from C1 and C2 are summarized in **TABLE 1**, and further detailed in **SUPPLEMENTARY TABLE S1** and **SUPPLEMENTARY TABLE S2**. In C1, the analysis was restricted to 54 patients after removing 3 mCRC samples with misdiagnosed dMMR/MSI status (false positive cases that were in fact MSS). Whole Exome Sequencing (WES) and RNA Sequencing (RNASeq) were performed on 23 and 44 collected mCRC +/- matched normal colonic mucosa paraffin-embedded

1
2
3
4 samples, respectively, after removing 29 samples with lack of materials and/or
5 insufficient quality (FIG.1A). In C2, targeted next-generation-sequencing (NGS) and
6 RNASeq were performed on 66 and 72 mCRC +/- matched normal colonic mucosa
7 paraffin-embedded samples, respectively, after removing unqualified samples for
8 similar reasons, i.e., insufficient quantity and/or low-quality level (FIG.1A). The
9 CONSORT-like clinical and molecular diagram in FIGURE 1 outlines the methodology
10 workflow of the study.
11
12
13
14
15

16 FIGURE 1 also summarizes the flow chart (FIG. 1A) and the current design of the
17 study (FIG. 1B). In brief, NIPICOL (C1) was used as a training and ImmunoMSI (C2)
18 as a validation cohort. Progression-free survival (PFS) by iRECIST (RECIST for
19 Response Evaluation Criteria in Solid Tumor) (iPFS)²⁹ was used as primary endpoint.
20 In an effort to optimize the available clinical data for the purpose of identifying available
21 RNA/DNA predictive markers of resistance to ICI in this prospective series of ICI-
22 treated patients with MSI mCRC, their putative clinical relevance was examined in C1
23 (training set) and yet in C2 (validation set) independently. C1 was a cohort from a
24 clinical trial including dMMR/MSI patients all treated with the same treatment, i.e., a
25 combination of nivolumab (anti-PD-1) and ipilimumab (anti-CTLA-4) after failure of
26 standards of care. C2 was a larger and more heterogeneous cohort concerning
27 regimen of ICI received (anti-PD1 alone or associated with ipilimumab) and inclusion
28 criteria were less restrictive compared to a clinical trial.

42 **The level of MSI and TMB in tumor DNA does not predict response to ICI in patients** 43 **following exclusion of ICI-treated mCRC with misdiagnosed dMMR/MSI status** 44

45 We first focused DNA analyses on the genomic quantitative indexes that are related
46 to MSI in tumor DNA, i.e., the TMB and MSISensor score, whose level was previously
47 reported to predict response to ICI in patients with metastatic dMMR tumor^{15, 16}
48 (SUPPLEMENTARY FIGURE S1). Our data establish in this study that there is no
49 influence of MSISensor score nor TMB on the iPFS of patients from C1 after exclusion
50 of the cases with false positive MSI status (that were MSS, n = 3 and may lead to
51 wrongly give a prognostic value to TMB and/or MSISensor regarding iPFS, see
52 SUPPLEMENTARY FIGURE S1) (FIG. 2C). As shown also in SUPPLEMENTARY
53 FIGURE S1, the MSICare score is no more clinically relevant for predicting iPFS to ICI

4 in patients with confirmed MSI mCRC, nor is the number of neoepitopes presented by
5 autologous class I HLA alleles when calculated using a dedicated pipeline which
6 combines several software³⁰⁻³³. In view of these results, we decided not to investigate
7 further the clinical relevance of MSIsensor score, TMB and number of neoepitopes in
8 C2 since none of them were associated with patients' prognosis in a true MSI mCRC
9 population.

17 **Identification of a 19-plex MSI signature predictive of response to ICI in mCRC patients**

18
19 We first examined by WES the impact of somatic variants occurring in true positive
20 MSI mCRC patients from C1 regarding iPFS upon ICI treatment. Expectedly, a great
21 number of variants occurred at both nonrepetitive (NR, in $n = 3,886$ genes, only coding
22 events) or repetitive (R, in $n = 20,472$ microsatellite-containing genes, both coding or
23 noncoding events) sequences in genes having or not an expected role in the MSI-
24 driven tumorigenic process. For survival analyses, we considered only somatic
25 microsatellite mutations in tumor DNAs, because frequent hotspot NR mutations are
26 rare in these tumors (**Fig. 2A** and **2B**). However, note that canonic NR mutations
27 recurrently associated with colon tumor among which some were previously proposed
28 to affect response to ICI, e.g., in *KRAS*, *BRAF*, *B2M* and other cancer-related genes,
29 were not associated to iPFS in C1 (**SUPPLEMENTARY FIGURE S2**). In **FIGURE 2B**
30 are shown the results of univariate cox analyses we performed to identify amongst the
31 microsatellite variants the 167 alterations with impact on the iPFS of MSI mCRC
32 patients in C1 ($p \leq 0.1$).

42
43

44 Like the NGS-based MSICare²⁸ or the PCR Pentaplex²⁶ genomic tools we
45 previously designed, which use multiple microsatellite analysis to predict the MSI or
46 MSS status of CRC, we hypothesized that response to ICI could be also predicted by
47 investigating a set of selected microsatellite markers mutated in these tumors. From
48 C1 (Training cohort), 19 candidate microsatellite markers (i.e., in *SUCO*, *LYST*,
49 *MACO1*, *PPRC1*, *COMMD3*, *OCA2*, *MTMR10*, *IGDCC4*, *NLK*, *RNF43*, *TSEN54*,
50 *ADGRE1*, *EDAR*, *TTN-AS1*, *IQCA1*, *RWDD4*, *CCDC158*, *CANX*, *MLIP*) were selected
51 since: (i) their somatic mutations were each associated with iPFS in C1 ($\alpha = 5\%$)
52 (**Fig 2A**) and (ii) their sequencing in C1 but also in additional public (TCGA COAD) and
53 private cohorts (personal data, not shown) using NGS was successful in at least 95%
54
55

1
2
3
4 percent of tumors (**Fig 2A**) or in other words that these loci were particularly easy to
5 analyze. A predictive nature of this 19-plex identified DNA signature based on the
6 concomitant analysis of their microsatellite somatic variations in tumor DNA as
7 compared to matched normal DNA was then evaluated by simply calculating for each
8 patient the mean count of all the mutations in those microsatellites
9 (**SUPPLEMENTARY FIGURE S3**). We also used Multinomial Naive Bayes (MNB) as
10 a simple Machine Learning method to predict the risk of progression with the 19-plex
11 signature ³⁴. We trained the MNB method on Nipicol (C1) and validated it on
12 ImmunoMSI (C2). Applying the trained model in C2 (Validation cohort), we were able
13 to show that the same 19-plex MSI signature was significantly associated to iPFS
14 ($HR_{C2} = 13.1$; 95% CI [2.71-63.8] ; $p = 1.4 \times 10^{-3}$) (**Fig 2B**). **FIGURE 2** further illustrates
15 how the 19 microsatellite mutations contribute to predicting resistance to ICI in MSI
16 mCRC patients (see the heatmap on **FIG. 2E**). In the multivariate analysis we
17 conducted in C2 including molecular and clinical data (e.g., *KRAS* and *BRAF* mutation
18 status) as well as the type of immunotherapy, the independent prognostic value of this
19 19-plex MSI signature was confirmed ($HR_{C2} = 13.5$; 95% CI [2.38-76.6] ; $p = 3.3 \times 10^{-3}$)
20 (**Fig. 2F**).

36 **Transcriptomic signatures and response to ICI in MSI mCRC patients**

37
38 Previous studies have provided evidence of the predictive value of RNA signature
39 for immunotherapies. Three types of established signatures of response to ICI were
40 systematically assessed in both discovery (C1) and validation (C2) cohorts: signatures
41 quantifying cellular components of the tumor microenvironment (n=99), single gene
42 expression levels (n= 19,116), and signaling pathway activity estimation from gene
43 expression levels (n= 3,365). None of these established transcriptomic-based
44 signature could be reproducibly associated to iPFS in the two ICI-treated MSI mCRC
45 cohorts, including those specifically associated to ICI response in previous studies in
46 MSS tumors (e.g., PD-1, PD-L1 +/- CTLA-4, T or B cells) (**SUPPLEMENTARY FIGURE**
47 **S4**). More specifically, gene sets involved in angiogenesis, epithelial-to-mesenchymal
48 transition, canonical TGF-beta and Wnt/Wingless signaling pathways, as well as TNF,
49 interferon, KRAS or mTOR had either a minor and unreproduced association with iPFS
50

55
56
57
58
59
60

1
2
3
4 in only one cohort but more generally no significant correlation with survival in any of
5 the two ICI-treated MSI mCRC cohorts (**SUPPLEMENTARY FIGURE S5**).

6
7 In order to identify context-dependent transcriptomic signatures (*i.e.*, phenotypic
8 descriptors effectively observable in MSI mCRC), an unsupervised blind source
9 separation approach was applied to the transcriptome profiles of the discovery cohort
10 (C1; *i.e.*, independent component analysis; ICA) (**SUPPLEMENTARY FIGURE S6**).
11 Only one of these components was associated to shorter iPFS in both C1 and C2
12 ($HR_{C1} = 1.87$; 95% CI [1.06-3.3] ; $p = 0.0282$ - $HR_{C2} = 1.75$; 95% CI [1.03-2.98] ; $p =$
13 0.035) (**Fig. 3B and 3C and SUPPLEMENTARY FIGURE S6**). The component was
14 significantly correlated to an RNA-based quantification of fibroblasts ($p < 0.001$) and
15 anti-correlated to the tumor cellularity ($p < 0.001$) confirming its stromal origin (**FIG. 3A,**
16 **SUPPLEMENTARY TABLE S3** for the list of genes most contributing to this stromal
17 component). This fibrosis signature was associated to a tendon-like phenotype,
18 extracellular matrix (ECM)-producing and interacting genes, enriched intra-tumor
19 CMS4 proportions, and a pan-fibroblast TGF- β response signature (PMID: 29443960)
20 (**FIG. 3A and SUPPLEMENTARY FIGURE S7**). The fibrosis signature was not related
21 to stromal abundance, as measured by Sirius Red staining (**SUPPLEMENTARY**
22 **FIGURE S8**). Exactly as this was previously performed with the DNA signature, we
23 confirmed the independent prognostic value of this RNA signature using a multivariate
24 analysis in C2 ($HR_{C2} = 1.78$; 95% CI [1.03-3.01] ; $p = 0.040$) (**Fig. 3D and**
25 **SUPPLEMENTARY TABLE S1**). We successfully reduced this RNA signature to a
26 more serviceable set of 182 biomarkers (**SUPPLEMENTARY TABLE S4**). Using this
27 raw sub panel, the spearman correlation with the original component was 0.98 in
28 NIPICOL and 0.96 in immunoMSI (**SUPPLEMENTARY FIGURE S9**). Both remained
29 associated with iPFS as continuous scores. **SUPPLEMENTARY FIGURE S9** shows
30 the Kaplan-Meier curves of iPFS using the same cut-off as with the original signature.

52 **Multivariate Analyses combining the DNA and RNA signatures**

53
54 We finally examined the effect of both RNA and DNA signatures in predicting iPFS
55 to ICI in MSI mCRC patients using a multivariate model (**FIG. 4**). Either when taking
56 into account both signatures in a continuous or a discrete way, the multivariate analysis
57 indicated that both signatures were independently predictive of iPFS (**FIG. 4A**). **Figures**
58
59
60

1
2
3
4 **4B** (and **SUPPLEMENTARY FIGURE S9**) show how these DNA and RNA signatures
5 are complementary and effective when used together in predicting the response of
6 patients to ICI treatment. One and/or another of the signatures was able to predict
7 progression in patients from C2 regarding iPFS to ICI ($HR_{C2} = 6.0$; 95% CI [1.80 –
8 19.9] $p = 9.12 \times 10^{-4}$). This makes these signatures a valuable classifier tool capable of
9 predicting relapse in MSI mCRC patients (see also on **SUPPLEMENTARY FIGURE**
10 **S10** the performance of this combined analysis when the RNA stromal signature was
11 reduced to 182 markers).

17 18 **DISCUSSION**

19
20
21
22
23 In this study, we examine the issue of response to ICI in patients with dMMR/MSI
24 mCRC. Two prospective cohorts of patients are examined to investigate this question.
25 The study is limited to CRC patients only, thus avoiding the risk that the origin of the
26 primary tumor might interfere with the results. The dual approach of high-throughput
27 analysis of tumor DNA and RNA enables us to perform both supervised and
28 unsupervised analyses in the aim of investigating ICI-response associated genotypes
29 and phenotypes. Note worthily, the dMMR/MSI status of the tumors was systematically
30 rechecked in our expert center as part of this ancillary study to avoid misdiagnoses
31 which can deeply impact the findings of such translational research studies, as
32 reported ^{24, 35}. All these points constitute methodological strengths of the present work
33 compared to others in the field which remain few and based on smaller number of
34 patients.
35
36
37
38
39
40
41
42
43

44
45 We first show that several previously suggested DNA and RNA indicators are
46 unlikely to have any robust predictive values regarding response to ICI in MSI mCRC
47 patients. This is primarily the case for the quantitative DNA markers MSIsensor score
48 and TMB ^{15, 16} when the diagnostic errors regarding the MSI status of the tumors are
49 corrected upstream and false positive MSI cases with expected low MSIsensor score
50 and TMB are therefore excluded. In addition, our analyses based on previously defined
51 candidate DNA/RNA markers of resistance, e.g., specific somatic DNA variants, the
52 activity of canonical signaling pathways or the presence of specific cellular contingents
53 within the tumor bulk, also failed to identify robust predictors of ICI response in patients.

Though some of these markers may contribute to some extent to modulate the patients' response to ICI in some dMMR/MSI mCRC as suggested by some studies carried out on smaller series of patients, and more generally may be predictive of ICI efficacy in MMR proficient tumors, they are unlikely to have major clinical relevance.

The breakthrough results we have achieved in this study stem from the fact that we report and validate in both cohorts two distinct original signatures derived from a global analysis of the DNA and RNA profiles of ICI-treated MSI mCRC. In brief, the DNA signature is epithelial in nature. It analyzes the combination of a 19-plex panel aggregating independent somatic mutational events in dMMR tumor cells involving both coding and noncoding microsatellite containing-genes associated to distinct biological processes. As some microsatellite mutations such as those in the pentaplex are relevant for MSI diagnosis in CRC, the combined analysis of these 19 microsatellites is of predictive interest for response to ICI as evaluated by iPFS in patients. In addition, the RNA signature is stromal in nature. Though it is TGFB-related with a desmoplastic orientation, the fact that Sirius Red staining does not discriminate between samples with and without this stromal signature illustrates its complex nature. Note worthily, all the previously defined signatures and pathways that were shown to be associated to the proposed transcriptomic-defined TGFB-related fibrotic signature were not themselves associated to progression in both cohorts. This highlights the importance of defining context-dependent signatures, in particular in such distinct carcinogenic and microenvironment context as those found in MSI mCRC. In relation to a rich literature that has already provided evidence that the extracellular matrix and its heterogeneous content could promote resistance to ICI in MSS tumor models associated with various primary locations (for review see ³⁶), the RNA contingent we are identifying could thus play such a role by promoting, for example, immune-exclusion or sequestration processes in the context of increased fibrosis generated in and around the tumor. It could also modulate the response to treatment through non-mutually exclusive mechanisms involving more specifically the cancer-associated fibroblasts hosted in or responsible for the matrix generation.

Our work has some limitations. First, it does not address the issue of the choice of immunotherapy, i.e., monotherapy with anti-PD1 or combination of anti-PD1 and anti-CTL4, which is an important issue today. Second, the question of epigenetics is an

1
2
3 especially important issue that is not here addressed and will require further
4 investigation in subsequent studies. Third, our work does not really shed light on simple
5 mechanisms underlying resistance to ICI in MSI mCRC. In this respect, it is not yet
6 very enlightening for the identification of novel therapeutic targets that could be of
7 interest in the future for patients with primary or secondary resistance to anti-PD-1 ±
8 anti-CTLA4. Finally, although our results were established on a large prospective
9 collection of patients including two independent cohorts, one of which is a clinical trial,
10 they still require validation in new populations of metastatic MSI cancer patients, with
11 colorectal tumor but possibly also other primary MSI cancer. Despite these
12 weaknesses, the 2 signatures we outline here from the analysis of the tumor bulk are
13 easy to investigate and can be implemented in the context of a clinical routine; the
14 DNA signature requires the analysis of the status of only 19 microsatellite markers
15 within the tumor, ideally by NGS but possibly also by other methods while the RNA
16 signature requires to perform 3'RNA-sequencing which is a simple, reproducible and
17 feasible method to be used with paraffin-embedded tumor samples, the cost of which
18 has now decreased considerably. Of interest, we demonstrate that the RNA signature
19 reduced to 182 markers is still clinically relevant for predicting iPFS to ICI. Finally, it is
20 very interesting to note that the DNA and RNA signatures have independent predictive
21 value and can be used jointly to predict progression in ICI-treated MSI mCRC patients.
22 This should be of interest for the design of future strategies improving ICI for MSI
23 cancer patients in clinics.

FIGURE LEGENDS

Table 1: Patients description from C1 and C2 cohorts with main corresponding clinical data

Figure 1: Workflow and Study Design

MSS, microsatellite stable; mCRC, metastatic colorectal cancer; ICI, immune checkpoint inhibitors; IHC, Immunohistochemistry; QC, quality control; pMMR, mismatch repair proficient.

Figure 2: Identification of a 19-plex MSI signature predictive of response to ICI in mCRC patients

A) Histogram of p -values from cox analysis for R variants (microsatellites) in the C1 Nipicol cohort. A zoom was performed on those having a p -value lower than 0.1 ($n = 167$). Genes' name of the 19 somatic MS variants with a known percentage of missing data $< 5\%$ in C1 and other public and private cohorts are indicated in green. They were used further for investigating iPS to ICI in C2.

B) Counts of microsatellite somatic variants according to their p -value (uni-variate Cox regression model) on the 23 patients of Nipicol (C1). Green and red bar represent the mutated microsatellites with a p -value < 0.05 and $0.05 \leq p$ -value < 0.1 , respectively. The top forestplot represent in C2 the Cox survival regression results on model prediction of risk output, represented by the hazard ratio (HR < 1 : beneficial, HR = 1 No effect, HR > 1 : deleterious). High (p -value < 0.05 , DNA signature) in green vs low stringency of Cox features selection based on p -value in red.

C) iPFS curve for the TMB and the MSIsensore score.

D) Kaplan-Meier curves of iPFS are shown accordingly to risk probability in ImmunoMSI only ($n= 66$). Red curve corresponds to patients with high MNB probability ($<20\%$) and blue curve corresponds to patients with low MNB probability ($>20\%$).

E) Heatmap representation of NIPICOL (C1) and ImmunoMSI (C2). Overview of mutations profile for each patient on the list of 19 selected microsatellites (MS, see

genes' name and chromosomal location on the left). Bottom bars represent their treatment (combo-therapy or mono-therapy), survival (time-to-event), event (Progressor or Non-Progressor), DNA.signature (probability of non-response according to iPFS given by the MNB), KRAS and BRAF mutational status. Patients are ordered based on predicted risk of progress and MS are ordered in function of mutation frequency in Nipicol cohort.

F) Forest plot of the multivariate Cox regression with iPFS in cohort C2, with its corresponding p -value. Included features are DNA signature (low to high risk), BRAF, KRAS (wild-type vs mutated status) and treatment (mono vs. combo).

Figure 3: Transcriptomic signatures and response to ICI in MSI mCRC patients

A) Heatmap of the stromal signature, patients (in column) are ordered by the estimated quantification of the stromal ICA signature. iRECIST status of patients²⁹ are shown along with gene-wise centered expression values of the gene most associated to the component, tumor purity estimated by the non-repeated variant allele frequency, MCPcounter -based fibroblast quantification estimate, the main CMS (consensus molecular subtype) and the intra-tumoral proportion estimate of CMS4, and TGFB response signature³⁷. Pathway-level activity estimate are also shown along with the Gene Set Enrichment Analysis estimates.

B) Univariate association with progression-free survival in Nipicol (C1, n=44) or ImmunoMSI (C2, n=71) of the continuous score of the signature or of a classification using the third quartile as a threshold (Q3 cut-off).

C) Kaplan-Meier estimates using the third quantile threshold of the stromal signature.

D) Forest plot of the multivariate Cox regression with progression-free survival in cohort C2, representing hazard ratio (HR < 1 : beneficial, HR = 1 No effect, HR > 1 : deleterious) with its corresponding p .value. Included features are stromal signature (low to high), BRAF, KRAS (wild-type vs mutated), and treatment (mono vs. combo).

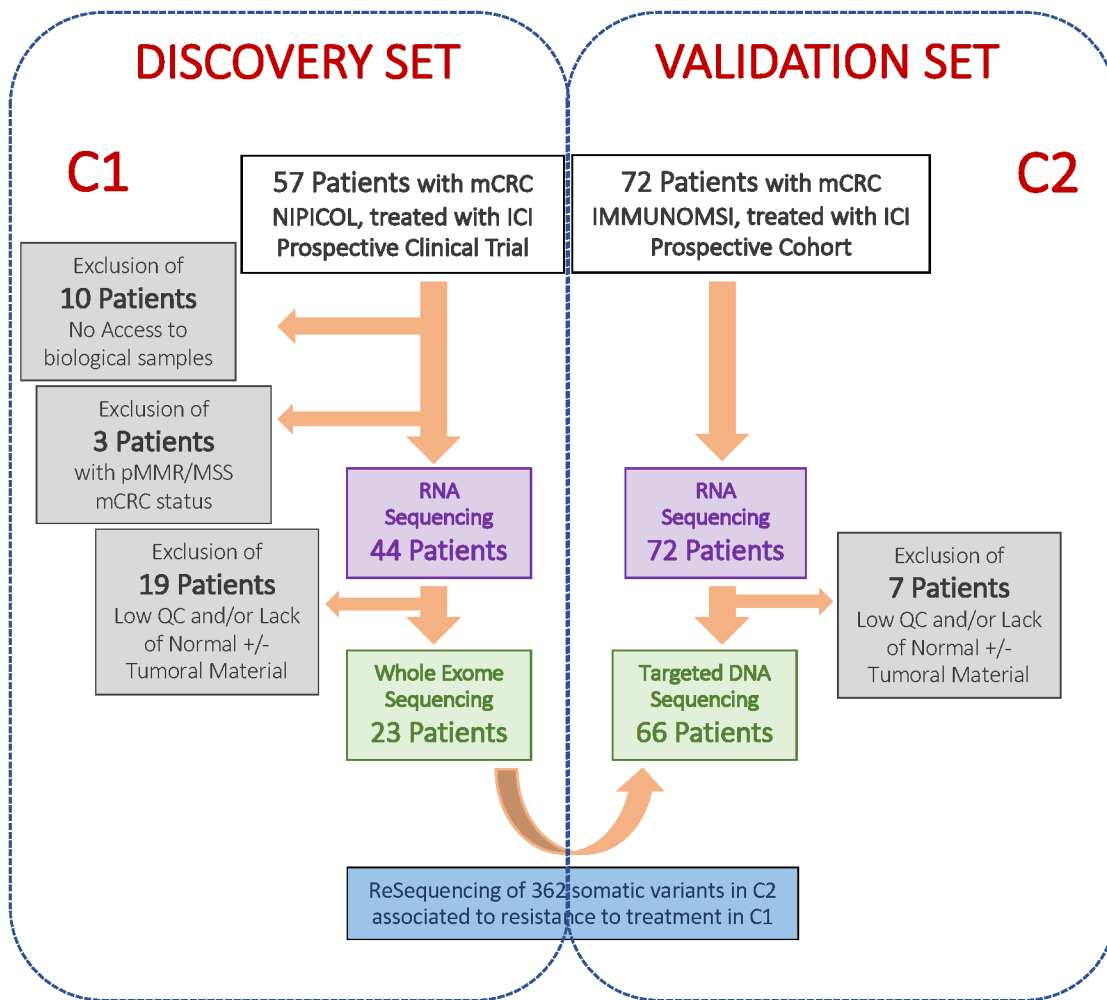

Figure 4: Multivariate Analyses combining the DNA and RNA signatures

1
2
3
4 **A)** Forestplot of the RNA or DNA signatures as well as the treatment type considering
5 the continuous value (upper panel) or by discretizing the values (lower panel) of the
6 signatures.
7

8 **B)** Kaplan-Meier estimates of iPFS as a function of the intensity combination of the two
9 signatures (n=66). High RNA and DNA signatures are shown in red. Low RNA and
10 DNA signatures are shown in green. High RNA signature and weak DNA signature are
11 shown in orange and low RNA signature and high DNA signature are shown in purple.

SUPPLEMENTARY MATERIALS AND METHODS

Sample preparation and sequencing

RNA sequencing was performed on the same platform for all patient cohorts included in this work, whether or not they were treated with ICI. For the DNA analyses, all exome sequencing was performed with comparable qualitative parameters (e.g., ~50X depth for normal samples and ~200X depth for tumor samples). The exome profiles were produced by the Integragen platform. For the C2 cohort (targeted NGS panel, ICM platform), depth of coverage was likely similar, comprised between 50X and 300X. For the C1 cohort, genomic DNA isolated from formalin- fixed paraffin- embedded (FFPE) were captured using Twist Human Core Exome Enrichment System (Twist Bioscience) + IntegraGen Custom as previously described ¹. For the C2 cohort, hybridization probes and extension primers were designed using Roche's HyperDesign Tool for NGS Target Enrichment process. Sequence capture, enrichment and elution were performed according to manufacturer's instruction and protocols without modification except for library preparation performed with NEBNext® Ultra II kit (New England Biolabs®). DNA samples were then sequenced on an Illumina NovaSeq as Paired-end 100 reads. The generated reads were mapped to the reference genome hg38 (GRCh38).

Exome Analysis and Mutational load

Variant calling for the identification of SNVs (Single Nucleotide Variations) and small insertions/deletions (up to 20bp), was performed via the Broad Institute's GATK Haplotype Caller GVCF tool (GATK3.8.1) for constitutional DNA and via the Broad Institute's MuTect tool (2.0, --max_alt_alleles_in_normal_count=2; --max_alt_allele_in_normal_fraction=0.04) for somatic DNA. A two-sided Fisher's Exact Test is applied after MuTect2 variant calling to improve filtering of variants with strand bias. The tumor mutational burden (TMB) is calculated by dividing the number of somatic mutations by the number of bases having a depth greater than 10. The somatic mutations used for the mutational load were filtered as follows: Somatic score ≥ 3 ,

1
2
3 Mutated Allele Frequency in Tumor tissue $\geq 5\%$, Mutated Allele Count in Tumor tissue
4 ≥ 3 , Mutated Allele Frequency in Constitutional tissue $< 4\%$.
5
6
7
8
9

10 MHC class-I neoepitopes prediction

11
12 Neopeptides prediction was performed using *Ideation@SiRIC* pipeline which
13 combines several software. First, HLA typing for MHC class-I genes was carried out
14 using seq2HLA ² software for all 26 normal-wes fastq files, with default parameters.
15 Next, Somatic mutation filtered VCF files from Mutect2 were annotated by Variant
16 Effect Predictor (Version 99) with default parameter, except for the using of 'Frameshift'
17 and 'wild-type' plugins offer by pVACseq from pVACtools suite ³. After annotation, the
18 variant items that lead to peptide changes were extracted out for downstream analysis.
19 vcf-expression-annotator from VAtools v5.0.1 were then used to add transcripts
20 expression levels (using 3' RNA sequencing) for each variant. Annotated non-
21 synonymous mutations, frameshift variants and sequencing-based information as well
22 as HLA class-I gene typing results inferred by seq2HLA were fed into pVACseq for
23 neoantigen prediction. For each pVACseq run, epitope prediction was done by both
24 NetMHC ⁴ and NetMHCpan ⁵ algorithms packed in pVACseq toolkit, epitope length
25 was set to 8–10 with default parameters used for all other settings. At last, we applied
26 coverage and expression-based filters besides median binding affinity filtering criteria
27 on the predicted neoepitopes. We filtered neoepitope with tumor DNA VAF $\leq 5\%$,
28 along with TPM ≥ 1 for transcript level expression. Afterward, we kept only
29 neoepitopes with TSL (Transcript Support Level) equal to 1 and median affinity binding
30 ≤ 500 . To calculate the number of neoepitopes per tumor, we sum up unique filtered
31 mutants peptides sequences per tumor.

49 Feature selection and data pre-processing

50
51 To reduce our dataset (over 279 positions explored) to the most relevant positions,
52 we decided to keep only the positions with a Cox regression p -value in Nipicol lower
53 than 0.05 ⁶. We also decided to only focus on variations in microsatellite regions.
54 Finally, we have applied a filter to the maximum rate of missing data allowed in a
55 position in Nipicol. To do so, we firstly calculated this value in other available WES
56 cohorts of MSI CRC, i.e., the public cohort TCGA and two other large private cohorts
57
58
59
60

1
2
3 we have already sequenced and analyzed in the lab (data not shown). This allows us
4 to exclude positions that are generally difficult to sequence. Secondly, we did the same
5 on the Nipicol cohort to exclude the remaining mis-sequenced positions. We have
6 chosen to allow a maximum of 5% of missing data per MS over the external WES or
7 Nipicol. With those filters we selected 19 microsatellite variations of interest.
8
9
10
11

12 In order to train a MNB model on our DNA sequencing data, we had process missing
13 sequencing data at certain locations for some patients. Indeed, MNB does not support
14 missing data in its learning or prediction. As a result, the missing data must be imputed.
15 We imputed missing data using by using a discrete uniform distribution drawing wild-
16 type or mutated based on the mutation frequency of the microsatellite.
17

19
20
21
22
23

24 **DNA signatures : mutation count and Multinomial Naives Bayes**

25
26 To calculate normalized mutation count we firstly had to take into account the
27 impact of the mutation on the ICI response. To do so, we inverted the status of the
28 microsatellite mutation associated with a good response to ICI. As a results we
29 obtained a matrix containing for each patient the genotype effect for each microsatellite
30 (0 for beneficial and 1 for deleterious). Then, for each patient, we summed up the
31 microsatellite status and divided it by the number of microsatellite sequenced.
32
33
34
35
36

37 For the MNB, we used a matrix containing the mutation status for each microsatellite
38 in every Nipicol patient (1 for mutated, 0 for wild-type) as the input values and the iPFS
39 status as the binary target values. We obtained a model that was able to predict the
40 progression risk of a patient taking into account its sequencing on the 19 microsatellites
41 investigated.
42
43
44
45

46 To validate our models, we calculated the mutation count and predicted the
47 progression risk for each ImmunoMSI patients. Then we ran an univariate Cox
48 regression model to investigate the association between the survival and those new
49 signatures.

Total RNA was extracted for every tumor sample using QIAGEN Allprep protocol (ref 10.2144/000113829). 150ng of total RNA was used to generate RNAseq sequencing library using Lexogen Quantseq 3' FWD kit and sequenced by the Institut du cerveau iGenseq platform on a NovaSeq 6000 aiming for a minimum of 10 million reads. Raw RNAseq reads were mapped to the human genome (Ensembl GRCH38) and Ensembl's reference transcriptome using STAR. Gene counts were obtained using FeatureCount, normalized by an UpperQuartile procedure and logged on a base 2.

Gene-set definitions of pathways were taken from the Molecular Signature Database (MSigDB v7.5.1) as well as the BioPlanet pathways database (2019) which was downloaded from the EnrichR website. Pathway-level activity was inferred from gene expression levels using the GSVA method with a Gaussian kernel. Based on the ImmuneDeconv evaluation and implementation, five methods for tumor microenvironment quantification were used: XCell, EPIC, Cibersort, MCPcounter and Estimate. Multiple hypotheses testing correction using Benjamini-Hochberg's to control False Discovery Rate (FDR) was only applied to select significant events using an alpha 5% to reject H0.

Independent Component Analysis (ICA) was performed on the sample-wise centered gene expression values of the 5,000 genes with the highest average and variable (as measured by standard deviation) expression. The JADE (joint approximation diagonalization of Eigen-matrices) algorithm was applied to extract 10 components as previously described ⁷. The ICA components were projected on other transcriptomic dataset by first selecting genes in common in the reference ICA (computed from the C1 cohort) and in the new transcriptomic dataset. The cross-product of the gene-weight inverted matrix was used as the projection of a new dataset, resulting in 10 scores (one per ICA component) for each new sample.

The intra-tumor proportion of the consensus molecular subtypes of colorectal cancer were estimated using the centroids of the original study ⁸ and the WISP deconvolution method (cit-bioinfo.github.io/WISP/).
