Abstract: Advances in optical trapping design principles have led to tremendous progress in manipulating nanoparticles (NPs) with diverse functionalities in different environments using bulky systems. However, efficient control and manipulation of NPs in harsh environments require a careful design of contactless optical tweezers. Here, we propose a simple design of a fibered optical probe allowing the trapping of dielectric NP as well as a transfer of the angular momentum of light to the NP inducing its mechanical rotation. A polarization conversion from linearly-polarized incident guided to circularly transmitted beam is provoked geometrically by breaking the cylindrical symmetry of a coaxial nano-aperture that is engraved at the apex of a tapered metal coated optical fiber. Numerical simulations show that this simple geometry tip allows powerful light transmission together with efficient polarization conversion. This guarantees very stable trapping of quasi spherical NPs in a non-contact regime as well as potentially very tunable and reversible rotation frequencies in both directions (up to 45 Hz in water and 5.3 MHz in air for 10 mW injected power in the fiber). This type of fiber probe opens the way to a new generation of miniaturized tools for total manipulation (trapping, sorting, spinning) of NPs.

1. Introduction

Since its discovery by Ashkin in 1970 [1], optical tweezers have become a tool of choice for physicists, chemists and biologists in the manipulation of nanoparticles (NPs). The advent of metamaterials in the field of optics has boosted research in this direction with the aim of miniaturizing these systems using them to explore physical and chemical properties in the field of the infinitely small scale (chemical bonds between molecules and even atomic bonds). At these scales, the tools must be adapted in size, so that they induce the minimum disturbance on the quantities to be measured. It is therefore privileged to set up standalone systems allowing both the trapping of NPs and their translation and rotation.

To this end, metamaterials, which have been extensively studied over the past decades, can be of great help. Indeed, they have shown their ability to address a wide variety of applications ranging from detection [2], beam shaping and polarization [3–6] to optical trapping through the control of light confinement via changes in the phase and group velocities of the waves passing through them [7]. This confinement is essential to the trapping itself and will allow the translation movement. The rotation, as for it, is generally induced by a transfer towards the NP of the angular momentum of the light. This last one requires the control of the light polarization at nanometric scales. Consequently, the design of standalone miniaturized optical tweezers lacks only one element which consists in the miniaturization of the wave-plates (quarter- and half-wave plates). However, optical rotation of NPs was already demonstrated since 1997 [8] and has seen considerable growth both theoretically and experimentally over the past 20 years [9–16] with great

46 interest for applications in biology [13, 15–18]. Recently, Lehmuskero *et al.* [19] demonstrated
 47 gold NP spinning within a circularly polarized focused beam. They measured spinning frequencies
 48 of several kHz for NP rotating around its center of mass. Nevertheless, they only had a 2D trapping
 49 (in the transverse plane) meaning the NP is pushed against a glass slide to restrict its motion
 50 along the beam propagation direction. Some authors [20–23] recently showed optical trapping in
 51 vacuum accompanied with high spinning motion around the beam axis with frequency beyond
 52 1GHz but their schemes involve bulky systems composed of propagating beams, conventional
 53 optical elements such as lenses, polarizers, wave-plates and/or diaphragms which makes the
 54 system very cumbersome.
 55 In these last four references, the spinning of the spherical NP is done around the axis of the
 56 illumination beam and not proper of the particle. The spin-orbit transfer induces an angular
 57 momentum to the spherical particle. Indeed, it is well known that a spin momentum transfer
 58 cannot take place in the case of a spherical dielectric particle made of an isotropic material
 59 even if it is illuminated by a circularly polarized beam. Nevertheless, in a recent paper [24], an
 60 experimental demonstration of such a spinning is performed for microparticle—a glycerol droplets
 trapped in a vortex beam even if they are nonbirefringent and nonabsorbing. In this study, our

Fig. 1. **Schematic of the proposed Optical Spinning-Trapping Tweezers (OSTT):**
 (a) Principle of the polarization conversion. (b): Artistic view of the simultaneous
 trapping and spinning of a NP.

61 fibred Optical Spinning-Trapping Tweezers (OSTT) combines simultaneously a contactless
 62 trapping and a linear-to-circular polarization conversion (see Fig. 1) allowing the NP translation
 63 simultaneously with its rotation. As it will be demonstrated in the following, the designed
 64 OSTT is able to induce a spinning of a quasi-spherical NP around its center of mass even if
 65 it is made of isotropic loss-less dielectric material. According to us, the presence of a vortex
 66 combined to the fact that a real particle is never perfectly spherical nor homogeneous at the
 67 nanometer scale are at the origin of the particle spinning around its proper axis. To take into
 68 account this geometrical anisotropy, we use in this study the FDTD method which is based on
 69 the discretization of the space into small parallelepipeds through which the NP is described by
 70 its electromagnetic properties (μ and ϵ). Even if the considered NP is spherical, this spatial
 71 discretization inevitably and naturally leads to an approximate geometry of the NP (staircase
 72 effect), which causes the appearance of a small (depending on the spatial FDTD cell size)
 73 asymmetry on the calculation of the electromagnetic field (see Appendix A). When operating in
 74 vacuum, such a OSTT could achieve spinning motion of trapped NPs around their center with
 75 relatively high frequency. The control of the NP rotation frequency could easily be performed by
 76 simply changing the polarization direction of the guided wave inside the monomode optical fiber
 77 through the use of a conventional polarization controller.
 78

79 2. Proposed structure and geometry optimization

80 Our structure is based on an individual coaxial aperture engraved on the apex of a metal (silver for
81 instance) coated tapered single-mode optical fiber. The geometry of the aperture was optimized
82 to exhibit an efficient transmission coefficient and a robust polarization conversion versus the
83 fabrication uncertainties. To this end, we made extensive Finite Difference Time Domain (FDTD)
84 numerical simulations using home-made codes (See Appendix A) to adapt the metal thickness to
85 the desired properties. The polarization conversion is obtained by light transmission through a
86 geometrical anisotropy of the coaxial aperture [25] (elliptical inner part instead of circular one).
87 The origin of this geometrical anisotropy is linked to the excitation of two orthogonally-polarized
88 (TE_{11}) guided modes through the coaxial aperture engraved into the metal layer and having
89 plasmonic/propagative hybrid character [26] with different effective refractive indices. This
90 anisotropy was described in details in refs. [25,27,28]. It could be exploited to induce the rotation
91 of the NP provided that it allows the necessary conversion of the linear polarization (in the fiber)
92 into circular polarization (at the tip output). Nevertheless, a stable trapping is simultaneously
93 necessary to fix the position of the NP in front of the tip. Therefore, electromagnetic confinement
94 within the aperture is essential to induce a sufficient gradient force capable of compensating for
95 the radiation pressure induced by the light flow (funnel effect) through the aperture.
96 Notice that, the major difference between our probe and other fiber probes comes from the
97 polarization properties of the emitted light. For example, a cylindrical nano-aperture probe [29]
98 with a circular section has no polarization selectivity but its transmission is very low compared
99 to that of coaxial one. A Bowtie nano-aperture antenna [30] only has confinement for linear
100 polarization and therefore cannot operate for spinning.

101
102 The geometry of the structure has been optimized by adapted calculations so that they are
103 less costly in terms of computing time and memory space. This consisted of two steps starting
104 from the consideration of a 2D grating of coaxial apertures and moving towards a single aperture
105 (please refer to the Appendix B). The latter is then transferred to the apex of a SNOM (Scanning
106 Near-field Optical Microscope) probe that consists on a metal-coated tapered monomode optical
107 fiber. The fiber core index is $n_c = 1.458$ and the cladding one is $n_g = 1.453$. The core diameter
108 is set to $D_c = 4.2 \mu\text{m}$ as for a SMF-28 or X1060 fibers from Thorlabs. The cone angle of the
109 tip has a typical value [31] of 28° . In the FDTD simulations, the fundamental guided mode of
110 the fiber is injected into the upper part of the probe (see Fig. 2a) at more than $5\mu\text{m}$ from the
111 apex. The geometrical parameters of the elliptical coaxial aperture are given as in Appendix
112 B. The thickness of the metallic layer is set to $h = 125 \text{ nm}$ allowing the aperture to behave as a
113 quarter-wave plate (the two transmitted transverse components of the electric field have the same
114 amplitude and are phase shifted by $\pi/2$ as presented in Fig. 2b). In this figure, the transmitted
115 intensities are calculated by normalizing the transmitted energy associated with each electric
116 field component to the total energy injected into the fiber. The operation wavelength is then
117 around $\lambda = 1080 \text{ nm}$. The temporal variation of the guided mode electric field (amplitude and
118 direction) in a transverse plane intersecting the fiber at $z = 4 \mu\text{m}$ from its apex is shown in the
119 video "**Visualisation1.avi**" when the polarization of the guided mode is supposed to be directed
120 at $\alpha = 45^\circ$ with respect to the axes of the ellipse (see inset of Fig. 2a).

121
122 As it can be seen from Fig. 2b, the intersection of the two spectra should correspond to
123 the required operating wavelength for which the phase difference $\Delta\phi = \text{Arg}(E_x/E_y)$ between
124 the two transverse components (E_x in red solid line and E_y in purple dashed line) is equal to $\pi/2$.
125 The variations of $\Delta\phi$ are also plotted in green dotted line on the same figure. One can clearly see
126 the latter condition to be fulfilled exactly for the wavelength value of $\lambda = 1080 \text{ nm}$ corresponding
127 to the abscissa of the intersection point. In addition, the positive value of $\Delta\phi$ means that the E_x
128 is in phase advance with respect to E_y . This indicates that the emitted wave by the aperture is

Fig. 2. (a) **Schematic of the modeled OSTT.** All geometric parameters and electromagnetic constants are given in the figure. The bottom left inset shows the polarization direction of the guided mode which is oriented at $\alpha = 45^\circ$ from the ellipse axes needed to get circularly polarized transmitted beam. (b) **Transmission spectra** of the two electric-field components (x in red solid line and y in purple dashed line) associated with the zero-order diffracted light for a silver coating thickness of $h = 125$ nm. The intersection of these two spectra corresponds to the operating point (quarter-wave plate) because the phase difference between the two transverse components of the electric field is well equal to $\pi/2$ as shown by the dotted green curve. (c) **Electric field distribution** (fifth root of the intensity) in a vertical plane at the operation wavelength. (d) **Zoom-in** on the area in front of the OSTT apex of Fig. (c) showing the electric field gradient necessary for trapping.

129 circularly right polarized. The temporal evolution of the transmitted electric field (amplitude
 130 and direction) by the OSTT in a transverse plane located at $z = 350$ nm in front of its apex is
 131 shown in the video "**Visualization2.avi**". A light angular momentum transfer from photons to
 132 the NP will then induce its rotation in the same direction that corresponds to a positive value of
 133 Q_z i.e. the z-component of the torque (see the coordinate system of Fig. 2a). Note that, at the
 134 operation wavelength, the transmission value is around $1.7\% \approx 2 \times 0.86\%$ (ratio of the transmitted

135 total energy to the injected energy into the fiber), a fairly efficient transmission compared to a
 136 simple cylindrical or rectangular aperture [26]. Let us notice that the small oscillations appearing
 137 on the spectra of Fig. 2b have a real physical meaning: they result from interference between
 138 the surface plasmon wave propagating along with the metal coating (probe external walls) and
 139 the transmitted guided field by the aperture itself [32]. Figure 2c shows the distribution of the
 140 electric field (fifth root of the intensity) at the operation wavelength $\lambda = 1080$ nm in a vertical
 141 plane parallel to xz containing the probe axis. Below we present (Fig. 2d) an enlargement of the
 142 area in front of the OSTT apex showing the large confinement of the electric field i.e. the high
 gradient needed to get efficient optical trapping.

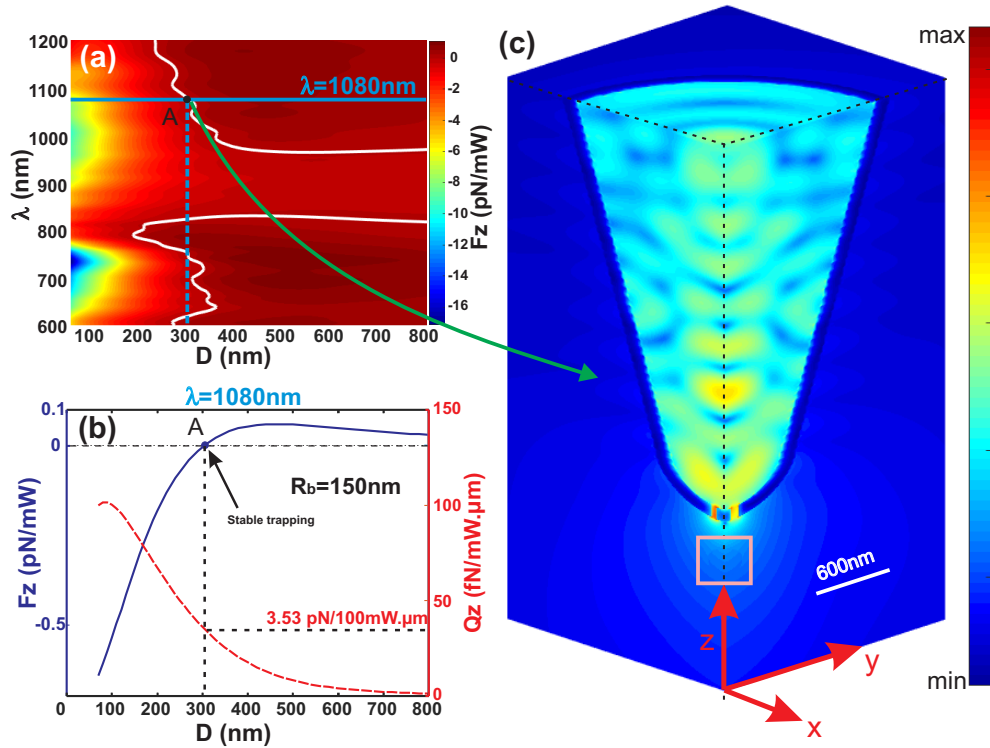

Fig. 3. **Trapping and Spinning of a $R_b = 150$ nm -radius NP.** (a) Vertical force F_z exerted on a 150 nm radius latex NP as a function of the injected wavelength and the OSTT-to-NP distance D . The white line denotes the NP position for which the optical force vanishes. The blue horizontal line corresponds to the quarter-wave operation wavelength ($\lambda = 1080$ nm). (b) Magnitude of the z-component of the force and the torque for the same NP ($R_b = 150$ nm, $n_b = 1.5$) as a function of D at $\lambda = 1080$ nm. Point A ($D = 305$ nm) corresponds to stable trapping (F_z vanishes) while the z-component of the torque does not cancel. (c) Electric intensity distributions (fifth root) in three perpendicular faces of a rectangular parallelepiped corresponding to the operation point A (trapping + spinning). The OSTT-axis coincides with the intersection of the two vertical planes. If we look closely inside the pink square, we could distinguish the presence of the trapped NP. Note that the three x , y and z -axis in (c) have the same scale indicated by the white bar of length 600 nm.

144 3. Optical forces and torques

145 To quantitatively evaluate the optical force \vec{F} and the torque \vec{Q} induced by the electromagnetic
 146 field transmitted by the probe on a given NP, we use, as in Ref. [30], the classical definitions
 147 given by:

$$\vec{F} = \oint\oint_s \vec{T} \cdot \vec{d}s \quad \vec{Q} = - \oint\oint_s \vec{T} \wedge \vec{r} \cdot \vec{d}s \quad (1)$$

148 Where, \vec{T} is the well-known Maxwell stress tensor with elements defined by:

$$T_{ij} = \varepsilon_0(E_i \cdot E_j - \frac{1}{2}\delta_{ij}E^2) + \mu_0(H_i \cdot H_j - \frac{1}{2}\delta_{ij}H^2) \quad (2)$$

149 Equations 1 are valid in harmonic regime ($e^{-i\omega t}$). Due to the conservative character of the
 150 optical forces and using the divergence theorem, the integration domains in both integrals consist
 151 of any surface surrounding the NP. Practically, we consider a cube that encompasses the NP
 152 and whose faces remain in the same medium (here water). Figure 3a shows the evolution of
 153 the vertical component F_z of the optical force applied on a NP made in latex ($n = 1.5$) with a
 154 radius $R_b = 150$ nm as a function of the wavelength and the distance D between the OSTT and
 155 the nearest point of the NP. The NP is supposed to move along the OSTT-axis so that, due to
 156 the symmetry of the configuration, only the vertical components of the force and of the torque
 157 are predominant. The white line on Fig. 3a corresponds to the positions where F_z becomes
 158 zero, which means possible NP trapping if the lateral components F_x and F_y also become zero
 159 simultaneously. Due to the symmetry of the configuration, this last condition on F_x and F_y is
 160 always fulfilled when the NP is in front of the OSTT ($x = y = 0$) as it will be shown in the
 161 following. Nonetheless, to be stable, the trapping must correspond to a potential well meaning
 162 a F_z variation from negative to positive values when the distance D increases (see the xyz
 163 frame on Fig. 2a). As can be seen in Fig. 3a, this stable trapping condition is well met at the
 164 A point corresponding to $D = 305$ nm and the operating wavelength of the quarter-wave plate
 165 ($\lambda = 1080$ nm).

166
 167 Figure 3b shows the vertical components of both the optical force F_z in solid blue line,
 168 and of the torque Q_z in dashed red line as a function of D for $\lambda = 1080$ nm. As predicted, the
 169 force cancels out for $D = 305$ nm (contactless trapping as obtained within a diabolo nano-antenna
 170 in ref. [33]) but not the torque whose value is equal $Q_z = 35.3$ fN/mW. μ m. This positive value is
 171 consistent with the rotation direction of the electric field associated with the circularly polarized
 172 wave emitted by the OSTT. Figure 3c corresponds to this trapping-spinning state (point A of
 173 Fig. 3a) and shows the electric intensity distributions in three perpendicular planes at the operation
 174 wavelength for a linearly polarized incident guided mode along $\alpha = 45^\circ$ (the angle α is shown
 175 in Fig. 2a). As expected, the mode inside the aperture is excited in both xz and yz planes even
 176 though its dimension is not the same in both planes.

177
 178 Note here that the numerical results seem to demonstrate a momentum transfer that induces the
 179 spinning of the particle. This is generally forbidden when considering a spherical purely dielectric
 180 particle made in isotropic medium and illuminated by a plane wave even if the latter is circularly
 181 polarized. As explained in the introduction, the reason for this transfer lies, in our case, in the fact
 182 that the FDTD mesh inevitably leads to a symmetry breaking for any three-dimensional object
 183 which is estimated, for a given direction, to be equal to the spatial step of discretization along this
 184 direction. Thus, in our case, the spatial step being 5 nm, this makes that the NP could have an
 185 elliptical shape of major axis $R + 5$ nm and a minor axis of $R - 5$ nm. In addition, the distribution
 186 of the electric field in the transverse plane (perpendicular to the axis of the probe) presents an
 187 asymmetry induced by the elliptical geometric shape of the aperture itself. To be convinced, we

Fig. 4. **Electric field and force distributions** at $\lambda = 1080$ nm. **(a-c)** Maps of the electric field component amplitudes in a transverse plane (xy plane) located at $D = 305$ nm from the OSTT apex corresponding to a stable trapping for the NP having a radius of 150 nm. An arbitrary unit is used to present these amplitudes as we only aim to show a qualitative aspect of the generation, in the near field, of a circularly polarized transmitted wave ($|E_x|$ of the same order of magnitude as $|E_y|$) but also the generation of a longitudinal component E_z due to diffraction by the coaxial aperture. **(d)** Distribution of the force components in the same plane : vertical component F_z in color level while white arrows correspond to the transverse force.

188 have plotted on Fig. 4a-c the distribution of the three components of the electric field amplitude
 189 in such a plane. As can be seen, these distributions do not show central symmetry especially
 190 the normal component (E_z) which looks like a distorted torus. The transverse components (E_x
 191 and E_y) lead to a perfectly circular polarization in the central region where the E_z component
 192 becomes zero.

193 In order to demonstrate that the trapping exists at the center (probe axis at $x = y = 0$) in
 194 the transverse plane corresponding to $F_z = 0$, we considered a particle sweeping this plane
 195 and we calculated the optical force on it for each position at different values of the wavelength.
 196 Figure 4d shows the vertical force F_z (in color level) and the transverse force component (white
 197 arrows) in the plane corresponding to $D = 305$ nm at $\lambda = 1080$ nm for a particle radius of
 198 $R_b = 150$ nm moving between $-1.24\mu\text{m}$ and $1.24\mu\text{m}$ along both the x and y directions. It can
 199 clearly be seen that the particle is pushed toward the axis $x = y = 0$ where $F_z = 0$. The movie
 200 "**Visualization3.avi**" shows the evolution of this transverse force as a function of the wavelength
 201 varying from 600 nm to 1200 nm. By looking closely to this video, we can see that the trapping
 202 only occurs around $\lambda = 1080$ nm for which the aperture behaves as a quarter-wave plate.

203 Figures 5a and b present the z-component of the force F_z and the torque Q_z respectively for
 204 different values of the NP radius R_b . Qualitatively, the force amount is comparable to that found

Fig. 5. **Optical force, optical torque, and potential variations.** (a) **Vertical force variations** exerted on a latex NP as a function of D for different values of the NP radius R_b . In all cases, the refractive optical index of the latter is fixed to $n_b = 1.5$. (b) **Magnitude of the z-component of the torque** as a function of D for the same R_b values as in (a). Vertical dashed lines denote stable trapping that occurs for all considered values of R_b except $R_b = 100$ nm. (c) **Potential derived from the optical force** as a function of D for the same R_b values as in (a) and (b). Notice that this value of $10k_B T$ is assumed to correspond to a stable trapping which exceeds by a factor of 10 that generally considered to correspond to stable trapping as recently suggested in [35]. This protects us from possible thermal effects that could break the trapping. (d) **Trapping distance and torque** as a function of R_b . In cases where trapping occurs, the torque is never equal to zero.

205 in Ref. [34] with coaxial aperture (around 50 pN/100mW for a small bead of 15 nm diameter)
 206 and it is at least twice as great as that obtained theoretically and experimentally with the bowtie
 207 nano-aperture antenna of Ref. [30]. The origin of this high efficiency is linked to the excitation
 208 of a frozen (small group velocity) guided mode inside the coaxial aperture resulting in significant
 209 energy funneling (large radiation pressure) together with high electric field confinement (gradient
 210 force). The torque seems to present an almost exponential decreasing with D as shown in Fig. 5d.
 211

212 To quantify the trapping strength, we plot on Fig. 5c the variations of the associated scalar
 213 potential (defined by $\vec{F} = -\vec{\nabla}(U)$) from which the optical force derives. One can clearly see that
 214 when trapping occurs, for $R_b \in [125;160]$ nm, an injected power into the fiber less than 1.31 mW
 215 leads to highly stable trapping for which the potential well is deeper than $-10k_B T$ [36] (horizontal
 216 orange dashed-dotted line on Fig. 5c). Notice that, recently, some authors [35], who carried out
 217 studies on the temperature effect on the optical trapping stability, consider that a potential of only
 218 $-k_B T$ is sufficient to have a stable trapping.
 219 The evolution of the stable trapping distance as a function of the NP radius R_b is given in Fig. 5d

220 (blue curve) in addition to the corresponding z-component of the torque for each NP radius.
 221 As expected, when the radius increases, the stable trapping position increases, and the torque
 222 decreases. Nevertheless, the behavior of these two variations is different: it is a fairly linear
 223 function of D while it is almost exponential for the torque.

224

225 As mentioned earlier, a conventional polarization controller can be used to tune the rota-
 226 tion frequency or even invert its sign (and even cancel it if desired). To demonstrate this effect,
 227 we have performed FDTD simulations by modifying the polarization direction of the guided
 228 mode defined by the angle α (see inset of Fig. 2a) as it can be done using such a controller. In
 229 these simulations, the NP has an optical index of $n_b = 1.5$ and we set its radius to $R_b = 150$ nm
 230 while the distance to the OSTT is $D = 305$ nm corresponding to the stable distance trapping
 231 previously calculated (see Fig. 5b).

232 Figure 6a shows a schematic view of the studied configuration. The variations of the z-components
 233 of the force and torque are presented in Fig. 6b. As expected, the force is quite constant and its
 234 value is very small (smaller than 0.01 pN/mW), so that the trapping distance is almost independent
 235 of the direction of polarization. The torque, on the other hand, undergoes a change in amplitude
 236 and a sign inversion when the incident polarization aligns with the axes of the ellipse (transmitted
 237 beam is then linearly polarized). As shown in figure 6b, the behavior is not symmetrical as in
 238 the ideal case of a quarter-wave plate where the torque should vary as $\sin 2\alpha$. This is due to the
 239 non-perfect geometry of the probe (aperture not perfectly aligned with the fiber axis & a symmetry
 240 of revolution which is broken by the mesh used in the FDTD [37]) which leads to a cancellation
 of the angular momentum for an angle $\alpha = 82^\circ$ instead of 90° . Figure 5c shows that an injected

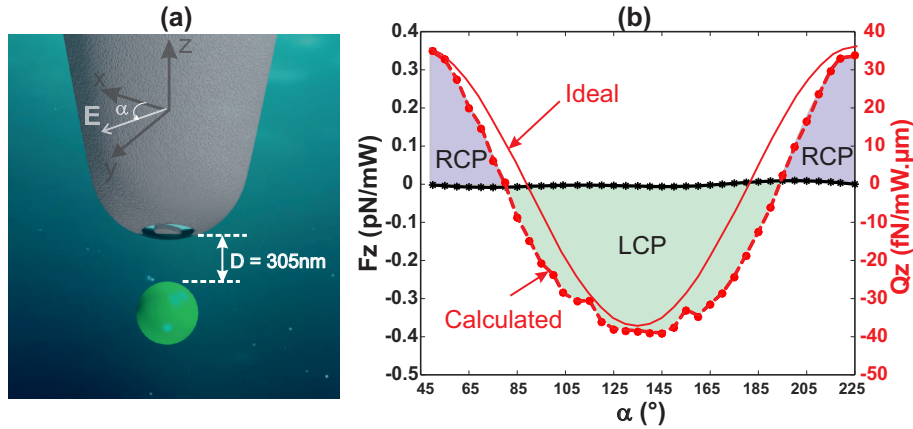

Fig. 6. **Trapping and spinning properties** as a function of the polarization direction of the guided mode inside the fiber given by the angle α . **(a) Schematic of the studied configuration** corresponding to a stable trapping of a NP radius $R_b = 150$ nm at a distance $D = 305$ nm. **(b) Variations of the z-components of the force (in black solid line) and the torque (red dashed line)** as a function of the guide mode polarization direction α . The solid red line corresponds to the torque variations within a perfect quart-wave plate.

241

242 power of 5 mW allows guaranteeing the stable trapping criterion of $U > 10k_B T$ [36] for NP radius
 243 R_b between 125 nm and 160 nm. The optical torques (median value of 25 fN $\cdot\mu\text{m}$ for only 1 mW
 244 injected power) are then as big as the one measured in Ref. [23] ($Q_z = 28 \pm 13$ fN $\cdot\mu\text{m}$) using a
 245 bulky configuration. This suggests an excellent spinning efficiency even if the NP is in water. In
 246 fact, the relation that corresponds to the steady-state rotation motion (torques equilibrium) in the

247 case of a pure dielectric sphere (without absorption) is given by [21, 38]:

$$\tau_{\text{drag}}^{\text{sphere}} = -Q_z = -\frac{4\pi^2\mu R_b^4\nu_r}{1.497\Lambda} \quad (3)$$

248 Where $\tau_{\text{drag}}^{\text{sphere}}$ is the viscous torque for a R_b -radius hard-sphere rotating at frequency ν_r in a liquid
249 of dynamic viscosity μ with a molecular mean free path of Λ . If we consider a $R_b = 125$ nm-
250 radius NP immersed in water ($\mu = \mu_{\text{water}} = 8.9 \times 10^{-4}$ Pa.s, $\Lambda = \Lambda_{\text{water}} = 2.5$) trapped within an
251 injected power of 1 mW, the spinning frequency of the rotational steady-state is evaluated to be
252 $\nu_r^{\text{water}} = 28.2$ Hz. This relatively small value of the rotation frequency can be greatly enhanced
253 when NP is trapped in air (up to $\nu_r^{\text{air}} = 3.34$ MHz for $\mu_{\text{air}} = 1.8 \times 10^{-5}$ and $\Lambda_{\text{air}} = 0.6$ μm) and
254 obviously higher values could be obtained in vacuum.

255
256 These theoretical above results show the possibility of developing standalone optical tweezers
257 allowing the trapping and spinning of NPs. It is essential that a manufacturing effort should
258 accompany the implementation of such trapping techniques. From a technological perspective,
259 many challenges remain in applying optical tweezers to the study of systems composed of
260 separated particles or of aggregates (molecules or biological compounds). Let us quote for
261 instance the improving of the spatial/temporal resolution and accuracy of force measurements,
262 the hybridizing with techniques for simultaneous measurement of multiple parameters such as
263 force, displacement along complementary axes, torque and angle. In other words, by using
264 multiple traps simultaneously, it should be possible to proportionally increase the amount of
265 data obtained from single-particle or molecule experiments. In addition, there is a growing
266 trend toward interdisciplinary research, which is an effective approach to promote the devel-
267 opment of techniques. As a cutting-edge field, machine learning provides an opportunity to
268 improve research efficiency. It has been shown that machine learning can improve light-matter
269 interactions [39], which provides a good overview of research on the design and applications of
270 plasmonic tweezers [40].

271 **4. Conclusion**

272 In summary, the proposed OSTT offers a unique fibered/miniaturized design of an optical
273 tweezers able to act as a quarter-wave nano-antenna inducing a contactless trapping together
274 with a spinning of a NP. The geometric parameters of the OSTT can be adapted to operate over
275 a wide spectral range as well as according to the physico-chemical nature of the NP and/or
276 of the host medium. The metal coating can also be treated to inhibit any chemical reaction
277 (oxidation, sulfurization, ...). Nevertheless, one should be aware of the fact that the presence of
278 metal could induce harmful effects (heating then destruction of the probe) in the case of high
279 injected power. This is why the coaxial aperture remains an excellent compromise due to its
280 high transmission efficiency allowing to use it as an OSTT with low optical power in many
281 optomechanics applications (optical pressure control, sorting of chiral and non-chiral particles,
282 translational and rotational nano-positioning,...) that require relatively low light powers.

289 The authors declare no conflicts of interest. Data availability.

290 Data availability

291 Data underlying the results presented in this paper are not publicly available at this time but may
292 be obtained from the authors upon reasonable request.

293 Appendix A Simulation method

294 We use home-made FDTD codes that were adapted to the studied geometry. The FDTD is
295 based on the solving of Maxwell equations through a temporal iterative scheme. The space
296 is discretized into small cells of dimension as small as $\lambda/30$ and the electromagnetic field is
297 calculated for each cell through a centered finite-difference schema [41]. Due to the temporal
298 character of the FDTD, dispersive materials need to be modeled through an analytical model
299 giving their permittivity as a function of the wavelength. The model is then integrated into the
300 FDTD algorithm using the auxiliary differential equation method or the recursive convolution
301 method.

302
303 In the case of periodic structure, periodic boundary conditions are applied in the x and y
304 directions while absorbing (Perfectly Matched Layer technique) ones are used in the z -direction
305 to cancel parasitical reflections on the limits of the simulation window. For the OSTT, a Full
306 3D-FDTD code is used where the absorbing boundary conditions are applied in the three
307 directions of the space due to the finite character of the configuration. In this case, the simulations
308 are much heavier and require a calculation time of about 3 days per NP position. In both codes,
309 we used a non-uniform mesh allowing us to describe the geometry of the structure (cell size) as
310 well as possible. The size of the cell varies from 5 nm near the probe apex and the NP to 20 nm
311 elsewhere. The force and torque calculations are done using Matlab software through a code that
312 allows implementing Eqs. 1. The integration is made over a cube which encompasses the NP
313 and having all its faces in the same medium (here water or air) in order to fulfill the condition of
314 conservation of the force to be able to use divergence theorem which allowed us to transform the
315 volume integral into a surface integral. In all simulations, the side of the cube was set to the
316 diameter of the NP increased by 6 FDTD cells (3 cells on each side).

317 On the other hand, to illustrate the intrinsic symmetry breaking of FDTD mentioned in the
318 introduction, we present in figure 7 a 2D mesh of a vertically symmetric structure made of two
319 different materials (gray and white). The Yee scheme used to calculate the electromagnetic field
320 of a cell is also highlighted for two specific cells (see the large circles). The expression of the
321 corresponding magnetic fields is given by :

$$322 \quad H_z(i, j, t) = H_z(i, j, t - \delta t) \\ 323 \quad + \frac{1}{\mu} \left\{ \frac{E_x(i, j+1, t - \delta t/2) - E_x(i, j, t - \delta t/2)}{\Delta y} - \frac{E_y(i+1, j, t - \delta t/2) - E_y(i, j, t - \delta t/2)}{\Delta x} \right\} \\ 324 \quad (4)$$

$$325 \quad H_z(i+4, j, t) = H_z(i+4, j, t - \delta t) + \frac{1}{\mu} \left\{ \frac{E_x(i+4, j+1, t - \delta t/2) - E_x(i+4, j, t - \delta t/2)}{\Delta y} \right. \\ \left. - \frac{1}{\mu} \left\{ \frac{E_y(i+5, j, t - \delta t/2) - E_y(i+4, j, t - \delta t/2)}{\Delta x} \right\} \right\}$$

326 When the structure is illuminated by a plane wave propagating along the y direction, the two
327 magnetic fields (H_z) of these two cells $[(i, j)$ and $(i+4, j)]$ must be equal. Unfortunately, Yee's
328 scheme does not fulfill this condition due to the fact that the electric field component $E_y(i+5, j)$,
329 highlighted in blue in equation 5, is relative to the gray material while the two components E_y of
330 cell (i, j) correspond to the white material. This symmetry breaking exists even if the whole

331 configuration is symmetric. Nevertheless, the smaller the size of the FDTD cell, the smaller
 332 the symmetry breaking is [37]. This induced symmetry breaking by FDTD has already been
 333 numerically exploited to reveal the presence of BICs (Bound states In the Continuum) and/or
 symmetry protected modes (SPMs) [37, 42] within specific structures.

Fig. 7. **Intrinsic symmetry breaking by FDTD** The scheme of an FDTD mesh applied to a geometrically symmetric structure (gray and white materials). The Yee scheme used to calculate the electromagnetic components is the source of the dissymmetry.

334

335 **Appendix B Optimization of the geometry**

336 The approach used is that described in Ref. [25]. We start by considering a 2D square lattice
 337 grating of elliptical coaxial apertures (see Fig.1 of Ref. [25]) deposited on a glass substrate and
 338 we adapt the metal thickness by taking water as superstrate instead of air as in [25]. In fact, for
 339 trapping applications, NPs are generally immersed in a liquid to counteract their weight by the
 340 buoyancy forces. Home-made FDTD codes were then used to simulate the light transmission
 341 through this grating. The geometrical parameters, according to the notions of Fig. 1 of Ref. [25],
 342 are: $p = 300$ nm is the period, $R_{iM} = 80$ nm is the major-axis of the inner ellipse, $R_{im} = 50$ nm
 343 is its minor-axis while $R_o = 120$ nm is the radius of the outer edge of the aperture). The glass
 344 substrate refractive index is fixed to $n_s = 1.458$ and the dispersion of the silver film is described
 345 through a Drude-Critical Points (DCP) model [43] which has been adapted to the studied spectral
 346 range ($\lambda \in [600 \text{ nm}, 1400 \text{ nm}]$). Figure 8a shows a diagram giving the transmission spectrum
 347 as a function of the metal thickness h . Similarly to Ref. [27], we superimposed dotted green
 348 lines corresponding to a phase difference of $\Delta\phi = \pi/2$ between the two transmitted transverse
 349 components of the electric field; essential condition to have a quarter wave plate. Moreover, the

Fig. 8. **Polarization conversion through a metallic grating of coaxial elliptical apertures.** (a) **Transmission spectra** as a function of the metal layer thickness h . The cyan contour lines are calculated for equivalent intensities of the two x - and y - components of the transmitted electric field while the dotted green lines denote couples (h, λ) for which the phase difference is equal to $\pi/2$. The blue dashed-dotted horizontal line passing through the operation point W corresponds to a metal thickness $h = 95$ nm. (b) **Transmission spectra** of the two electric field components, E_x in black dotted line and E_y in purple dashed line, in addition to the total transmission T in blue dotted-dashed line for a metal thickness of $h = 95$ nm corresponding to the horizontal blue dotted-dashed line on (a). The phase difference $\Delta\phi$ is also plotted in red solid line. As expected, the intersection between the black and the purple curves corresponds exactly to a phase difference of $\pi/2$ as indicated by the vertical green dashed line.

350 cyan lines correspond to another condition for which the transmission coefficients of these two
 351 components are identical. This fulfills the requirement on the transmitted amplitudes to obtain a
 352 circular polarization instead of an elliptical one. All intersections of the green lines with the cyan
 353 lines give solutions that fulfill a quarter-wave plate behavior. The last step is then to choose the
 354 intersection point corresponding to the higher value of the transmission coefficient. From Fig. 8a,
 355 the more adapted thickness is obtained for $h = 95$ nm and the operation wavelength value is then
 356 around $\lambda = 1093.5$ nm for which transmission spectra and phase difference are shown on Fig. 8b.
 357 Note that the geometry has been adapted to obtain an operating wavelength value corresponding
 358 to low light absorption by water [30, 44]. Considering a single elliptical coaxial aperture etched
 359 at the apex of a metal-coated SNOM probe, the transmission properties, in terms of polarization,
 360 deviate slightly from those of a periodic structure (same aperture grating), especially because the
 361 illumination conditions are not the same (fiber mode in the case of the probe instead of a plane
 362 wave in the case of the grating). For this reason, the geometric parameters have been adapted
 363 leading to an operating wavelength around 1080 nm. This was achieved through additional full
 364 3D-FDTD simulations with the same aperture geometry leading to a slightly different value of
 365 the metal thickness $h = 125$ nm instead of 95 nm as presented in Fig. 2b.
