#### 23 ABSTRACT

In anisogamous species, sexual selection is expected to be stronger in males. Bateman's principles 24 25 state that the variance in (i) reproductive and (ii) mating success is greater for males and (iii) the relationship between reproductive success and mating success (the Bateman gradient) is also 26 27 stronger for males than for females. Sexual selection, based on Bateman's principles, has been 28 demonstrated in animals and some angiosperms, but never in a seaweed. Here we focus on the oogamous haploid-diploid rhodophyte Gracilaria gracilis in which previous studies have shown 29 30 evidence for non-random mating, suggesting the existence of male-male competition and female 31 choice. We estimated mating and reproductive success using paternity analyses in a natural 32 population where up to 92% of fertilizations occurred between partners of that population. The 33 results show that the variance in mating success is significantly greater in males than in females and that the Bateman gradient is positive only in males. Distance to female partners also explains a 34 35 minor part of the variance in male mating success. Although there is no evidence for sexual 36 dimorphism, our study supports the hypothesis that sexual selection occurs in G. gracilis, likely on 37 male traits, even if we cannot observe, characterize or quantify them yet.

38

#### 39 INTRODUCTION

Sexual selection arises from competition among individuals for the access to mates and/or to their gametes [1]. Historically developed to explain the sexual dimorphism of secondary sexual traits in animal species [2], sexual selection theory postulates that anisogamy should lead to strong competition among males for the access to females and ovules [3]. Therefore, under this postulate, any trait that increases the successful access to female mating partners should greatly affect male reproductive success [4]. This theory thus constitutes a satisfying explanation for the frequently

observed male-biased sexual dimorphism in several categories of traits, including ornaments and 46 47 armaments (but see [5]). Sexual selection in both sexes has been quantified in a large number of 48 animal species using metrics derived from Bateman's principles [6]: (i) the opportunity for selection *I*, i.e. the variance in relative reproductive success; (ii) the opportunity for sexual selection *Is*, i.e. 49 50 the variance relative in mating success and (iii) the Bateman gradient, i.e. the slope of the regression of relative reproductive success as a function of relative mating success [7]. The sex associated with 51 52 the highest value of these three metrics is considered as the one under stronger sexual selection. A 53 recent meta-analysis focusing on animals indeed shows that both the Bateman gradient and the opportunity for sexual selection are more often higher in males [8]. Although this trend appears 54 stronger in species with male-biased sexual dimorphism in terms of morphological or behavioural 55 traits (i.e. males developing large body, bright colours or exuberant and acrobatic courtship 56 57 displays), a number of studies have reported stronger sexual selection, or opportunities of sexual 58 selection, in males within species in which no sexual dimorphism has been documented [8].

59 The use of these metrics of sexual selection has been largely biased towards animals, mainly vertebrates and non-sessile invertebrates [8]. Although it has been acknowledged that stronger 60 61 sexual selection in males should occur in any anisogamous species [9], very few studies have attempted to directly verify this prediction in other anisogamous eukaryotes which typically lack 62 copulation and for which cognitive traits (such as those involved in partner choice behaviours, 63 64 sensus stricto). Therefore, these anisogamous eukaryotes, such as plants, provide stimulating study models for the empirical test of sexual selection. Sexual selection in angiosperms, although once 65 fiercely debated [9,10], is now widely recognized as a possible evolutionary force, which may indeed 66 67 be stronger through the male function of hermaphrodites or in male individuals in dioecious species, at least when pollen supply is not limiting [11–13]. Among the arguments in favour of the existence 68 of sexual selection in plants, the occurrence of male-biased sexual dimorphism in dioecious plant 69

species (e.g. males with larger or more numerous flowers than females) suggests that selection 70 71 through the male function to attract pollinators or to invest in reproduction may be indeed stronger 72 [14–16]. Nevertheless, Bateman's metrics have been estimated and compared between males and females in only three angiosperm species. In all three cases, sexual selection was found to be 73 stronger in males, and results were at least partly consistent with the sexual dimorphism 74 documented in these species [17–19]. Nonflowering plant species have been investigated even less 75 76 on the topic of sexual selection. Only one study, carried out on a non-sexually dimorphic moss, 77 estimated Bateman gradients and found evidence for a steeper relationship between reproductive and mating success in male gametophytes [20]. These results suggest a potential for stronger sexual 78 79 selection in males of this anisogamous species, but this does not appear to have driven the evolution of sexually dimorphic traits. Noteworthily, this particular study was performed in a population with 80 81 an extreme male-biased sex ratio, a feature that has been found to be associated with higher 82 opportunities for sexual selection and higher Bateman gradients in males [21].

One situation in which stronger opportunity for sexual selection in males would not be associated 83 with sexual dimorphism is when variation in mating success is not determined by heritable traits. In 84 85 plants, their inability to move forces pollen or male gametes to disperse in the environment via pollinators or abiotic factors, so that the exact spatial location of individuals is likely to be a strong 86 determinant of mating success. Several studies have explored the impact of geographical location 87 88 and of local sex ratio on male and/or female reproductive success [22-26], but without explicitly linking their results to sexual selection. Like plants and some animals, red algae are sessile and 89 anisogamous [27]. Male gametes are released in the water and fertilizations occur on the females, 90 91 which is referred as spermcast mating for sessile marine invertebrates [28]. In red algae, male 92 gametes are non-flagellated and we recently demonstrated that isopod-mediated fertilization increases fertilization success [29]. In Florideophyceae, after fertilization, the diploid zygote divides 93

mitotically in a diploid structure, protected and nourished by the parental female haploid 94 95 gametophyte [30]. These characteristics of the reproductive life cycle suggest that fertilization 96 success in this group may be driven by different selection pressures between males and females (i.e. competition between males for access to females or selective cystocarp abortion by the females) 97 98 [31]. In the dioicous red alga Gracilaria gracilis, male fertilization success shows high variance [31,32], suggesting that there may be male-male competition or female choice, a sign of sexual 99 selection. However, to date in this alga, the relationship between reproductive success and mating 100 101 success has not been tested to determine if the Bateman gradient is steeper in males. Here, we compare potentials for sexual selection among male and female gametophytes in G. gracilis by 102 103 estimating the three Bateman indexes in a natural population characterized by a balanced sex ratio. 104 We also explore the role of individual location, relative to individuals of the other sex, on the 105 variation of mating success in both males and females. The investigation of Bateman principles in 106 species outside the clades classically studied for sexual selection should help to understand how and when anisogamy triggers differences in the magnitude of sexual selection between sexes, and 107 108 when such differences can drive the evolution of sexual dimorphism.

#### 109 MATERIAL & METHODS

#### 110 (a) Study species

Populations of the rhodophyte *Gracilaria gracilis* are patchily distributed in the intertidal zone on rocky shores. Individuals occupying rock pools remain immersed at ebb tide. Its life cycle is haploiddiploid, including male and female haploid gametophytes and diploid tetrasporophytes (**figure 1**). Tetrasporophytes produce haploid spores via meiosis that develop into dioicous male and female gametophytes. This species is characterized by a highly specialized type of oogamous reproduction [26]. Spermatia (non-flagellated male gametes) are released into the environment, but female gametes (carpogonium) are retained on the female gametophyte. After fertilization, the zygote

remains on the female gametophyte and develops into diploid sporogenous tissue (gonimoblast) 118 119 protected and nurtured by the parental female thallus, forming a complex, macroscopic post-120 fertilization structure called the cystocarp. The cystocarp is fully mature approximately one month after fertilization. One fertilization event gives rise to thousands of identical diploid spores that, 121 122 after release, can germinate into new tetrasporophyte individuals [33]. The tetrasporophyte, female gametophyte and male gametophyte individuals are considered isomorphic, even though males are 123 slightly smaller than females and tetrasporophytes [34]. Both haploid and diploid individuals are 124 125 long-lived [35]. The thallus is formed of a few erect deciduous main axes, irregularly branched, reaching up to 30 cm long, arising from a small perennial discoid holdfast, fixing the individual to 126 the bedrock. Previous studies have shown that the reproductive period occurs from March to 127 128 September with cystocarp production peaking in August–September [33,36]. Individuals less than 8 129 cm in length are generally non-reproductive.

#### 130 (b) Study population and sampling

131 The study population was located on the coast of the North Sea at Cape Gris-Nez (in the Strait of 132 Dover region, northern France, 50°53'N, 1°35'E) in a pool of ca. 5 m<sup>2</sup> isolated from other populations 133 at low tide [31,33]. In August 2020, every individual in the rock pool was sampled and spatially mapped relative to a pair of fixed points. Maximum thallus length and maximum diameter, 134 135 measured using all the thalli emerging from the holdfast, were recorded for each individual to estimate biomass [35]. Several branches of each individual were sampled and examined under a 136 137 dissecting microscope to establish the sexual phenotype (tetrasporophyte, female or male gametophyte) of each individual based on the observed reproductive structures. Of a total of 238 138 reproductive individuals sampled, 97 tetrasporophytes, 70 females and 71 males were identified 139 (figure 2). There was a balanced sex ratio (1:1). For every female, cystocarps were counted on the 140 10 cm distal extremity of five branches. Thallus fragments were excised from each individual for 141

142 DNA extraction. An average of 32 large cystocarps (ranging from 12 to 48 cystocarps) were randomly

sampled and dissected from each female and stored at -20°C.

#### 144 (c) DNA extraction and microsatellite genotyping

145 For individuals, DNA extraction was performed on approximately 10 mg of dried thallus tissue using 146 the NucleoSpin<sup>®</sup> 96 Plant II kit (Macherey-Nagel, GmbH & Co. KG, Düren, Germany) following the manufacturer's instructions. For cystocarps, DNA extraction was performed using the Chelex 147 148 method (Chelex TM 100; Biorad, Hercules, California), following the protocol described in Wattier 149 et al. [37]. All male and female gametophyte individuals as well as the sampled cystocarps were 150 genotyped using 13 microsatellite loci: Gv2CT [37], Gg121, Gg155, Gg173, Gg182, Gg216 [38], Ggrac 02, Ggrac 03, Ggrac 04, Ggrac 05, Ggrac 08, Ggrac 09, Ggrac 11 [39]. PCR was performed 151 152 in a total volume of 10  $\mu$ L containing 2  $\mu$ L of DNA template diluted 1:50 (gametophytes) or not diluted (cystocarps), 1 X GoTaq Flexi buffer (Promega Corporation), 2 mM MgCl<sub>2</sub>, 150 µM of each 153 dNTP (Thermo Fisher Scientific Inc., USA), 30 pmol of forward fluorescent-labelled primer, 30 pmol 154 155 of reverse primer (Eurofins MWG Operon, Germany), and 0.35 U GoTaq Flexi Polymerase (Promega 156 Corporation). Amplifications were carried out under the following conditions: initial denaturation at 95°C for 5 min, 30 cycles of denaturation at 95°C for 30 s, annealing at 60°C for 30 s, and extension 157 at 72°C for 30 s, followed by a final extension of 72°C for 10 min. Next, 2 µL of the diluted PCR 158 159 product 1:10 was added to 10 µL of loading buffer made up of 0.5 µL of the SM594 size standard [40] and 9.5 μL of Hi-Di formamide, denatured at 95°C for 3 min, and run in an ABI 3130 XL capillary 160 161 sequencer (Applied Biosystems, USA). Genotypes were scored manually in Genemapper version 4.0 (Applied Biosystems). The gametophytes being haploid, for each cystocarp, we were able to deduce 162 the paternal genotype by subtracting the maternal genotype from the diploid cystocarp genotype 163 164 across all loci using the Multilocus Matches option in GenAlEx ver. 6.5 [41,42].

#### 165 (d) <u>Reproductive and mating success</u>

Page 9 of 29

Mating and reproductive success were estimated on the 50 females (out of the 70 initially present in the population, see **figure 2**) for which there was sufficient information (i.e. estimated biomass, cystocarp count per centimetre, and more than 24 cystocarps genotyped).

Mating success is the total number of mating partners per individual. In this study, we estimated 169 170 the genetic mating success, i.e. the number of individuals of the other sex with which at least one 171 zygote was produced, based on the results of the parentage assignment (table S1). Slightly unequal numbers of cystocarps were genotyped across females, which may cause an artificial overestimation 172 173 of mating success for females associated with a higher sampling effort. Mating success for both 174 sexes was thus estimated using a bootstrapping procedure in which we resampled 24 genotyped offspring (cystocarps) 1000 times for each female. The genetic mating success for each individual 175 176 was calculated from each resampling and, in further analyses, the mean "individual" mating success value was used. 177

Female reproductive success is the total number of offspring a female produces. We estimated the female reproductive success by multiplying the mean number of cystocarps per cm<sup>3</sup> counted on 5 branches by the total volume of the individual (**table S2**) as a proxy for individual biomass [34].

181 Male reproductive success is the total number of offspring a male sires. Male reproductive success can thus be estimated as the proportion of each female's cystocarps sired by that male, as 182 183 determined from the parental assignment (table S1), multiplied by female reproductive success and summed over all surveyed females (table S3). At each sampling step of the bootstrapping procedure 184 performed for estimating mating success described above we calculated the proportion of 185 186 cystocarps sired by each male in all male-female pairs, to obtain an estimate of male reproductive 187 success for each male individual. The mean value of male reproductive success resulting from the bootstrapping procedure was retained as an estimate of male reproductive success. 188

- 189 The relative reproductive and mating success of females and males were calculated by dividing the
- 190 obtained values for each individual by the respective mean for each sex (**tables S2, S3**).

#### 191 (e) Distance to partners

To estimate the effect of distance on variation in male and female mating success, the distance of each individual to all potential mating partners (i.e. individuals of the other sex) was calculated using individual geographic coordinates within the population. The mean of these distances was used as a proxy for the potential access to mating partners (**tables S2, S3**).

#### 196 (f) Statistical analyses

All analyses were performed using R Statistical Software (v 4.0.3; R Core Team 2020) [43]. Function
lm() was used for all the linear regression analysis. Function leveneTest() was used for Levene
tests. The complete script of bootstrapping procedure and path analyses are available in Dryad
(see data availability section).

#### 201 Bateman's metrics

202 We quantified the strength of sexual selection in each sex using Bateman's metrics [44–46]. First, we estimated the standardized variance in reproductive success, I and in mating success Is. I and Is 203 were calculated by dividing respectively the variance of reproductive and mating success by the 204 205 square of their mean value. We tested for differences in reproductive and mating success variances 206 between sexes using Levene's test. In addition, we estimated the slope of the linear regression of 207 relative reproductive success as a function of relative mating success (Bateman gradient), on each sex separately. We then analysed the whole dataset with a linear model that tested for the effect 208 of mating success and of the interaction between mating success and sex. Because uneven sampling 209 210 between males and females may artificially increase the estimates of variance and the statistical 211 power of the estimate of the Bateman gradient in males, a bootstrapping procedure was used to (i)

compare both *I* and *Is* between males and females 50 times and (ii) test for the Bateman gradient

in males, based on a subsample of 50 males only.

#### 214 **Distance to partners**

A linear regression of relative mating success over the mean distance to potential partners was tested for males and females separately. A similar model was built, this time to test the effect of distance to partners on reproductive success, again testing males and females separately. Finally, we built a multiple linear regression of relative reproductive success over relative mating success and distance to potential partners (i.e. the equivalent of a partial Bateman gradient), to test whether any detected effect of the distance to partners on reproductive success was mediated through an impact of distance on mating success.

#### 222 Path analyses: indirect effects of distance and biomass on mating and reproductive success

In addition, we used a pathway analysis approach (Structural Equation Modelling, see also [47]), in 223 order to dissect direct from indirect effects of distance to potential mating partners on reproductive 224 225 success. More precisely, we tested whether the distance to potential partners affected mating success and whether this had an indirect effect on reproductive success, while testing the 226 227 relationship between mating and reproductive success. We also assessed the direct relationship between distance to partners and reproductive success. This was done simultaneously on males and 228 229 females, using the piecewiseSEM package in R [48]. We then performed a multigroup analysis using 230 local estimation of the parameters, by first providing statistics for sex × distance interaction using type III ANOVA. This allowed us to test whether the direct or indirect effects of distance to partners 231 232 on reproductive success were significantly different between sexes. Testing the effect of sex x 233 mating success interaction on reproductive success provided an additional test of a difference in the 234 Bateman gradient between sexes. In a second step, the analysis provides correlation estimates and

significant sex × variable interactions are free to vary between males and females. These results were compared to results of the linear models described above. Finally, we used the same path analysis approach by additionally testing for indirect and direct effects of individual biomass on reproductive success. Because biomass was used to estimate female reproductive success, this last analysis was performed only on males.

240 **RESULTS** 

Paternity analysis, performed by genotyping 1495 cystocarps from 50 females, revealed that 92% of the fertilization events (1371 cystocarps) occurred with males located in the population and only 8% (124 cystocarps) with males from outside. Of the 71 reproductive males in the population, we did not detect any sired cystocarps for five of them (**tables S1, S2**) and these five were thus assigned a null reproductive and mating success.

#### 246 (a) <u>Bateman's metrics</u>

Reproductive success, i.e. the total number of offspring, ranged from 0 to 48,112 for males and from 247 1215 to 66,495 for females (figure 3A-D, tables S1, S3). Mating success, i.e. the number of sexual 248 249 partners, ranged from 0 to 27 for males and from 4 to 18 for females (figure 3 B-E, tables S1, S3). 250 Both the opportunity for selection I and the opportunity for sexual selection Is were stronger for 251 males than for females (I: 1.18 versus 0.66; Is: 0.74 versus 0.05), although this difference was significant only for mating success in males (Levene's test: I: F<sub>1,119</sub>=0.47, P=0.49; Is: F<sub>1,119</sub>=28.75, P< 252 0.001). These results were not qualitatively affected when these analyses were performed on a 253 subsample of 50 males to obtain equal sample sizes for males and females. Bateman gradients 254 255 investigated for each sex separately provided different results in males and females: no significant 256 relationship was found between relative mating and reproductive success in females (slope ± s.e.:  $0.46 \pm 0.53$ , P=0.39), whereas it was significantly positive in males (slope  $\pm$  s.e.: 1.17  $\pm$  0.05, P<0.001) 257 (figure 3C-F). This result still held when the Bateman gradient was analysed on a subsample of 50 258

Page 13 of 29

males to have the same sample size as in the female dataset. However, when relative reproductive success of males and females were analysed conjointly, mating success had no effect (slope  $\pm$  s.e.: 0.46  $\pm$  0.39, *P*=0.25) and the interaction between mating success and sex was non-significant but with a p-value of 0.08 (slope  $\pm$  s.e.: 0.71  $\pm$  0.40, *P*=0.08). When using the path analysis approach, we detected a significant effect of sex x mating success interaction on reproductive success, with mating success positively affecting reproductive success in males only (**figure S2**).

One potential weakness of our approach is that we set a maximum value of female mating success (i.e. the number of genotyped offspring per female), which could artificially decrease the estimated female mating success and flatten the Bateman gradient in females. This is an unavoidable limit of such an approach, when exhaustive genotyping is not an option, as already underlined in similar studies [19,49]. However, in our case, the observed shared paternity among offspring of the same female (see **table S1**) suggests that estimated female mating success would not necessarily strongly increase if we had genotyped a higher number of offspring for each female.

(b) <u>Distance to partners and male biomass explained part of the variance in mating success</u>

273 The mean distance to potential mating partners ranged from 0.88 m to 2.18 m for females, and from 0.78 m to 2.59 m for males (tables S1, S3). In males, mating success significantly decreased when 274 their distance to potential female partners increased (slope ± s.e.: -0.93 ± 0.21, P<0.001) (figure 4A). 275 The same result was observed for reproductive success (slope  $\pm$  s.e.: -1.01  $\pm$  0.28, P<0.001) (figure 276 277 **S1**). However, when the distance to potential partners and mating success were simultaneously 278 included in a linear regression of reproductive success, only mating success was found to have a 279 significant effect (slope ± s.e.: 1.21 ± 0.07, P<0.001) and the distance effect was no longer significant 280 (P=0.40). This result suggests that the effect of distance to potential partners on male reproductive success was mediated through an effect on male mating success. In contrast, distance to potential 281 male partners had no effect on either female mating success (P=0.48) (figure 4B) or reproductive 282

success (*P*=0.23) (**figure S1**). The path analysis approach provided very consistent results, with an indirect effect of the distance to potential partners on reproductive success, mediated through the interaction between mating and reproductive success, in males but not in females (**figure S2**). Finally, when focusing on males only, we found that individual biomass positively affected mating success, thus having an indirect positive effect on reproductive success. Adding the biomass in the model did not qualitatively modify the effects of distance to potential female partners described above (**figure S3**).

#### 290 DISCUSSION

In this first ever test of Bateman's principles in an oogamous red alga, we found evidence in support of two of Bateman's three principles, suggesting a greater potential for sexual selection in males than in females in *Gracilaria gracilis*. We also detected an effect of individual location relative to potential mating partners on male mating success, which indirectly affects their reproductive success. Below, we discuss these different results in the light of red algal reproduction biology and their possible implications for processes of sexual selection in this species.

The first result of our study was that the variance in mating success was significantly higher in males than in females, thereby validating Bateman's second principle. This result is consistent with the Darwinian sex-role hypothesis linked to anisogamy, which predicts that sexual selection is often strongest in the sex that produces the smallest and most abundant gametes, i.e. males by definition [5]. This expected consequence of anisogamy [3,50], even if not observed in all studies (see [8]), has been detected in a large number of animal species [1,8], but also in some angiosperms [12,13,51], mosses [20], fungi [52,53] and a red alga [31,32].

Second, our results also validate Bateman's third principle because the Bateman gradient showed a significant positive relationship between reproductive and mating success in males, but not in females. The stronger dependence of reproductive success on mating success in males compared

with females has been widely documented in animals (see for review [8]), but has only recently been 307 308 reported in three species of angiosperms [17–19] and one aquatic species of peat moss [20], while 309 it had never been tested in seaweeds before. Bateman's third principle has generally been interpreted as the existence of strong competition between males for access to females, whereas 310 311 the reproductive success of females is not strongly tied to their ability to access mates. The transferability of methods used for investigating the Bateman gradient and how to interpret it in 312 animals to angiosperms was recently discussed in Tonnabel et al. [17] and Barbot et al. [19]. In 313 314 particular, in mating systems in which females have multiple mating partners during a mating season, frequently reported in angiosperms (see for review [54]) but rare in motile animals, may bias the 315 estimation of sexual selection. Multiple mating partners should result in high values of mating 316 317 success, but the fact that genetic mating success is typically estimated on a subsample of offspring 318 may lead to an underestimation of the mating success at least in some individuals, and ultimately 319 to an underestimation of the variance in mating success. Such bias has been discussed in a few papers based on meta-analyses of studies focused in animals and simulated data sets, suggesting 320 321 that the Bateman gradient may be overestimated in such a case [49,55]. In red algae, gametophytes are haploid and produce gametes by mitosis, and — given that male gametophytes thus produce 322 323 genetically identical gametes — fertilization of multiple females by individual males can be readily 324 detected. To date, the few paternity analyses published in red algae (i.e. G. gracilis, [31] and 325 Chondrus crispus, [56]) have confirmed high levels of polyandry in natural populations, which 326 suggests that in our study the Bateman gradient, as in other plants, may be overestimated in males. 327 Nevertheless, in the handful of investigated plant species, the positive Bateman gradient found in 328 males, but not in females, has been interpreted as the direct result of female reproductive success not being limited by pollen supply, at least in the experimental conditions in which these studies 329

were conducted [17,19]. Pollen limitation is another common feature in angiosperms [11,57] that

should, when it occurs, decrease the difference in magnitude of sexual selection between females 331 332 and males because in pollen-limiting situations, female reproductive success becomes limited by 333 access to male gametes. Although this relationship has not been directly tested yet, in situations of low plant and/or pollinator densities, despite the much higher production of male gametes 334 335 compared with female gametes at the population level, female Bateman gradients are expected to become significant [3,19]. In sessile marine organisms, female fertility has been assumed to be 336 limited due to short sperm lifespans and their dilution in turbulent flow [58,59], but several 337 338 mechanisms such as synchronous release of motile gametes and chemotaxis have evolved in a range of invertebrates and brown seaweed, to ensure fertilization rates of up to 80-100% (for reviews, 339 see [60,61]). In red algae, it has long been hypothesized that fertilization success should be 340 particularly low due to the characteristics of their life cycle [62,63]. Male gametes are not 341 342 flagellated, have a short lifespan and fertilization takes place on a remote female organ. The absence 343 of any documented mechanism of synchronous gamete release or chemotaxis has raised questions on the efficiency of gamete encounters in rhodophytes [63]. Searles [62] even hypothesized that 344 345 the evolution of cystocarps in which the female nurtures, amplifies and protects the zygote is 346 probably a response to low rates of fertilization. Rare gamete encounters should lead to a positive 347 Bateman gradient in female G. gracilis, a result that was not found in the current study. Therefore, 348 in the studied population, dispersal appears to be efficient enough to ensure the sufficient access 349 of female gametophytes to reproduction and thus the production of cystocarps. This argument is 350 further supported by our evidence that all measured females had multiple fertilization partners. 351 Although data on natural fertilization success are still sparse in red algae, Engel et al. [31] and Maggs et al. [64] reported that male gametes did not appear to be limiting because the majority of 352 fertilization takes place during low tide when the spermatium concentration is high [65]. In addition, 353 354 isopod-mediated transport of male gametes, a phenomenon similar to pollination, recently

demonstrated in a red alga [29] may compensate for the lack of flagella, increasing fertilization rates and thus explaining any absence of gamete limitation. Further work is needed to investigate whether the Bateman gradient can become significant for females under spermatium-limiting conditions, i.e. without "pollinators" or in a more open environment.

359 Here, the variance in mating success was greater in males and strongly correlated with their reproductive success. This relationship seems to suggest that variance in reproductive success is 360 higher in males than in females. However, even if the opportunity for selection (1) tended to be 361 stronger in males, the difference between sexes was not significant, and therefore did not confirm 362 363 Bateman's first principle. These results differ from what has been found in other animal and plant species [7,8]. One possible explanation for this discrepancy is that female reproductive success 364 depends on other factors not related to their access to reproduction but, for example, to their ability 365 366 to mobilize resources. Interestingly, a trade-off between sexual reproduction and growth has been demonstrated in females for two species of red algae (G. chilensis, [66] and G. domingensis, [67]). 367

Our results thus suggest that sexual selection may be stronger in males in G. gracilis. Consequently, 368 369 any heritable trait increasing individual access to mating partners may be under sexual selection in 370 males, leading to some sort of sexual dimorphism. In animals, numerous studies have focused on 371 dimorphic traits that allow males to increase the number of partners, such as ornaments or 372 armaments [4]. In angiosperms, some sexually dimorphic traits such as different metrics of flower size and phenology have been shown to be under stronger selection [68,69] or sexual selection [19] 373 in males. In the current study, some constraints in our data collection prevented us from 374 375 investigating the impact of biomass on female reproductive success. When focusing on males, we 376 found that biomass increased mating success, suggesting that this trait may thus be under sexual 377 selection, although nothing is currently known about its heritability in G. gracilis.

If the variance in male mating success largely depends on the geographical location of individuals, a 378 379 typically non-heritable trait, a distance effect may explain why sexual selection seems stronger in 380 males in a species in which no obvious sexual dimorphism seems to occur. A distance effect on 381 reproductive success has been commonly reported in plants [22–26] and also in G. gracilis [30]. In 382 the current study, our tests indeed revealed that only male (and not female) reproductive success depends on the distance to potential mates. This effect arises from the dependence of mating 383 success on distance. However, distance explains only a small part of the variance in male mating 384 385 success, and specific male traits, not yet identified, may nevertheless be involved in this variable access to mates. 386

Given that red algae are cryptogams (i.e. without visible sexual organs) and have a simple morphology (i.e. thallus), the identification of dimorphic sexual characters remains a real challenge. In *G. gracilis* there is no marked sexual dimorphism [33,34]. Nevertheless, some male traits may help increase access to females by improving gamete quality and/or efficiency, such as the phenology of gamete production, or the level of production of mucilage strands in spermatia that may aid dispersal and animal transport [29,70]. These traits may be subject to sexual selection in males, and offer exciting avenues for future research.

By investigating the Bateman gradient, the current study mainly focused on the equivalent of pre-394 copulation sexual selection mechanisms [8], i.e. those involved in the transport of gametes from 395 396 male to female reproductive structures. However, other processes, can occur after mating such as 397 the selection of some particular male gametes by female tissues, a mechanism often referred to as 398 cryptic female choice in animals and which may also occur in plants [55]. It is thus possible that our 399 estimate of the Bateman gradient in G. gracilis also captured the consequences of such cryptic choice. In red algae, female choice could occur within a female structure called the trichogyne [71]. 400 401 Several spermatia may adhere to a trichogyne [72], but only one male nucleus goes on to fuse with

the female gamete nucleus [73]. Due to the long and costly development of cystocarps, female choice may play an important role after fertilization in *G. gracilis*. Through this process, females can improve offspring quality by selectively aborting zygotes, on the basis of their paternity. This phenomenon has been widely described in plants where abortions are frequent [74–77] and also in fungi [78]. Post-mating abortions have also been described after controlled crosses in Gracilariaceae [79–81], including individuals of *G. gracilis* sampled from the same population as that studied here [32].

In conclusion, our study suggests that sexual selection occurs with a higher intensity in males than in females in *G. gracilis*, a species that shows no clear sexual dimorphism. Our results pave the way for future research to examine particular traits and their susceptibility to sex-specific sexual selection. Finally, our investigation on a non-obvious candidate species shed light on sexual selection being a possible evolutionary driver in a hitherto little-studied phylum of the tree of life.

597 Acknowledgments: We want to thank the Genomer platform of the Station Biologique de Roscoff 598 in particular Gwenn Tanguy, Biogenouest genomics and EMBRC France partner core facility for their 599 technical support. The authors are deeply grateful to Colin Destombe, Antoine Faure and Stéphane 600 Loisel for sampling and Carolyn Engel for comments on the last version of the manuscript. We thank 601 the associated editor Maurine Neiman and two anonymous reviewers for comments that have 602 improved this article

603

604	Funding: This work was supported by the Centre National de la Recherche Scientifique (CNRS) PhD
605	fellowship to E.L.; core funding was provided by the IRL 3614, Evolutionary Biology and Ecology of
606	Algae, CNRS and Sorbonne Université and by the International Research Network (IRN), Diversity
607	and Biotechnology of Marine Algae, CNRS, to M.V., S.M., C.D. and ML.G. This work was also funded
608	by ANID – Millenium Nucleus Marine Agronomy of Seaweed Holobionts - NCN2021_033 to ML. G.

609

610 **Competing interests:** The authors declare no competing interests.

611

Data availability: Genotypic data, complete script of bootstrapping procedure and path analyses
 were deposited and are available in Dryad <u>doi.org/10.5061/dryad.t4b8gtj6c</u>. All other data used in
 the analyses are available in the paper or the supplementary materials (tables S1-S3 and figure S1 S3)

616 Figure Captions

Figure 1 - Life cycle of *Gracilaria gracilis*. The individuals are fixed to the rocky substrate via a perennial holdfast. The deciduous erect thalli decay after reproduction in late autumn and grow back from the holdfast in spring. Diploid tetrasporophytes produce haploid spores from meiosis that

develop into dioicous male and female haploid gametophytes. Spermatia (non-flagellated male gametes) are released into the water column. After fertilization, the zygote is retained on the female and develops into a complex, macroscopic post-fertilization structure: the cystocarp. One fertilization gives rise to thousands of identical diploid carpospores that, after release and germination, grow into new tetrasporophyte individuals.

625

**Figure 2** - Map of the Cape Gris-Nez intertidal rock pool showing the locations of the 71 male (triangles) and the 70 female (circles) gametophyte individuals sampled within the population (the tetrasporophyte individuals are not shown). Mating success, i.e. the numbers of sexual partners, is proportional to (filled) symbol size. Females with missing information that were not included in Bateman analyses are indicated with open circles. The rock pool edges are shown in grey. The grey polygons within the rock pool indicate the presence of rocks.

632

**Figure 3** - Relationship between reproductive and mating success and their distribution in males (dark blue) and females (green). Distribution of reproductive success (A,D), mating success (B, E) and the Bateman gradient (C,F) for males and females, respectively. The significance of the Bateman gradient, estimated by the slope of the linear regression, is indicated on the graph (C, F).

637

Figure 4 - Relationship between mating success and mean distance to partners (A) in males and (B)
in females. The significance of the relationship, estimated by the slope of the linear regression, is
shown on each graph.
