Mangoni<sup>1</sup>, Céline Landon<sup>1</sup>, Chris Jopling<sup>1</sup>, Michel De Waard<sup>1</sup>

Cardiac rhythm, conduction, and electrical activity synchronization require the coordinated action of several ion channel types that differ according to the transmural and regional specificities. Classical pharmacology affects these channels in a nonregionalized way, which explains the limited efficacy in treating focalized arrhythmias in addition to negative side-effects on nontargeted organs. Through spatio-temporal control of channel activity by light, optogenetics and photopharmacology are promising approaches to solve the selectivity and temporal issues in treating arrhythmias. While convincing reports illustrate the power of optogenetics for terminating arrhythmias,<sup>1</sup> this approach is irreconcilable with clinical applications because genetic modification of the heart are required to express photosensitive ion channels. In contrast, photopharmacology counteracts the negative aspects of classical pharmacology and optogenetics by restricting drug activity in a spatio-temporal manner.<sup>2</sup> As previously described, photoactivatable caged peptides are engineered by grafting a UV-photocleavable o-nitroveratryloxycarbonyl protecting group (the cage) onto an amino-acid key for channel interaction<sup>3</sup> (Figure [A]). Caged natural peptides are advantageous because small quantities can be used in vivo owing to the high target affinity of the uncaged compounds and the preservation of the pharmacokinetics, thanks to limited peptide size modification. Here, a caged version of BeKm-1, a natural ether-a-go-go-related gene channel

peptide inhibitor, was used to regulate heart activity. Caged-BeKm-1 was produced by addition of o-nitroveratryloxycarbonyl to the lateral chain of K<sup>18</sup> because it is key for BeKm-1/hERG (human ether-a-go-go-related gene) interaction.<sup>4</sup> According to docking modeling and nuclear magnetic resonance analyses, o-nitroveratryloxycarbonyl induces severe van der Waals steric clashes with hERG and chemical rearrangements in the lateral chains of K<sup>18</sup>-surrounding amino-acids within BeKm-1 pharmacophore, all factors diminishing peptide activity. As a result, caged-BeKm-1 no longer inhibits hERG K<sup>+</sup> currents in human embryonic cells (HEK293) at 0.1 to 100 nmol/L concentrations at which noncaged BeKm-1 is highly potent, while production of uncaged-BeKm-1 by 365-nm illumination restores peptide potency (noncaged BeKm-1: concentration providing 50% inhibition [IC<sub>50</sub>]=1.6 nmol/L; caged-BeKm-1: IC<sub>50</sub>=3847 nmol/L; uncaged-BeKm-1: IC<sub>50</sub>=1.5 nmol/L; Figure [A]). In acute experiments, 100 nmol/L caged-BeKm-1 has no effect on hERG K<sup>+</sup> currents, whereas a 3-minute illumination at 365-nm (45 mW/cm<sup>2</sup>) produces a gradual inhibition (Figure [B]). Photoactivation of caged-BeKm-1 was investigated on human iPS-derived cardiomyocytes, dynamically clamped at -80 mV and paced at 1000-ms cycle length. The 200 nmol/L caged-BeKm-1 has no effect on action potential duration at 90% repolarization (action potential duration<sub>90</sub>: 279.1±47.2 ms versus 276.7±44.9 ms), whereas caged-BeKm-1

**Key Words:** arrhythmias ■ bradycardia ■ cardiomyocytes ■ peptides ■ photochemotherapy ■ potassium channels ■ zebrafish

## Nonstandard Abbreviations and Acronyms

<b>hERG</b>	human ether-a-go-go-related gene
<b>IBI</b>	interbeat interval
<b>IC<sub>50</sub></b>	concentration providing 50% inhibition

photoactivation induces a significant 1.3-fold increase in both action potential duration<sub>70</sub> (322.9±54.2 ms versus 256.7±46.9 ms) and action potential duration<sub>90</sub> durations (358.4±55.7 ms versus 279.1±47.2 ms). Uncaging of BeKm-1 also induces early afterdepolarization in 47% of the cells (Figure [C]) demonstrating our ability to control hERG currents by UV-illumination in several cell models. Langendorff-perfused rat hearts were used to assess hERG channel control by illumination of caged-BeKm-1 in cardiac tissue. Perfusing 250 nmol/L caged-BeKm-1 has minimal effects on interbeat intervals (IBIs), whereas a 3-minute illumination of the right atrium produces bradycardia (IBI increase: 25.7±2.9 ms for uncaged-BeKm-1 versus 8.6±2.5 ms for caged-BeKm-1 compared with IBI before caged-BeKm-1 perfusion; Figure [D]), indicating that caged-BeKm-1 is photoactivatable in adult rat heart ex vivo. Next, based on ERG blockade bradycardic effects in zebrafish,<sup>5</sup> we studied how photoactivation interferes with cardiac rhythm in vivo in zebrafish larvae. About 2 nL of 50 μmol/L caged-BeKm-1 injected into larvae has no effect on IBI, whereas larvae illumination (365 nm, 3 minutes) induces an increase in IBI (648.7±75.2 ms in illuminated condition versus 379.7±13.8 ms nonilluminated one and 420.2±13.6 ms in control) and episodes of atrio-ventricular desynchrony in 7 of 11 larvae. As control, 2-hour white-light illumination of larvae injected with caged-BeKm-1 does not induce any functional effect (Figure [E]). Heart rhythm control by photopharmacology was demonstrated in anesthetized rats undergoing right mini-thoracotomy, enabling visualization and illumination of the right atrium. Intravenous injection of 350 μg/kg caged-BeKm-1 produces a minor effect on sinus rhythm with a ΔRR of 6.6±1.5 ms, while a 10-minute UV-illumination with a 1-mm diameter light guide (365 nm, 75 mW/cm<sup>2</sup>) led to a final ΔRR of 15.9±2.9 ms compared with control condition (Figure [F]). Thirty minutes after illumination, bradycardia further increased (final ΔRR of 54.2±9.3 ms versus control condition), indicating delayed in situ binding of uncaged-BeKm-1 on cardiac ERG. Within this time frame, no reversibility was observed. These results highlight that cardiac heart rhythm can be controlled experimentally in mammals by peptide-based photoactivation in vivo.

In conclusion, this report demonstrates that photopharmacology, using the caged peptide strategy, can be used for regulating cardiac electrical activity in vivo in a time-defined manner and that spatial illumination restriction dissociates the bradycardic effect from the

arrhythmic one. This technology is applicable to other channels also involved in cardiac pacemaker activity such as G protein-activated K<sup>+</sup>, hyperpolarization-activated cyclic nucleotide-gated, Ca<sub>v</sub>3.1, Ca<sub>v</sub>1.3, and Na<sub>v</sub>1.1 channels. Several candidate peptides exist (tertiapin Q for G protein-activated K<sup>+</sup> channels and huwentoxin-IV for Na<sub>v</sub>1.1<sup>3</sup>) that can be caged. Photoactivation of natural peptides will also help defining and outlining proarrhythmic cardiac areas with regard to the distribution of a given channel type.

All animal care and experimental procedures were performed in animal facilities accredited by the French Ministry of Agriculture (APAFIS 34541-2022010310194375 and APAFIS 4054-2016021116464098 v5). All data analyses were performed in a blinded manner.
