Abstract

Applications of generative models for genomic data have gained significant momentum in the past few years, with scopes ranging from data characterization to generation of genomic segments and functional sequences. In our previous study, we demonstrated that generative adversarial networks (GANs) and restricted Boltzmann machines (RBMs) can be used to create novel high-quality artificial genomes (AGs) which can preserve the complex characteristics of real genomes such as population structure, linkage disequilibrium and selection signals. However, a major drawback of these models is scalability, since the large feature space of genome-wide data increases computational complexity vastly. To address this issue, we implemented a novel convolutional Wasserstein GAN (WGAN) model along with a novel conditional RBM (CRBM) framework for generating AGs with high SNP number. These networks implicitly learn the varying landscape of haplotypic structure in order to capture complex correlation patterns along the genome and generate a wide diversity of plausible haplotypes. We performed comparative analyses to assess both the quality of these generated haplotypes and the amount of possible privacy leakage from the training data.

As the importance of genetic privacy becomes more prevalent, the need for effective privacy protection measures for genomic data increases. We used generative neural networks to create large artificial genome segments which possess many characteristics of real genomes without substantial privacy leakage from the training dataset. In the near future with further improvements in haplotype quality and privacy preservation, large-scale artificial genome databases can be assembled to provide easily accessible surrogates of real databases, allowing researchers to conduct studies with diverse genomic data within a safe ethical framework in terms of donor privacy.

Author summary: Generative modelling has recently become a prominent research field in genomics, with applications ranging from functional sequence design to characterization of population structure. We previously used generative neural networks to create artificial genome segments which possess many characteristics of real genomes but these segments were short in size due to computational requirements. In this work, we present novel generative models for generating artificial genomes with larger sequence size. We test the generated artificial genomes with multiple summary statistics to assess the haplotype quality, overfitting and privacy leakage from the training dataset. Our findings suggest that although there is still room for improvement both in terms of genome quality and privacy preservation, convolutional architectures and conditional generation can be utilised for generating good quality, large-scale genomic data. In the near future with additional improvements, large-scale artificial genomes can be used for assembling surrogate biobanks as alternatives to real biobanks with access restrictions, increasing data accessibility to researchers around the globe.

Introduction

Machine learning is an important staple in modern genomic studies. There have been numerous applications in demographic inference [1], detecting natural selection [2], genome-wide association studies [3] and functional genomics [4], many of which became state of the art [5, 6]. In the recent few years, generative machine learning approaches for the genomics field have also begun to gain research interest thanks to algorithmic advances and widespread availability of computational resources [7, 8, 9, 10, 11]. Broadly speaking, generative machine learning involves the utilisation of generative models which are trained to model the distribution of a given dataset so that new data instances with similar characteristics to the real data can be sampled from this learned distribution. Especially since the introduction of generative adversarial networks (GANs) in the preceding decade [12], generative modelling has become a widely-researched subject with a diverse scope of applications such as image and 11 text generation [13, 14], dimensionality reduction [15] and imputation [16].

The amount of genetic data, both in sequence and SNP array formats, is now increasing at an 13 unmatched rate, yet its accessibility remains relatively low. The main reason for this is the crucial 14 protocols prepared to protect the privacy of donors. Genetic data belongs to a special category similar to 15 private medical records in the General Data Protection Regulation (GDPR) [17] and is defined as 16 protected health information in the Health Insurance Portability and Accountability Act (HIPAA) [18]. 17 Although these protective measures are vital, they create an accessibility issue for researchers who must 18 go through these protocols and, in many circumstances, might have to commit to collaborations to 19 conduct research or simply test ideas. In our previous study, we introduced the concept of high quality 20 artificial genomes (AGs) created by generative models as a possible future solution for this problem and 21 as an alternative to other methods such as differential privacy [19] and federated learning [20]. We 22 demonstrated that AGs can mimic the characteristics of real data such as allele frequency distribution, 23 haplotypic integrity and population structure, and can be used in applications such as genomic 24 imputation and natural selection scans [21]. However, our previous models lacked the capacity to 25 generate large-scale genomic regions due to the computational requirements caused by the high number 26 of parameters defining the fully connected architectures. In this study, we present two novel 27 implementations better adapted to large sequential genomic data: (i) generative adversarial networks 28 with convolutional architecture and Wasserstein loss (WGAN) [22], and (ii) restricted Boltzmann 29 machines with conditional training (CRBM) [23] used together with an out-of-equilibrium procedure [24]. 30 In more detail, we implemented a WGAN with gradient penalty (WGAN-GP) [25] which involved a deep 31 generator and a deep critic architecture, multiple noise inputs at different resolutions for the generator 32 [26], trainable location-specific vectors for preserving the positional information [27], residual blocks to 33 prevent vanishing gradients [28] and packing for the critic to eliminate mode collapse [29]. For the 34 CRBM, we used the more efficient out-of-equilibrium training scheme differently from our previous study 35 and developed a novel procedure for conditionally training multiple RBMs based on shared genomic 36 regions [30]. We assessed the AGs generated by these models with multiple statistics measuring data 37 quality and possible privacy leakage. First, we compared the new models with the ones from [21] using 38 the same 10,000 SNPs extracted from the 1000 Genomes human dataset [31] and then trained these 39 models with a larger 65,535-SNP dataset to generate long sequence AGs. We performed multiple tests to 40 evaluate (i) the quality of the generated haplotypes via allele frequency spectrum, linkage disequilibrium, 41 population structure and complex haplotypic integrity analyses such as 3-point correlations and 42 distribution of k-mer motifs; and (ii) privacy preservation via distance-based metrics, membership 43 inference attacks and overfitting/underfitting scores. 44

Materials and Methods

Data

The two sets of 1000 Genomes [31] data we used include: (i) 10.000 SNPs from chromosome 15 (between 47 27,379,578 - 29,625,035 base pairs, ~ 2 megabase pairs) identical to the ones picked by [21], and (ii) 48

2/20

45

8

9

10

65,535 SNPs from chromosome 1 between 534,247 - 81,813,279 base pairs, ~ 80 megabase pairs) within 49 the Omni 2.5 genotyping array framework. Further downsampling of the array framework was performed 50 to create a dataset with a reasonable SNP number for faster training trials and the specific number of 51 65,535 SNPs was decided to be in the form of (2n - 1) for easy implementation of convolutional scaling. 52 For the 10,000-SNP dataset, we used padding with zeros to match the (2n - 1) form. Both datasets have 53 the same 2504 individuals and 5008 phased haplotypes used for training the models. The data format is 54 the same as [21] where the rows are phased haplotypes and columns are positions which hold alleles 55 represented by 0 (reference) and 1 (alternative). 56

WGAN implementation

57 58

59

60

61

62

We implemented a Wasserstein GAN with gradient penalty (WGAN-GP) consisting of a critic which estimates the earth mover's distance between real and generated data distributions, and a generator which generates new genomic data from Gaussian noise (Fig 1). Unlike the discriminator in naive GAN which performs a classification task, the critic provides a "realness" score (an approximation of Earth-mover's distance) for generated and real samples. WGAN loss function is as follows:

$$E_x[C(x)] - E_z[C(G(z))]$$

where C is the critic, G is the generator, x is real data point and z is Gaussian noise. The critic function 64 C must be Lipschitz continuous; thus, the original study relied on weight clipping to enforce an upper 65 bound for the gradient [22]. However, we designed a WGAN with gradient penalty (WGAN-GP) rather 66 than weight clipping, as GP was shown to be a better alternative [25]. In our implementation, the critic 67 uses convolution layers whereas the generator uses convolution and transposed convolution layers (Fig 68 1a). Both the generator and the critic have trainable location-specific vectors as additional channels at 69 every block except for the residual blocks. These vectors, similar to the ones integrated by [27] in their 70 autoencoder, consist of trainable variables that allow the models to preserve positional information which 71 would otherwise diminish due to the invariance of convolution operations. In addition to this, the 72 generator has two noise channels at every block. This gives the generator flexibility to decide at which 73 depth the mapping to latent space can occur. We also implemented "packing" to overcome mode 74 collapse by adjusting the discriminator to take multiple samples as input [29]. In our implementation, 75 the input sample number for the discriminator was set to 3 intuitively, to match the 3 main population 76 modes (Africa, West Eurasia, Asia) observable in the 1000 Genomes data. The initial length of the input 77 for the generator is 4, which is gradually transformed into features of larger sizes until it reaches the 78 sequence size of 65,535 or 16,383 in the output (Fig 1b). 79

Figure 1. Wasserstein GAN (WGAN) model for the 65,535-SNP dataset. a) Representation of the generator, critic and residual blocks. Channel dimensions are not proportional and do not reflect the real implementation. The generator block has one trainable location-specific variable (blue) and two latent space vectors (red) as additional channels concatenated to the input. The critic block has one trainable location-specific variable (blue) as an additional channel concatenated to the input. b) Architecture of the WGAN model. White rectangles correspond to generic generator and critic blocks whereas grey rectangles correspond to generic residual blocks. Numbers in parentheses above blocks show channels and length, respectively (C, L). Dotted connections are residual connections where the input value is added to the output value of the block before passing to the next block. Yellow input and output blocks differ from the generic ones for proper dimension adjustments.

The generator layers are followed by batch normalisation and leaky ReLU activation (alpha = 0.01) 80 except for the final layer which has a sigmoid activation. The critic layers are followed by instance 81 normalisation and leaky ReLU activation (alpha = 0.01) except for the final layer which is a fully 82 connected layer with no activation. We used Adam optimizer to train both the generator and the critic 83 with a learning rate of 0.0005 and β_1 , $\beta_2 = (0.5, 0.9)$. β_1 was set to 0.5 as suggested by [13]. For each 84 batch training of the generator, the critic was trained 10 times as suggested by the authors of the 85 original WGAN [22]. We assessed the outputs of the generator at each epoch during training via PCA. 86 We stopped training when generated and real genome clusters visually overlapped in PC space 87 (components 1 to 4). In the case of 65,535-SNP data, this initial training was not sufficient to reach a 88 good overlap of higher degree principal components, thus, we performed a second brief training (up to 89 200 epochs) with 10-fold lower generator learning rate (0.00005). Our WGAN architecture for the 90 10,000-SNP data was conceptually the same as for the 65,535-SNP data, but shallower with fewer blocks. 91

All WGAN models were coded with python-3.9 and pythorch-1.11 [32]. The detailed python scripts can be accessed at https://gitlab.inria.fr/ml_genetics/public/artificial_genomes.

RBM implementation

An RBM is a generative stochastic neural network [33] defined as a probability distribution over a set of visible units, \underline{s} , representing SNPs in our case, and hidden units, $\underline{\tau}$, where both type of variables interact via a pairwise weight matrix \underline{w} and the local biases $\underline{\theta}$ and η help to adjust the mean value of each unit:

$$p(\underline{s},\underline{\tau}) = \frac{1}{Z} \exp(\sum_{ia} w_{ia} s_i \tau_a + \sum_i \theta_i s_i + \sum_a \eta_a \tau_a)$$

In this study, we used binary units $\{0, 1\}$ for both the visible and hidden nodes, and the number of ⁹⁹ hidden units was chosen to be about the same order as the number of visible ones. The likelihood of such ¹⁰⁰ model is given by: ¹⁰¹

$$L = \sum_{m=1}^{M} \left[\sum_{i} \theta_{i} s_{i}^{(m)} + \sum_{a} \log(1 + \exp(\sum_{i} w_{ia} s_{i}^{(m)} + \eta_{a})) \right] - M \log(Z)$$
 102

where the index m is indexing the samples of the dataset (M being the total number of samples) and Z_{103} is the normalization constant, or partition function, of the probability distribution.

Learning an RBM consists in maximising this likelihood using gradient descent in order to optimize 105 the weights and biases w, θ and η . In our implementation, the training was based on the 106 out-of-equilibrium method [34, 24]. The main difference with the more conventional learning is that the 107 sampling which is done to compute the correlation of the model is performed in a very precise way: a 108 random initial condition is chosen amongst a certain probability distribution $p_0(x)$ (kept fixed during the 109 learning), and a fix (all along learning) number of Monte Carlo steps is done during the training. When 110 using this particular training procedure, in order to sample new data, it is enough to generate the Monte 111 Carlo chains following the same dynamical process: same initial conditions $p_0(x)$ and same number of 112 MC steps. In the provided experiments, the initial conditions were chosen uniformly at random (each 113 unit having equal probability to be 0 or 1) and the number of MC steps was either 100 (for the 114 65,535-SNP dataset) or 200 (for the 10,000-SNP dataset) but the qualitative results were mostly not 115 affected. The learning rate of the model was chosen such that the eigenvalues of the learning weight 116 matrix are smoothly increasing during the first epochs from almost zero to values of $\sim O(1)$. 117

For the generation of very long sequences, we designed a novel procedure based on conditional-RBMs (CRBMs) [35, 23] (Fig 2). The CRBM consists in the learning of correlation patterns conditionally to some input variables. Hence, instead of considering all the dataset X, we separate it into two parts $X = X_P \cup X_I$, and the CRBM will learn to generate X_I (the inferred variables) based on X_P (the pinned variables). Therefore, we design a gradient that will learn how to generate the variables X_I given that we provide the variables X_p . In practice, denoting \underline{s} as the variables to be inferred and \underline{x} as the pinned ones, we will maximize the following quantity:

$$p(\underline{s} \in I | \underline{x} \in P) = \frac{1}{Z} \exp(\sum_{ia} w_{ia} s_i \tau_a + \sum_i \theta_i s_i + \sum_a \eta_a \tau_a + \sum_a \tau_a \sum_j w_{ja} x_j)$$
¹²⁵

Therefore, for each sample of the dataset, this construction is similar to a classical RBM with additional 126 biases for the hidden nodes which depend on the pinned variables. During the learning, we infer the 127 parameters of the model such that when showing a configuration of pinned variables X_P , the model will 128 generate a sample that is correlated to it accordingly. This conditional model can be used to learn very 129 long chains of variables. Let us consider that we have a dataset with 100,000 input variables. We can 130 learn initially a regular RBM on the first 10,000 input variables. In parallel, we can also learn a 131 conditional RBM on the input variables s_i with i in [5,000:15,000] using the first 5,000 variables as 132 pinned variables. Therefore, this second RBM will, given 5,000 pinned variables, learn how to generate 133 the 5,000 following ones. The same procedure is repeated with various input sets, always using the first 134 5,000 input nodes as pinned variables. Once learning is completed for all the RBMs, we can proceed 135 using the following sequential method to generate new data: 136

1. Use the first RBM (non-conditional) to generate the first 10,000 input.

137

94

95

96

2. Use the first CRBM to generate the next [10,000:15,000] inputs. To do that, we use the generated nodes [5,000:10,000] as pinned variables and generate the rest.

3. We follow the same procedure until we finally generate the whole 100,000 variables.

Figure 2. Illustration of the learning and sampling of a large sequence using a "classical" and a conditional RBM (CRBM). Initially, we train RBM1 (left) and RBM2 (right) in parallel. Both RBMs are essentially trained in a similar manner: random inputs are drawn and k MC steps are performed before computing the gradient and updating the weights using gradient descent. The difference for the CRBM (RBM2) is that half of the variables in the visible layer are pinned (crossed squares) to the real data during training while the rest is generated conditionally on these pinned variables. After training both machines, we can sample a complete new sequence. To do so, we start from random input and perform k MC steps to generate the first part of the sequence (light yellow-red) using RBM1. Then, we use half of this generated sequence (light red) as the pinned visible variables of the RBM2 (crossed squares) and initialise the rest as random input. We perform k MC steps on RBM2 while keeping the pinned variables fixed to generate the rest of the sequence (light blue). The letters next to arrows show the order of this sampling procedure.

This method was used to generate the large-scale 65,535-SNP dataset. We first trained a "normal" 141 RBM on the first 5,000 input variables. Then, we made a set of 10,000 conditional RBM, where the first 142 5,000 variables were used as pinned variables. All the models were trained with 1000 hidden nodes, and 143 a learning rate of $\beta = 0.005$. The learning dynamics uses the Rdm-k method: each chain was generated 144 starting from the uniform Bernoulli distribution, with k=100 for the training of the RBM and the 145 CRBMs. A recurrent issue with RBM (or training in general) is to decide when to stop the training. 146 While in supervised setting it is easy to monitor the loss function (or the number of correctly classified 147 samples), it is not the case for RBM since the partition function is intractable. In this work, the learning 148 was affected by the small number of samples given the dimension of the inputs. Therefore (and to avoid 149 overfitting), the meta-parameters such as the number of hidden nodes and the number of epochs were 150 fixed a posteriori, by investigating various trained machines with different values of these parameters and 151 choosing the one giving a good AA_{TS} score. The detailed python scripts can be accessed at 152 https://gitlab.inria.fr/ml_genetics/public/artificial_genomes. The RBM implementations 153 are based on the pytorch library and handle GPU to perform both training and sampling. Another 154 example of the out-of-equilibrium code applied to images can be found at 155 https://github.com/AurelienDecelle/TorchRBM. 156

VAE implementation

157

177

The VAE [36] architecture is very similar to the GAN architecture but somehow reversed: the encoder is 158 an analogue to the critic and the decoder is an analogue to the generator (Supp fig S1). The last layer of 159 the encoder outputs two vectors containing means (μ) and standard deviations (σ) so that the latent 160 space can be sampled based on these values and fed to the decoder. The loss function consists of the 161 reconstruction term, which measures the likelihood of the generated genomes (via log loss in our 162 implementation), and the regularisation term which is the Kullback-Leibler divergence between the 163 standard normal distribution and the prior distribution of the latent space. The regularisation term 164 directs the latent space towards a standard normal distribution. After training completion, this allows 165 sampling of new latent points from the standard distribution which are further transformed into new 166 data points (new genomic sequences) through the decoder. 167

Each layer in our implementation is followed by batch normalisation and leaky ReLU with alpha set 168 to 0.01, except for the final layers. The decoder final layer is followed by a sigmoid function, whereas the 169 encoder final μ and σ layers have linear activation. We used Adam optimizer with default settings and 170 the learning rate set to 0.001. Similarly to the WGAN, we evaluated the training based on coherence of 171 the PCA performed on real and generated genomes (components 1 to 4). We could not successfully train 172 a VAE model which generates plausible AGs for the 65,535-SNP dataset. Further architecture and 173 hyperparameter optimization is needed to better assess VAE models in this context. VAE models were 174 coded with python-3.9 and pythorch-1.11 [32]. The detailed python scripts can be accessed at 175 https://gitlab.inria.fr/ml_genetics/public/artificial_genomes. 176

Nearest Neighbour Adversarial Accuracy (AA_{TS})

Similarly to [21], we assessed the overfitting/underfitting characteristics of AGs using the AA_{TS} score [37]. AA_{TS} is calculated as follows:

$$AA_{truth} = \frac{1}{n} \sum_{i=1}^{n} \mathbf{1}(d_{TS}(i) > d_{TT}(i))$$
 180

$$AA_{syn} = \frac{1}{n} \sum_{i=1}^{n} \mathbf{1}(d_{ST}(i) > d_{SS}(i))$$
181

$$AA_{TS} = \frac{1}{2}(AA_{truth} + AA_{syn})$$
¹⁸²

where n is the number of samples in each dataset (real and generated), $d_{TS}(i)$ is the distance between 183 the real (truth - T) sample indexed by i and its nearest neighbour in the generated (synthetic - S) 184 dataset, $d_{TT}(i)$ is the distance between a real sample i and its nearest neighbour in the real dataset, 185 $d_{ST}(i)$ is the distance between a generated sample i and its nearest neighbour in the real dataset, $d_{SS}(i)$ 186 is the distance between a generated sample i and its nearest neighbour in the generated dataset, and 1 is 187 the indicator function which returns 1 if the argument is true and 0 otherwise. Based on this equation, 188 an AA_{TS} value below 0.5 indicates overfitting and an AA_{TS} value above 0.5 indicates underfitting. We 189 additionally obtained a privacy score in another analysis where we separated the datasets into two 190 equal-sized train and test sets (2504 phased haplotypes each). The score is defined as follows: 191

$$Privacy\ score = Test\ AA_{TS} - Train\ AA_{TS}$$

where $Test AA_{TS}$ (resp. $Train AA_{TS}$) is the AA_{TS} computed with the test (resp. training) samples as truth. The expected value for the privacy score is 0 when there is no privacy leakage, with higher scores indicating higher leaks.

Summary statistics

For the 65,535-SNP dataset, LD was computed only on a subset of pairs in order to fasten computation. ¹⁹⁷ To sample these pairs in an efficient way (i.e. approximately uniformly along the SNP distance log scale ¹⁹⁸ without computing the full matrix of SNP distances), we used the script from [38]. The remaining ¹⁹⁹ summary statistics (allele frequencies, haplotypic pairwise distances, PC scores, 3-point correlations and ²⁰⁰

LD for the 10,000-SNP dataset) were computed as in [21] using the publicly available scripts at 201 https://gitlab.inria.fr/ml_genetics/public/artificial_genomes. For the radar plots, we 202 transformed the scores so that they span values between 0 and 1, where 0 represents poor performance 203 and 1 high or perfect performance. Precisely, we used the allele frequency correlation for alleles with low 204 frequency (≤ 0.2) for the Allele frequency score and correlation of SNPs separated by random 205 distances for the 3-point correlations score. For the Pairwise distance score, we used the Wasserstein 206 distance between the distributions of haplotypic pairwise distances of real and generated data. We 207 performed min-max scaling, using the value for a simple binomial generator model (from [21]) for the 208 lowest bound 0. For the other scores, we used the following equations: 209

$$Overfitting = 1 - (0.5 - \min(AA_{truth}, 0.5)) - (0.5 - \min(AA_{syn}, 0.5))$$

$$Underfitting = 1 - (\max(AA_{truth}, 0.5) - 0.5) - (\max(AA_{syn}, 0.5) - 0.5)$$

$$LD = 1 - \sum (LD_{real} - LD_{generated})^2 / \sum LD_{real}^2$$
²¹²

where $LD_{generated}$ and LD_{real} are average LD values for bins in the LD decay analyses (Fig 5c, Supp fig S2b). Overfitting and Underfitting equations were formulated to focus on below and above 0.5 AA_{TS} sweet spot, respectively, to provide a better resolution in terms of overfitting/underfitting assessment.

To analyze the correlation of k-mer haplotypes between real and generated genomes, we divided 10,000-SNP and 65,535-SNP genomes into non-overlapping windows of size 4 and 8. We counted the number of occurrences of each unique motif in these windows and assessed the correlation of these counts between real and generated genomes for each window.

Nearest neighbour chain analysis

Since AA_{TS} scores for the CRBM AGs were anomalous, we performed a nearest neighbour chain analysis for further investigation. For this analysis, the frequencies of all observable patterns for the nearest neighbour chains of size 2 to 5 were computed. A pattern indicates the succession of data type (synthetic/S or truth/T) when starting from a point (the first letter) and moving successively to the nearest neighbour, then the nearest neighbour of the nearest neighbour, and so on until reaching the chain size. Hamming distance was used for identifying the nearest neighbours.

Membership inference attacks

We performed membership inference attacks on WGAN and RBM generated AGs using the approach 229 proposed in [39]. We trained the WGAN and RBM models using half of the haplotypes (2504) of the 230 10,000-SNP data and kept the rest as test set. We considered the two following scenarios: a white-box 231 attack where the adversary has access to the original critic optimized weights and architecture, and a 232 black-box attack where the adversary has only access to the WGAN architecture (without its weights) 233 and generated samples. For both scenarios, we also assume the adversary knows the size of the original 234 training set and has a collection of samples some of which are suspected to belong to the training set. 235 For the white-box attack, we used the already trained critic to score all the samples (a total of 5008) 236 samples consisting of 2504 from training and 2504 from test sets) and sorted them based on these scores. 237 The top n ranking samples are then predicted as belonging to the training set. For the black-box attack, 238 we trained new models on generated AGs, using the exact same architecture as the previously trained 239 WGAN, and the same stopping criterion, but we overtrained further up to 5000 epochs to induce 240 overfitting. Since this attack is model agnostic, we trained one model on WGAN AGs and one on RBM 241 AGs. Similar to the white-box attack, all samples are scored by the critic after the training and the top 242 n ranking samples are assigned to the training set. In our experiments, n varies such that we assign 1%, 243 10%, 25%, or 50% of the total 5008 samples to the training set. The computed accuracy is simply the 244 percentage of correct assignments for each value of n. 245

Comparisons with the previous models

As our GAN concept has changed substantially compared to the previous models both in terms of 248 architecture and loss functions, we initially performed training and analysis on 1000 Genomes data with 249 the same 10,000 SNPs as [21] to be able to conduct one-to-one comparisons. For these tests, we 250 additionally implemented a new RBM scheme along with a new variational autoencoder (VAE) which 251 has a very similar architecture to our WGAN model. We used the VAE as a supplementary benchmark 252 since the encoder-decoder form of the VAE can be seen as an analogue to the critic-generator form of the 253 WGAN model. The objective function of VAE, on the other hand, is substantially different, which allows 254 us to assess the robustness of the architecture we used (see Materials and Methods). 255

Figure 3. Principal component and allele frequency analyses of artificial genomes with 10,000-SNP size. a) Density plot of the PCA of combined real and artificial genome datasets. Density increases from red to blue. (b) Allele frequency correlation between real (x-axis) and artificial (y-axis) genome datasets. Bottom figures are zoomed at low frequency alleles (from 0 to 0.2 overall frequency in the real dataset). Values presented inside the figures are Pearson's r, ordinary least squares regression slope and intercept.

Based on the PCAs, all models generated AGs which could capture the population structure of the 256

data, albeit new WGAN and RBM models were better at representing the real PC densities compared to 257 the other models (Fig 3a). In our previous study, we reported that the GAN model had difficulty 258 learning low frequency alleles observed in real genomes. The new WGAN and RBM showed improvement 259 in capturing the real allele frequency distribution, especially for the low frequency (≤ 0.2) alleles with 260 correlation coefficients for previous GAN (GAN_prev), previous RBM (RBM_prev), VAE, WGAN and 261 RBM being 0.94, 0.83, 0.94, 0.96 and 0.99, respectively (Fig 3b). In terms of LD structure, RBM 262 generated AGs seemed to have the closest decay scheme to the real data while WGAN. GAN and VAE 263 generated AGs all had similar results without substantial difference (Supp fig S2). In addition, the new 264 WGAN and RBM models preserved 3-point correlations better than the other models (Supp fig S3). To 265 assess whether AGs could preserve short motifs in real genomes, we also analyzed the correlation of 266 non-overlapping 4-mer and 8-mer motifs between real and generated datasets (Supp fig S4). AGs 267 generated by all models showed high correlation and good fit overall, although RBM_prev had the 268 highest variance despite the high correlation coefficient. 269

None of the models have produced identical sequences and no full sequences were copied from the 270 training dataset except for the benchmark VAE. In addition, the distribution of haplotypic pairwise 271 differences between real and generated datasets overlapped well with the distribution of haplotypic 272 pairwise differences within the real dataset (Supp fig S5). The AA_{TS} scores for GAN_prev, RBM_prev, 273 VAE, WGAN and RBM were 0.73 ($AA_{truth} = 0.57$, $AA_{syn} = 0.89$), 0.49 ($AA_{truth} = 0.46$, $AA_{syn} = 0.46$), $AA_{syn} = 0.46$, AA_{syn} 274 $(0.52), 0.48 \ (AA_{truth} = 0.47, AA_{syn} = 0.50), 0.82 \ (AA_{truth} = 0.77, AA_{syn} = 0.87) \text{ and } 0.47 \ (AA_{truth} = 0.50), 0.82 \ (AA_{truth} = 0.77, AA_{syn} = 0.87) \text{ and } 0.47 \ (AA_{truth} = 0.50), 0.82 \ (AA_{truth} = 0.77, AA_{syn} = 0.87) \text{ and } 0.47 \ (AA_{truth} = 0.87), 0.82 \ (AA_{truth} = 0.87), 0.83 \ (AA_{$ 275 $0.47, AA_{syn} = 0.47$), respectively. These values indicate underfitting (a hypothetical extreme case 276 demonstrated in Fig 4a) for GAN generated AGs, and slight overfitting (a hypothetical extreme case 277 demonstrated in Fig 4b) for the RBM and VAE generated AGs (Supp fig S6). Although the new WGAN 278 demonstrated slightly more underfitting than the previous GAN, the gap between the two components of 279 AA_{TS} (AA_{truth} and AA_{syn}) was decreased (see Materials and Methods for the details of the 280 terminology). We previously hypothesised that the low value of AA_{truth} and high value of AA_{sun} for the 281 previous GAN might be due to the generator creating AGs based on averages from a local set of samples 282 in small pockets (extreme case demonstrated in Fig 4c). This can be seen as a generative aberration 283 which does not generalise to the whole dataset but is observed only regionally in small subsections of the 284 data. We do not observe this behaviour in the new WGAN model. A general comparison of all the 285 models based on multiple aggregated statistics is provided in Supp fig S7. 286

Generating large-scale genomic data

Following the main motivation of the study, we trained the new WGAN and CRBM models on 1000 288 Genomes data with 65,535 SNPs. The WGAN model for this data was deeper compared to the model 289 used for the 10,000-SNP data (see Materials and Methods). We again implemented a VAE similar to the 290 WGAN architecture vet we could not train this model with satisfactory results (see Discussion). Both 291 WGAN and CRBM generated AGs were able to capture the real population structure and PCA modes 292 quite well (Fig 5a) along with allele frequencies (correlation coefficient for low frequency alleles being 293 0.97 for both models; Fig 5b), yet WGAN AGs had substantially more fixed alleles which had low 294 frequency in the real dataset (Supp fig S8). Since computation of the full correlation matrix is very 295 intensive due to large sequence size, we calculated an approximation of the LD decay based on a subset 296 of SNP pairs (see Materials and Methods). AGs generated by both models had on average lower LD 297 than real genomes, similarly to our previous findings (Fig 5c). In 3-point correlation analysis, CRBM 298 performed better than WGAN for SNP triplets separated by 1, 4, 16, 64, 256, 512 and 1024 SNPs. 299 However, the score was similar for SNP triplets separated by random distances (WGAN = 0.43, CRBM 300 = 0.41; Supp fig S9). Furthermore, 4-mer and 8-mer motif distributions both for WGAN and CRBM 301 generated AGs seemed to be similar to real genomes (Supp fig S10). 302

Similarly to the 10,000-SNP dataset, neither of the models produced identical sequences and no full sequences were copied from the training dataset. WGAN captured the haplotypic pairwise distribution better than CRBM (pairwise distance radar score for WGAN = 1.00, CRBM = 0.94; Supp fig S11) but the two main peaks in real data were correctly represented by both models (Supp fig S12)). The AA_{TS} value for WGAN AGs showed underfitting ($AA_{TS} = 0.91$) whereas the value for CRBM was slightly 307

Figure 4. Schematic representation of different problematic training outcomes for generative models. Distances to the nearest neighbours are denoted by d_{xx} where x can be T (truth/real) and S (synthetic/generated). a) An extreme case of underfitting (or optimization issue) in which the nearest neighbours of real data points are real and the nearest neighbours of synthetic data points are synthetic, revealing two distinct clusters ($AA_{TS} >> 0.5$). b) An extreme case of overfitting in which the nearest neighbours of real data points are systematically synthetic and vice versa ($AA_{TS} << 0.5$). c) An extreme case of a specific type of generative aberration in which the nearest neighbours of both real and synthetic data points are synthetic ($AA_{syn} >> 0.5$ and $AA_{truth} << 0.5$). Hypothetically, this might occur when the generator generates new instances based on average information from a small collection of samples, causing low local variation. d) An extreme case of a specific type of generation in which the generative aberration in which the nearest neighbours of both real and synthetic data points are real ($AA_{syn} << 0.5$ and $AA_{truth} >> 0.5$). This might possibly be observed when the generative model learns the main modes in real data but fails to mimic the densities and generates instances in the axes of the main modes with high variance.

above the 0.5 sweet spot $(AA_{TS} = 0.56;$ Fig 5d. However, there was a huge contrast between AA_{truth} and AA_{syn} values for CRBM AGs $(AA_{truth} = 0.86, AA_{syn} = 0.26)$, which might be an indication of the anomaly depicted in Fig 4d. This is the opposite of what we observed for the previous GAN (GAN_prev) model and might be due to AGs which exist outside the real data space as can be seen from the PCA analysis (Fig 4a, Supp fig S13). A general comparison of the two models based on multiple aggregated statistics is provided in Supp fig S11.

To further investigate the anomaly for the CRBM AGs, we performed a nearest neighbour chain analysis (Table 1). Starting with a synthetic point, we observed substantially higher frequencies for chains of true data points (ST, STT, STTT, STTTT) compared to chains of synthetic data points (SS, SSS, SSSS, SSSS).

Table 1. Nearest neighbour chain analysis. Frequencies of series of generated (synthetic - S) and real (truth - T) samples in chains of nearest neighbours (from size 2 to 5). To avoid loops, a sample was removed once reached in the chain. Expected frequency for chains of size 2 is 0.25, size 3 is 0.125, size 4 is 0.0625 and size 5 is 0.03125.

Figure 5. Principal component, allele frequency and linkage disequilibrium (LD) analyses of artificial genomes with 65,535-SNP size. a) Density plot of the PCA of combined real genomes and artificial genomes generated by WGAN and CRBM. Density increases from red to blue. b) Allele frequency correlation between real and artificial genome datasets. Bottom figures are zoomed at low frequency alleles (from 0 to 0.2 overall frequency in the real dataset). Values presented inside the figures are Pearson's r, ordinary least squares regression slope and intercept. The dashed black line is the identity line. c) LD decay approximation for real (grey), WGAN generated (blue) and CRBM generated (red) genomes (see Materials and Methods for details). d)Nearest neighbour adversarial accuracy (AATS) of artificial genomes generated by different models for the 65,535-SNP dataset. Values below 0.5 (black line) indicate overfitting and values above indicate underfitting.

Membership inference attacks and privacy leakage

Assessing privacy leakage and performing membership inference attacks require an additional test set but we could not obtain good quality AGs using a subset of 65,535-SNP dataset. Therefore, we trained the new WGAN and RBM models using half of the samples from the 10,000-SNP dataset (2504 haplotypes). AGs generated via the WGAN model had similar summary statistics to the AGs generated via the model trained with the whole dataset. For the RBM model, results were slightly worse but better than the previous RBM model (RBM_prev) trained with the whole dataset (Supp fig S14a-c). AA_{TS} analysis showed underfitting for WGAN AGs ($AA_{TS} = 0.80$, $AA_{truth} = 0.76$, $AA_{syn} = 0.83$) and almost perfect 325

scores for RBM AGs ($AA_{TS} = 0.50, AA_{truth} = 0.49, AA_{syn} = 0.51$). Based on the test set, WGAN AGs 326 had good privacy score (0.03) and RBM AGs showed possible privacy leakage (0.23) (Supp fig S14d). 327 Furthermore, both white-box attack on WGAN AGs and black-box attack on RBM AGs reached high 328 accuracies (WGAN: 1%: 0.82, 10%: 0.826, 25%: 0.754, 50%: 0.677; RBM: 1%: 0.84, 10%: 0.70, 25%: 329 0.62, 50%: 0.57) for detecting a portion of the training samples whereas black-box attack on WGAN 330 AGs produced substantially lower accuracies (1%: 0.56, 10%: 0.55, 25%: 0.54, 50%: 0.51), suggesting 331 relatively better privacy preservation. The distribution of the critic scores for train and test samples also 332 showed that the black-box attack on WGAN AGs was mainly unsuccessful for differentiating training 333 and test samples (Supp fig S15). 334

Discussion

335

In this study, we implemented generative neural networks for large-scale genomic data generation and 336 assessed various characteristics of the artificial genomes (AGs) generated by these networks. Initially, we 337 generated AGs from the 10,000-SNP dataset to be able to compare to the previous results from [21]. For 338 this dataset, we introduced a new RBM training scheme, a convolutional WGAN and a convolutional 339 VAE. Both WGAN and new RBM models substantially improved the quality of AGs in terms of all 340 summary statistics. For the 65,535-SNP dataset, we used a similar WGAN architecture (which is 341 essentially deeper in comparison to the architecture for the 10,000-SNP dataset) and a conditional RBM 342 (CRBM) protocol. AGs generated by these new models preserve population structure, allele frequency 343 distribution and haplotypic integrity of real genomes reasonably well with little or no privacy leakage 344 from the training data. Generative models trained with similar-sized genomic data have been reported in 345 the literature but the main goal of these studies was characterization of population structure via 346 dimensionality reduction and the generated genomes did not possess good haplotypic integrity [27, 40]. 347 There have been other studies focusing on demographic parameter estimation [41] and data generation 348 [8, 9, 10, 11] for population genetics but these only included training with smaller genomic segments. 349

The upscaling to a larger sequence size in comparison to our previous study is an essential step for 350 AGs to be utilised in real-life applications as publicly accessible alternatives for sensitive genomic 351 samples, yet obstacles remain. Although we could generate substantially larger sequences by 352 incorporating convolutions for the WGAN and a conditional approach for the RBM, training these large 353 models requires computational time and fine-tuning in most cases. The WGAN is usually preferred over 354 naive GAN in literature as it mitigates hyperparameter optimization and provide more stable training 355 [22]. However, we had to go through multiple combinations of architectures and hyperparameter values 356 to reach satisfying results. Even then, the training in our application involved further adjustment of the 357 generator learning rate after a certain epoch to capture the details of the population structure observable 358 in higher PC dimensions. This second round of training was helpful but some of the runs did not reach 359 an acceptable equilibrium (i.e., generated genomes had low quality after training), especially when 360 experimenting with reduced training sample sizes. For future applications, automated architecture and 361 hyperparameter tuning methods can help significantly for finding the optimal combinations without 362 extensive trial and error [42, 43]. VAEs might be seen as better alternatives in terms of training stability 363 compared to GANs since they do not suffer from the difficulty of balancing two networks in an 364 adversarial manner, yet we could not obtain high-quality AGs for the 65,535-SNP dataset. Presumably, 365 considerably better outcomes can be achieved with further architectural, hyperparameter and loss 366 function exploration, which is outside the scope of this study. 367

Another future research direction for the generative models could be the exploration of alternative 368 stopping criteria for the training. Unlike image generation, where the generated outcomes can be 369 assessed easily by visual inspection, assessment of generated genomic data is not trivial. For VAE and 370 WGAN models, we decided to use PCA plots for initial inspection and as the stopping criterion since the 371 highest variation in most genomic datasets is due to population structure which PCA captures well. This 372 PCA match, inspected visually or measured through Wassertein distance, had been used previously as 373 the stopping criterion [21, 8]. Although an obvious candidate for the stopping criterion of WGAN is the 374 convergence of the critic's loss to a value close to zero (since this loss provides an estimation for the 375 Earth mover's distance between real and generated data), we observed that it does not always coincide with good PCA outcomes for the AGs. For the RBM models, we had to inspect AA_{TS} score instead since overfitting was a more prominent issue. A possible alternative to these would be using some aggregate statistics crafted based on multiple summary statistics related to LD, site frequency spectrum, ancestry and overfitting scores.

The other approach we presented to incorporate large-scale data was the conditional training of 381 RBMs. Instead of a single training of a large and deep model as in the case of WGAN, CRBM training 382 includes multiple training runs of a small model. A main advantage of this method is that any sequence 383 size can theoretically be generated as long as the positional conditionality is not broken over the target 384 genome segment. Therefore, the only bottleneck in terms of computation is the time needed to train all 385 the RBMs. Currently, the learned weights are specific to each machine and no parameters are shared 386 between RBMs. This advantageously allows parallel training when needed, but produces a large number 387 of parameters to be optimized since the number of weights and biases has to be multiplied by the 388 number of machines. Further studies could investigate whether parameter sharing between machines (i.e., 389 between regions) and/or within each machine (through convolutions) is advantageous or instead 390 complicates training. In addition, many datasets also present a difficulty during training, because the 391 equilibrating time for Markov chains diverges as the training goes on, causing issues for sampling (and 392 re-sampling) [44]. To overcome this, we relied on out-of-equilibrium training as described in Materials 393 and Methods. While this approach improved training stability and also the quality of the generated 394 samples with respect to other approaches, it has the disadvantage that the learned features cannot be 395 easily interpreted. 396

For the assessment of overfitting and underfitting, we utilised the AA_{TS} score and haplotypic 397 pairwise distances as in [21]. An interesting finding was the large difference between two terms of the 398 AA_{TS} score (AA_{truth} and AA_{sun}) for AGs generated by the CRBM even though the averaged AA_{TS} 399 score was good. Interestingly, this is the opposite of what we had observed for our previously published 400 GAN model and possibly points to the type of generative aberration demonstrated in Fig 4d. In fact, it 401 is known that the likelihood function used to infer the parameters of RBMs tends to create potentially 402 spurious modes -that do not match any region of the dataset-, which might explain these patterns. For 403 further investigation, we performed a nearest neighbour chain analysis since we would expect the nearest 404 neighbours of the nearest neighbours for CRBM AGs to be mostly real genomes with this anomaly 405 (Table 1). High frequency of ST, STT, STTT, STTTT and low frequency of SS, SSS, SSSS, SSSS 406 measurements provide additional evidence that what we observe for the CRBM AGs is possibly similar 407 to the scenario seen in Fig 4d. To the best of our knowledge, this type of anomaly for generative models 408 has not been reported in literature and could have been missed by classical evaluation metrics. Such 409 complex overfitting/underfitting phenomena require vigilance and further investigation in future 410 generative studies. 411

We furthermore performed membership inference attacks on AGs generated by WGAN and RBM 412 models to assess possible privacy leakage. While the white-box attack on WGAN AGs and black-box 413 attack on RBM AGs produced high accuracy for detecting a portion of the samples used in training, 414 black-box attack on WGAN AGs was mainly not successful (Supp fig S15). This indicates that even if 415 the model architecture is available publicly and the adversary is in possession of some samples from the 416 training dataset, it is not trivial to pinpoint the training samples via this attack without access to the 417 model weights. We highlight that providing the critic's weights of a GAN is not useful to the general 418 user interested only in its generative properties, the white-box is thus a conservative attack (i.e., 419 unrealistically beneficial for the adversary). Similarly, both the white and black-box attacks are 420 conservative for evaluating privacy leaks as they assume that the adversary has the huge advantage of 421 already possessing some genetic sequences from the original training set. However, it is crucial to 422 underline here that this is only a single type of attack and more research on privacy preservation is 423 essential before AGs are used in real-life scenarios [45]. 424

Despite these issues which remain to be further studied, additional improvements in model training and increased privacy guarantees for generated genomes can pave the way for the first artificial genome banks in the near future, accelerating global access to the vast amount of restricted genomic data. Unlike

conventional approaches for genomic simulations, generative neural networks do not require a priori information about the target dataset (such as underlying evolutionary history), allow the generated data to be utilized alongside real data and provide substantially better privacy outcomes in comparison to haplotype copying methods [21].

Supplementary Figures

Figure S1. Architecture of the variational autoencoder (VAE) model for the 10,000 SNP dataset. Generic blocks of the encoder and decoder (white rectangles) are conceptually the same with the generic critic and generator blocks respectively (Fig 1a), except that there are no latent space channels concatenated to the input and no additional noise vectors at each block. The major difference from WGAN in terms of architecture is the last block of the encoder, which encodes mu and sigma as the mean and the standard deviation of the generated distribution, which are used to sample the latent space. Dotted connections are residual connections where the input value is added to the output value of the block before passing to the next block. Numbers in parentheses above blocks show channels and length, respectively (C, L).

Figure S2. Comparative linkage disequilibrium (LD) analysis of artificial genomes generated by different models for the 10,000-SNP data. a) LD heatmap based on r^2 matrices. Sections below diagonals correspond to LD in real genomes and sections above diagonals correspond to LD in artificial genomes. b) LD decay as a function of SNP distance. SNPs were binned based on distance and average LD was calculated. c) LD decay correlation between real and artificial datasets. x axis corresponds to real LD bins and y axis corresponds to generated LD bins. Sites fixed in any of the datasets were removed for all the LD calculations.

Figure S3. 3-point correlation analysis of SNP triplets for the 10,000-SNP data with inter-SNP distances of 1, 4, 16, 64, 256, 512 and 1024 (from left to right, top to bottom). The last panel (bottom right) shows correlation for triplets of SNPs drawn randomly. In each plot, drawing order (z-order) of each AG group is shuffled.

Figure S4. Analysis of small haplotype motifs between real and generated 10,000-SNP datasets for a) 4-mer and b) 8-mer non-overlapping windows. For each unique k-mer in each window, number of occurrences in the real dataset was compared to the same number in the AG dataset. Each point corresponds to the occurrence number in real (x-axis) and AG (y-axis) datasets. Values presented inside the figures are Pearson's r, ordinary least squares regression slope and intercept.

Figure S5. Distribution of haplotypic pairwise difference within (left figure) and between (right figure) 10,000-SNP datasets.

Figure S6. Nearest neighbour adversarial accuracy (AATS) of artificial genomes generated by different models for the 10,000-SNP dataset. Values below 0.5 (black line) indicate overfitting and values above indicate underfitting. See Materials and Methods for the details of the metrics.

Figure S7. Radar plot comparing artificial genomes generated by different models for the 10,000-SNP dataset. Values closer to 0 indicate poor performance whereas values closer to 1 indicate good performance. See Materials and Methods for the details of the representative statistics.

Figure S8. Analysis of fixed alleles in artificial genomes with 65,535 SNPs. Left figures show the number of fixed alleles in artificial genomes (x axis) versus the frequency of these alleles in the real dataset (y axis). Right figures show the distribution of the frequency of alleles fixed in the artificial dataset but not fixed in the real dataset.

Figure S9. 3-point correlation analysis of SNP triplets for the 65,535-SNP data with inter-SNP distances of 1, 4, 16, 64, 256, 512 and 1024 (from left to right, top to bottom) for a) WGAN and b) CRBM AGs. The last panels (bottom right) shows correlation for triplets of SNPs drawn randomly. In each plot, drawing order (z-order) of each AG group is shuffled.

Figure S10. Analysis of small haplotype motifs between real and generated 65,535-SNP datasets for a) 4-mer and b) 8-mer non-overlapping windows. For each unique k-mer in each window, number of occurrences in the real dataset was compared to the same number in the AG dataset. Each point corresponds to the occurrence number in real (x-axis) and AG (y-axis) datasets. Values presented inside the figures are Pearson's r, ordinary least squares regression slope and intercept.

Figure S11. Radar plot comparing artificial genomes generated by WGAN and CRBM models for the 65,535-SNP dataset. Values closer to 0 indicate poor performance whereas values closer to 1 indicate good performance. See Materials and Methods for the details of the representative statistics.

Figure S12. Distribution of haplotypic pairwise difference within (left figure) and between (right figure) 65,535-SNP datasets.

Figure S13. Principal component analysis (PCA) of combined real and artificial genomes with 65,535 SNPs.

Figure S14. Analysis of WGAN and RBM generated AGs using 2504 samples from 10,000-SNP dataset. a) Principal component analysis (PCA) of combined real and artificial genomes. b) Allele frequency correlation between real (x-axis) and artificial (y-axis) genome datasets. Bottom figures are zoomed at low frequency alleles (from 0 to 0.2 overall frequency in the real dataset). Values presented inside the figures are Pearson's r, ordinary least squares regression slope and intercept. c) Nearest neighbour adversarial accuracy (AATS) of artificial genomes generated by different models and the test set. Values below 0.5 (black line) indicate overfitting and values above indicate underfitting. d) Privacy score for WGAN and RBM generated AGs. Values close to 0 indicate no privacy leakage.

Figure S15. Membership inference attack on generated 10,000-SNP genomes. a) White-box attack (adversary has access to the model architecture and weights) on WGAN AGs and black-box attacks with auxiliary information (adversary has only access to the model architecture) on b) WGAN and c) RBM AGs. For all attacks, the adversary is assumed to know the size of the training set (2504 in this analysis) and possesses a set of samples (5008 in this analysis) suspected of belonging to the training data. For each attack, the critic scores the samples and the adversary sets a threshold for assigning the top n scoring samples to the training dataset. Figures in the upper row show the accuracy of attacks depending on these thresholds (assigned samples ranging from the top 1% to the top 50%). The red dashed lines indicate the accuracy if the n samples were chosen randomly and not based on their scores. Figures in the lower row show the distribution of the critic score for train and test datasets. See Materials and Methods for more details.
