**ABSTRACT.** The structure of  $\text{MOF}_3$  ( $M = \text{Nb}, \text{Ta}$ ) compounds was precisely modeled by combining powder X-ray diffraction, solid-state NMR spectroscopy and semi-empirical dispersion corrected DFT calculations. It consists of stacked  $\alpha(\text{MOF}_3)$  layers along the  $\vec{c}$  direction formed by heteroleptic corner-connected  $\text{MX}_6$  ( $X = \text{O}, \text{F}$ ) octahedra.  $^{19}\text{F}$  NMR resonance assignments and occupancy rates of the anionic crystallographic sites have been revised. The bridging site is shared equally by the anions and the terminal site is occupied by F only. An O/F correlated disorder is expected since *cis*- $\text{MO}_2\text{F}_4$  octahedra are favored, resulting in one-dimensional  $-\text{F}-\text{M}-\text{O}-\text{M}-$  strings along the  $\langle 100 \rangle$  and  $\langle 010 \rangle$  directions. Ten different  $2 \times 2 \times 1$  supercells per compound, fulfilling these characteristics, were built. Using DFT calculations and the GIPAW approach, the supercells were relaxed and the  $^{19}\text{F}$  isotropic chemical shift values were determined. The agreement between the experimental and calculated  $^{19}\text{F}$  spectra is excellent for  $\text{TaOF}_3$ . The  $^1\text{H}$  and  $^{19}\text{F}$  experimental NMR spectra revealed that some of the bridging F atoms are substituted by OH groups, especially in  $\text{NbOF}_3$ . New supercells involving OH groups were generated. Remarkably, the best agreement is obtained for the supercells with the composition closest to that estimated from the  $^{19}\text{F}$  NMR spectra, *i.e.*,  $\text{NbOF}_{2.85}(\text{OH})_{0.15}$ .

## 1. Introduction

Heteroanionic materials, such as oxyhalides, offer opportunities for developing new materials with targeted functionalities.<sup>1</sup> Understanding their properties requires a complete structural characterization. When these materials contain anions with similar X-ray or neutron scattering factors, such as oxides and fluorides, diffraction data alone is often insufficient to fully predict the anionic substructure. In these cases, if the anions are well-ordered, a complete structural model may be proposed by combining long-range diffraction data with bond-valence sum analysis. However, for those in which the different anions have joint occupancy of equivalent crystallographic sites, the structure cannot be fully described using a single unit cell, even if it does not necessarily imply a random distribution of the anions. Indeed, between the limits of fully ordered and randomly disordered anions, there are many cases of intermediate anion orders with local clustering or extended correlations that may give rise to non-random site occupancies in the averaged crystal structure.<sup>1,2</sup>

Pentavalent (Nb,Ta)-based inorganic oxyfluorides represent a rich family of compounds,<sup>3</sup> synthesized and structurally characterized from the 1950s to the 2000s, including NbO<sub>2</sub>F,<sup>4-7</sup> TaO<sub>2</sub>F,<sup>4,8</sup> Nb<sub>3</sub>O<sub>7</sub>F,<sup>5,9,10</sup> Ta<sub>3</sub>O<sub>7</sub>F,<sup>8,11</sup> Nb<sub>5</sub>O<sub>12</sub>F,<sup>9</sup> Nb<sub>17</sub>O<sub>42</sub>F and Nb<sub>31</sub>O<sub>77</sub>F,<sup>12,13</sup> Nb<sub>3</sub>O<sub>5</sub>F<sub>5</sub>,<sup>14</sup> and NbOF<sub>3</sub> and TaOF<sub>3</sub>.<sup>15</sup> They exhibit interesting physical properties such as photocatalytic activity (MO<sub>2</sub>F (M = Nb,<sup>16,17</sup> Ta<sup>18,19</sup>) and M<sub>3</sub>O<sub>7</sub>F (M = Ta,<sup>19</sup> Nb<sup>17,20,21</sup>)), electrochromism (NbO<sub>2</sub>F),<sup>22</sup> almost zero thermal expansion (TaO<sub>2</sub>F),<sup>23-25</sup> and Li<sup>+</sup> intercalation (NbO<sub>2</sub>F,<sup>7,26,27</sup> Nb<sub>3</sub>O<sub>7</sub>F<sup>27,28</sup>). Except in Nb<sub>17</sub>O<sub>42</sub>F<sup>13</sup> and MOF<sub>3</sub> (M = Nb, Ta)<sup>15</sup> crystal structures, O<sup>2-</sup> and F<sup>-</sup> are randomly distributed on all anion sites.<sup>4,6,7,9-11,13,14</sup> In Nb<sub>17</sub>O<sub>42</sub>F, O<sup>2-</sup> and F<sup>-</sup> are randomly distributed on only two of the anion sites, and in MOF<sub>3</sub>, O<sup>2-</sup> and F<sup>-</sup> are preferentially distributed.

In disordered oxyfluorides, the short-range structures must deviate from the average crystal structures to accommodate the different M–O and M–F bond lengths. This has been indeed shown for  $\text{MO}_2\text{F}$  (M = Nb, Ta) and  $\text{Nb}_3\text{O}_5\text{F}_5$  in four studies using various techniques: electron diffraction study of  $\text{NbO}_2\text{F}$ <sup>29</sup> and  $\text{Nb}_3\text{O}_5\text{F}_5$ <sup>30</sup> and variable-temperature neutron diffraction<sup>23</sup> and total X-ray scattering<sup>25</sup> studies of  $\text{TaO}_2\text{F}$ .

$\text{NbO}_2\text{F}$  and  $\text{TaO}_2\text{F}$  both adopt an average cubic  $\text{ReO}_3$ -type structure. Brink et al.<sup>29</sup> have shown the coexistence in  $\text{NbO}_2\text{F}$  of (i) uncorrelated with each other one-dimensional O/F-ordered strings of atoms,  $-\text{Nb}-\text{O}-\text{Nb}-\text{O}-\text{Nb}-\text{F}-$ , with significant displacements of Nb from the ideal cation site, along the three  $\langle 001 \rangle$  directions, and (ii) correlated rigid unit model (RUM) rotation of  $\text{NbX}_6$  octahedra. It was suggested that the high transverse anisotropic displacement parameters, evidenced in  $\text{TaO}_2\text{F}$ , likely result from the static tilting of the  $\text{TaO}_4\text{F}_2$  octahedra and Ta–(O/F)–Ta angles inferior to  $180^\circ$ .<sup>23</sup> In addition, Morelock *et al.*<sup>25</sup> demonstrated that a cubic  $3 \times 3 \times 3$  supercell model featuring  $-\text{Ta}-\text{O}-\text{Ta}-\text{O}-\text{Ta}-\text{F}-$  chains along the three  $\langle 001 \rangle$  directions, with different Ta–O and Ta–F distances and O/F off-axis displacements, gave much better agreement with PDFs. Finally, the structural modeling of  $\text{NbO}_2\text{F}$  and  $\text{TaO}_2\text{F}$  by DFT geometry optimized supercells, supported by the very good agreement between experimental and calculated  $^{19}\text{F}$   $\delta_{\text{iso}}$  values, leads to realistic disordered structures.<sup>31</sup>

$\text{Nb}_3\text{O}_5\text{F}_5$ <sup>14</sup> is the  $n = 3$  member of an  $\text{Nb}_n\text{O}_{2n-1}\text{F}_{n+2}$  ( $1 \leq n \leq \infty$ ) homologous series of oxyfluoride compounds. Their average structure consists of two-dimensional slabs regularly stacked along the  $c$  direction and shifted one from another by  $(1/2 a + 1/2 b)$ . The thickness of each slab is formed by  $n$  octahedral layers of corner-linked  $\text{Nb}(\text{O},\text{F})_6$  octahedra. The continuous planes of diffuse intensity observed by electron diffraction imply the existence of strings of ordered oxygen and fluorine atoms for equatorial anion sites along  $[100]$  and  $[010]$  albeit without correlation from one

such string to the next, and octahedral rotation RUM modes of distortion, analogous to those observed in NbO<sub>2</sub>F.<sup>30</sup> Additionally, a bond valence sum (BVS) argument has been used to derive a plausible site occupation model for the remaining apical and median anion sites.

MOF<sub>3</sub> (M = Nb, Ta), the n = 1 members of the M<sub>n</sub>O<sub>2n-1</sub>F<sub>n+2</sub> series, then adopt the SnF<sub>4</sub> type structure (tetragonal system, SG: *I4/mmm* (139)). The slabs consist of one octahedral layer formed by MX<sub>1.5</sub>X<sub>2.5</sub> corner-linked octahedra, and are stacked, via van der Waals (vdW) interactions, along the *c* direction. According to Rietveld refinements of the powder X-Ray diffraction (PXRD) data, O and F atoms are distributed on both the bridging (X1) and the terminal (X2) sites with site occupancies significantly different for the two compounds : 0.725 F/0.275 O for X1 and 0.775 F/0.225 O for X2 in NbOF<sub>3</sub> and 0.90 F/0.10 O for X1 and 0.60 F/0.40 O for X2 in TaOF<sub>3</sub>.<sup>15</sup> Furthermore, based on BVS calculations,<sup>32,33</sup> the authors conclude that F atoms should preferentially occupy the X2 site for both compounds. In contrast, their analysis of the <sup>19</sup>F NMR spectrum of TaOF<sub>3</sub> led them to conclude that the X2 site is preferentially occupied by O atoms. On the other hand, and in agreement with previous BVS calculations, Brink *et al.* predict that, in NbOF<sub>3</sub>, the apical (terminal) X2 anion site is overwhelmingly occupied by F rather than O (0.523 F/0.477 O for X1 and 0.977 F/0.023 O for X2) along with a RUM rotation angle equal to 7.8°.<sup>30</sup>

To capture structural features of complex materials on various length scales and generate realistic models, the combination of complementary quantitative experimental measurements is crucial.<sup>34</sup> Both intermediate-range chemical disorder and short-range geometrical disorder give rise in local spectroscopies such as NMR to distributions of resonance frequencies. The prediction of the spectroscopic responses by means of electronic structure calculations therefore plays an essential role not only to assign the different spectral contributions, but also to understand the structural origins of the experimental parameter distributions.<sup>35-39</sup> This has been successfully

exploited in numerous studies of disordered inorganic crystalline materials by coupling solid-state NMR and DFT calculations on supercells.<sup>31,40–62</sup>

Herein, we describe the structural modeling of NbOF<sub>3</sub> and TaOF<sub>3</sub>. Based on BVS calculations,<sup>33</sup> and on experimental  $\delta_{\text{iso}}$  and relative intensity values extracted from the <sup>19</sup>F NMR spectra, assignment of the resonances and occupancy rates of the two anion crystallographic sites have been revised.

The average structures issued from PXRD refinements were used to construct 2×2×1 supercells fulfilling the expected O/F correlated disorder. Three arrangements of O and F in the ( $\vec{a}, \vec{b}$ ) planes are possible and combining them results in ten possible models for each compound. All models were geometry optimized and magnetic shielding values were calculated using the GIPAW<sup>63,64</sup> approach, converted to chemical shifts and then compared to the experimental data. Despite the MOF<sub>3</sub> compounds being prepared using solid-state synthesis, the <sup>1</sup>H and <sup>19</sup>F experimental NMR spectra revealed that some of the bridging F1 atoms are substituted by OH groups, leading to the general formulation MOF<sub>1-x</sub>(OH)<sub>x</sub>F<sub>2</sub>. Due to the higher OH group content in NbOF<sub>3</sub>, a satisfactory agreement between experimental and calculated <sup>19</sup>F spectra could not be obtained without introducing OH groups in the models. Then, new models were built considering different OH substitution rates, and their influence on the calculated <sup>1</sup>H and <sup>19</sup>F spectra is evidenced.

## 2. Experimental details

**2.1 Synthesis.** NbOF<sub>3</sub> has been known since the second half of the 19<sup>th</sup> century.<sup>65</sup> A hundred years later its presence as a by-product was mentioned in two studies on NbO<sub>2</sub>F<sup>66</sup> and NbF<sub>3</sub>,<sup>67</sup> and then in the gas state as a product of the decomposition of NbO<sub>2</sub>F.<sup>5</sup> MOF<sub>3</sub> (M = Nb, Ta) have been previously synthesized by Nieder-Vahrenholz *et al.*,<sup>68</sup> by reaction of MF<sub>5</sub> with oxide glass or M<sub>2</sub>O<sub>5</sub> and by Köhler *et al.*<sup>15</sup> by reaction of MF<sub>5</sub> with MO<sub>2</sub>F. The aqueous solution synthesis proposed by Frevel and Rinn,<sup>4</sup> which was used by Köhler *et al.* leads to compounds that both contain hydroxyl defects and metal vacancies.<sup>31,68</sup> Consequently, in the present work, MO<sub>2</sub>F were prepared by solid-state synthesis from a mixture of MF<sub>5</sub> (Alfa Aesar, 99.9% and 99% for TaF<sub>5</sub> and NbF<sub>5</sub>, respectively) and M<sub>2</sub>O<sub>5</sub> (Alfa Aesar, 99.85% and 99.9% for Ta<sub>2</sub>O<sub>5</sub> and Nb<sub>2</sub>O<sub>5</sub>, respectively) with an excess of MF<sub>5</sub> (5% and 10% for NbF<sub>5</sub> and TaF<sub>5</sub>, respectively) relative to the ideal 2:1 molar ratio. M<sub>2</sub>O<sub>5</sub> compounds were dried under secondary vacuum at 150 °C for 9 h with heating and cooling rates of 2 °C.min<sup>-1</sup>, and then kept under nitrogen atmosphere inside a glove box before use. Considering the moisture sensitivity of MF<sub>5</sub>, the steps of weighing, mixing and grinding were carried under nitrogen atmosphere using a glove box. The mixtures were then put inside platinum tubes, sealed and heated up to 210 °C for 18 h with a heating rate of 5 °C.min<sup>-1</sup> and then quenched in water at room temperature. MOF<sub>3</sub> were prepared from a mixture of MF<sub>5</sub> and MO<sub>2</sub>F. The steps of weighing, mixing and grinding were carried under nitrogen atmosphere inside a glove box. The mixtures were then loaded in platinum tubes, sealed and heated at 210°C for 18 h with heating and cooling rates of 5 °C.min<sup>-1</sup>. An excess of 10% of MF<sub>5</sub> relative to the molar 1:1 ratio is required to avoid the presence of unreacted MO<sub>2</sub>F. The final products are sensitive to moisture.

## 2.2 Characterization techniques.

**2.2.1 Powder X-ray diffraction.** The PXRD patterns were recorded at room temperature with a PANalytical EMPYREAN diffractometer equipped with a PIXcel1D X-ray detector using monochromatic Cu K $\alpha$  radiation ( $\lambda = 1.5406 \text{ \AA}$ ). The samples were loaded in a domed sample holder using a glove box under nitrogen atmosphere. The patterns were measured in a  $2\theta$  range of  $5^\circ$  to  $\sim 120^\circ$  with a  $0.0131^\circ$  step size. The recording time was approximately 6 h.

**2.2.2 Solid-state NMR spectroscopy.** Magic Angle Spinning (MAS) NMR spectra of  $^{19}\text{F}$  and  $^1\text{H}$  ( $I = \frac{1}{2}$ ) were recorded with a Bruker Avance III spectrometer functioning at 4.7 T ( $^{19}\text{F}$  and  $^1\text{H}$  Larmor frequencies of 188.3 MHz and 200 MHz, respectively) using a 1.3 mm CP-MAS probe-head. The Hahn echo sequence was used with an interpulse delay of one rotor period and a recycle delay of 10 s and 5 s for  $^{19}\text{F}$  and  $^1\text{H}$ , respectively. For both nuclei, the  $90^\circ$  pulse was set to 1.5  $\mu\text{s}$ , corresponding to a 167 kHz RF field.  $^{19}\text{F}$  and  $^1\text{H}$  spectra are referenced to  $\text{CFCl}_3$  and tetramethylsilane, respectively. The  $^{19}\text{F}$  chemical shift anisotropies were determined from the spinning sideband intensities according to Herzfeld and Berger.<sup>70</sup>  $^{19}\text{F}$  “infinite spinning frequency” MAS spectra were obtained from the full projection (onto the frequency dimension) of a Two-dimensional One Pulse (TOP) spectrum issued from the stacking of subspectra shifted by the spinning frequency from the conventional MAS spectrum.<sup>71</sup> These “infinite spinning frequency” isotropic spectra allow a direct quantification of the inequivalent fluorine sites (environments) in the structure and represent an alternative to the simulation of the spinning sideband manifolds. The reconstructions of the one-dimensional MAS (including spinning sidebands) and the TOP processing spectra were performed with the DMFit software.<sup>72</sup>

### 3. Ab initio calculations

**3.1 Definitions.** The calculated magnetic shielding parameters are defined by the Haeberlen convention.<sup>73</sup> The isotropic magnetic shielding ( $\sigma_{\text{iso}}$ ), the anisotropy of the magnetic shielding ( $\sigma_{\text{CSA}}$ ) and the asymmetry parameter ( $\eta_{\text{CSA}}$ ), are respectively defined as  $\sigma_{\text{iso}} = (\sigma_{\text{xx}} + \sigma_{\text{yy}} + \sigma_{\text{zz}})/3$ ,  $\sigma_{\text{CSA}} = \sigma_{\text{zz}} - \sigma_{\text{iso}}$  and  $\eta_{\text{CSA}} = (\sigma_{\text{yy}} - \sigma_{\text{xx}})/\sigma_{\text{CSA}}$ , with the magnetic shielding tensor components  $\sigma_{ii}$  defined in the sequence  $|\sigma_{\text{zz}} - \sigma_{\text{iso}}| \geq |\sigma_{\text{xx}} - \sigma_{\text{iso}}| \geq |\sigma_{\text{yy}} - \sigma_{\text{iso}}|$ . The chemical shift tensor is also defined by three parameters, the isotropic chemical shift ( $\delta_{\text{iso}}$ ), the anisotropy of the chemical shift ( $\delta_{\text{CSA}}$ ) and the asymmetry parameter ( $\eta_{\text{CSA}}$ ), which are given by  $\delta_{\text{iso}} = (\delta_{\text{xx}} + \delta_{\text{yy}} + \delta_{\text{zz}})/3$ ,  $\delta_{\text{CSA}} = \delta_{\text{zz}} - \delta_{\text{iso}}$  and  $\eta_{\text{CSA}} = (\delta_{\text{yy}} - \delta_{\text{xx}})/\delta_{\text{CSA}}$ , with the chemical shift tensor components defined in the sequence  $|\delta_{\text{zz}} - \delta_{\text{iso}}| \geq |\delta_{\text{xx}} - \delta_{\text{iso}}| \geq |\delta_{\text{yy}} - \delta_{\text{iso}}|$ . The relation between the isotropic magnetic shielding and the isotropic chemical shift is  $\delta_{\text{iso}} \approx \sigma_{\text{ref}} - \sigma_{\text{iso}}$ .

**3.2 DFT calculations.** Solid-state DFT calculations with periodic boundary conditions were performed on  $2 \times 2 \times 1$  supercells (from 40 to 42 atoms). The ground state electronic structure was obtained by the generalized gradient approximation (GGA) using the Perdew-Burke-Ernzerhof (PBE) functional (GGA-PBE).<sup>74</sup> The atomic position optimization (APO) and the full optimization of the supercells (FO, relaxation of atomic positions and supercell parameters) were performed using the VASP package (6.2.1 version).<sup>75,76</sup> The projector augmented wave (PAW)<sup>77,78</sup> potentials used for Ta, Nb, F, O and H are respectively: Ta\_sv\_GW ( $5s^2 5p^6 6s^2 5d^3$ ), Nb\_sv\_GW ( $4s^2 4p^6 5s^1 4d^4$ ), F\_GW ( $2s^2 2p^5$ ), O\_s\_GW ( $2s^2 2p^6$ ) and H\_GW ( $1s^1$ ). The wave functions were expanded on a plane-wave basis set with a 550 eV kinetic energy cut-off and  $(3 \times 3 \times 3)$  shifted Monkhorst-Pack k-point mesh. The total energy was converged up to change below  $10^{-8}$  eV. Terminal F from different  $\infty(\text{MOF}_3)$  layers are weakly bonded to each other via vdW interactions. Since this interaction is not included in the standard DFT-GGA algorithm, zero damping semi-empirical

dispersion correction of Grimme *et al.*<sup>79</sup> called DFT-D3 was included to the calculations. The damping function parameters ( $\alpha_6$ ,  $\alpha_8$ ,  $s_6$ ,  $s_8$ ,  $s_{R,6}$  and  $s_{R,8}$ ) were kept at the default values as well as the cut-off radius for pair interactions and the cut-off coordination radius. For both compounds, two methods of relaxation were performed, APO and FO, respectively referred in the following as APO\_DFT-D3 and FO\_DFT-D3.

The GIPAW approach<sup>63,64</sup> was used to calculate the magnetic shielding for the different nuclei, using the VASP package.<sup>75,76</sup> The PAW potentials, plane-wave energy cut-off and shifted Monkhorst-Pack k-point mesh were set to the same values as for the geometry optimization. NMR parameter calculations were performed on APO\_DFT-D3 and FO\_DFT-D3 supercells.

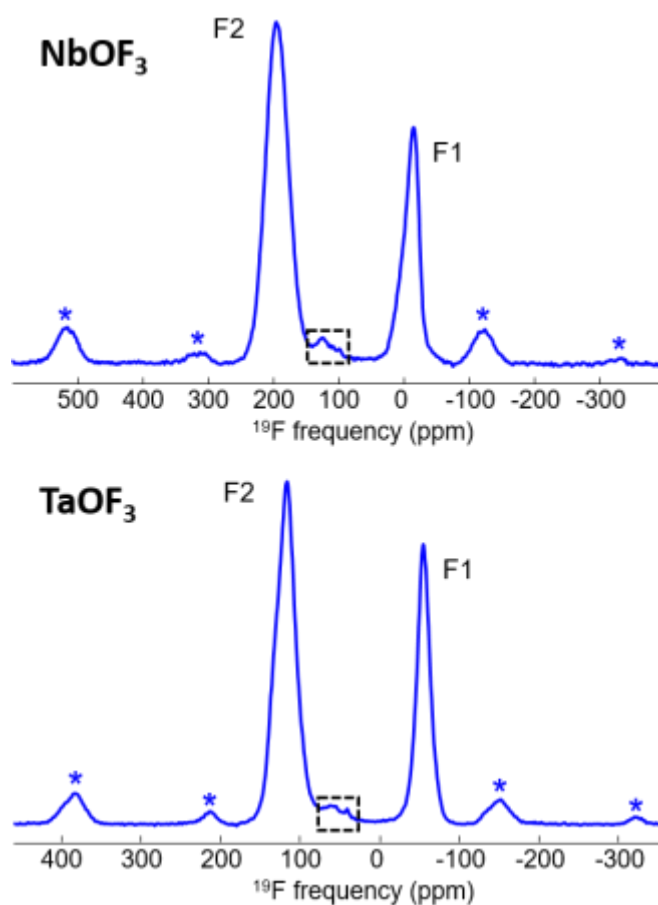

For  $^{19}\text{F}$  in inorganic fluorides, several linear relationships between calculated  $\sigma_{\text{iso}}$  values, using the GIPAW approach, and experimental  $\delta_{\text{iso}}$  values,  $\delta_{\text{iso}} = \sigma_{\text{ref}} - a \sigma_{\text{iso}}$ , have been established to convert calculated  $\sigma_{\text{iso}}$  values into “calculated”  $\delta_{\text{iso}}$  values. The absolute values of the slopes depend on the metal atom(s) constituting the fluoride(s) and are often significantly less than 1.<sup>80–92</sup> Then, in this paper, distinct  $\delta_{\text{iso}} = \sigma_{\text{ref}} - a \sigma_{\text{iso}}$ , equations determined by linearly correlating the calculated  $\sigma_{\text{iso}}$  values to the experimental  $\delta_{\text{iso}}$  values<sup>83</sup> of  $\text{NbF}_5$  and  $\text{TaF}_5$ , are used for  $\text{NbOF}_3$  and  $\text{TaOF}_3$ , respectively, as previously done for  $\text{NbO}_2\text{F}$  and  $\text{TaO}_2\text{F}$ .<sup>31</sup> Since the previous  $\delta_{\text{iso}} = \sigma_{\text{ref}} - a \sigma_{\text{iso}}$  equations<sup>83</sup> have been established using the CASTEP code,<sup>93,94</sup> to ensure the consistency of our calculations, new linear regressions were determined using the VASP package and keeping the conditions used for calculations on  $\text{MOF}_3$  supercells. These linear regressions are discussed in further detail later on in the paper (see 4.5). The  $^1\text{H}$   $\delta_{\text{iso}}$  calculated values were deduced using the equation:  $\delta_{\text{iso}} (\text{ppm}) = - \sigma_{\text{iso}} + 31$ .<sup>95</sup>

## 4. Results and discussion

### 4.1 Structural characterization: solid state NMR.

For (oxy)fluorides,  $^{19}\text{F}$  solid-state NMR is the ideal technique for determining the proportion of fluorine atoms in each crystallographic site (in each different environment) through the relative intensities of the NMR lines. The  $^{19}\text{F}$  MAS NMR spectra of  $\text{NbOF}_3$  and  $\text{TaOF}_3$  are presented in **Figure 1**. Their fits, those of the corresponding  $^{19}\text{F}$  “infinite spinning frequency” isotropic spectra and the corresponding fit parameters are reported in SI (**Figures S1-S4** and **Tables S1-S4**). The parameters relevant for the discussion are gathered in **Table 1**. Both  $^{19}\text{F}$  MAS NMR spectra present two main resonances, one more intense with higher  $\delta_{\text{iso}}$  and  $\delta_{\text{CSA}}$  values and one less intense with lower  $\delta_{\text{iso}}$  and  $\delta_{\text{CSA}}$  values, as well as additional low intensity resonances located in between but closer to the more intense. For both compounds the less intense  $^{19}\text{F}$  main resonance is assigned to the X1 (bridging) anion site and the more intense  $^{19}\text{F}$  main resonance, as well as the additional low intensity resonances, are assigned to the X2 (terminal) anion site (**Table 1**). These assignments are the opposite of those published previously.<sup>15</sup> However they are supported by the evolution of the  $^{19}\text{F}$   $\delta_{\text{iso}}$  values with the number of surrounding cations. For a given cation, the higher the coordination number, the lower the  $^{19}\text{F}$   $\delta_{\text{iso}}$  values,<sup>31,96</sup> as observed, for instance, in  $\text{NbF}_5$  (bridging: -42 ppm; terminal: 193 to 268 ppm),  $\text{TaF}_5$  (bridging: -70 ppm; terminal: 106 to 174 ppm).<sup>83</sup> and  $\text{TiF}_4$  (bridging: -2 to 30 ppm; terminal: 422 to 479 ppm).<sup>90</sup> These assignment are also supported by the higher  $\delta_{\text{CSA}}$  values of the resonances assigned to the terminal F atoms, as also observed for instance in  $\text{NbF}_5$ ,  $\text{TaF}_5$ <sup>83</sup> and  $\text{TiF}_4$ ,<sup>90</sup> the environment of a terminal F atom being more anisotropic than the environment of a bridging F atom surrounded by two identical cations located approximately opposite each other.

If we assume that the X2 site is fully occupied by F, and thus that the X1 site is half occupied by F and O atoms, the relative intensities of the corresponding NMR lines should be 2/3 for the terminal F2 NMR line and 1/3 for the bridging F1 one. NbOF<sub>3</sub> and TaOF<sub>3</sub> being moisture sensitive, the most likely hypothesis to explain that the relative intensities of the bridging F1 NMR lines are less than 1/3 (**Table 1**) is the substitution of a part of the F atoms of the bridging X1 site by OH groups.

**Figure 1.** <sup>19</sup>F MAS NMR (4.7 T) spectra of NbOF<sub>3</sub> (60 kHz) and TaOF<sub>3</sub> (50 kHz). The stars indicate spinning sidebands. The main contributions are assigned and additional resonances, assigned to F2 site, are outlined by the dashed rectangles.

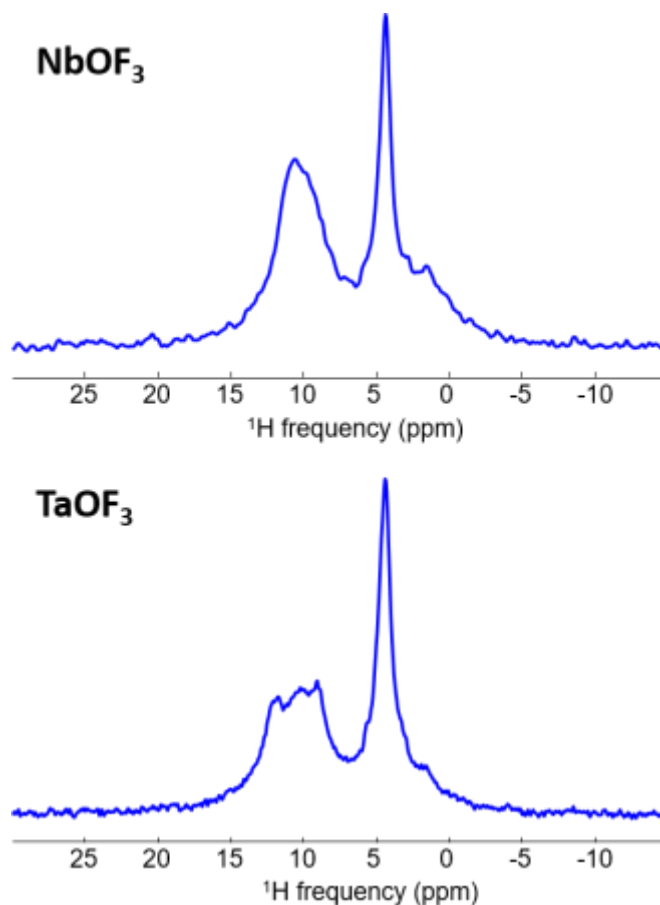

**Table 1.** Compound, weighted average experimental  $^{19}\text{F}$   $\delta_{\text{iso}}$ ,  $\delta_{\text{CSA}}$  and  $\eta_{\text{CSA}}$  values ( $\langle\delta_{\text{iso,exp}}\rangle$ ,  $\langle\delta_{\text{CSA,exp}}\rangle$ , ppm and  $\langle\eta_{\text{CSA,exp}}\rangle$ ), relative intensities ( $I$ , %) and corresponding assignments.

Compound	$\langle\delta_{\text{iso,exp}}\rangle$	$\langle\delta_{\text{CSA,exp}}\rangle$	$\langle\eta_{\text{CSA,exp}}\rangle$	$I$	Assignment
<b>NbOF<sub>3</sub></b>	-8.2	-162.4	0.51	30.4	F1
	124.7	n. a.	n. a.	3.2	H-bonded F2
	195.1	-291.6	0.72	66.4	F2
<b>TaOF<sub>3</sub></b>	-54.9	-170.0	0.5	32.3	F1
	60.6	n. a.	n. a.	4.0	H-bonded F2
	118.1	-283.4	0.1	63.7	F2

To confirm this hypothesis,  $^1\text{H}$  MAS NMR spectra of NbOF<sub>3</sub> and TaOF<sub>3</sub> were recorded (**Figure 2**) and reconstructed (**Figures S5-S6** and **Tables S5-S6**). They show similar features with two main contributions, one with  $\delta_{\text{iso}}$  values ranging from 1 to 5 ppm and the other with  $\delta_{\text{iso}}$  values ranging from 8 to 13 ppm (**Table 2**). Both are assigned to OH groups coordinated by Nb(Ta) atoms but the latter are H-bonded, as evidenced by their higher  $^1\text{H}$   $\delta_{\text{iso}}$  value (for a X–H $\cdots$ Y hydrogen bond, the shorter the H $\cdots$ Y distance, the lower the  $^1\text{H}$  magnetic shielding and the higher the  $^1\text{H}$  chemical shift<sup>97–99</sup>). Equivalently, for an X–H $\cdots$ F hydrogen bond, the shorter the H $\cdots$ F distance, the higher the  $^{19}\text{F}$  magnetic shielding and the lower the  $^{19}\text{F}$  chemical shift.<sup>100</sup> Therefore, the existence of intermediate NMR lines with lower  $^{19}\text{F}$   $\delta_{\text{iso}}$  (higher  $\sigma_{\text{iso}}$ ) values is explained by the formation of O–H $\cdots$ F2 bonds.

The substitution of F1 atoms by OH groups leads to the general formulation MOF<sub>1-x</sub>(OH)<sub>x</sub>F<sub>2</sub>. From the relative intensities of the  $^{19}\text{F}$  MAS NMR lines, the OH substitution rates (x) are estimated to be 0.15(2) and 0.05(1) for NbOF<sub>3</sub> and TaOF<sub>3</sub>, respectively (**Tables S7-S8**). Similarly to NbF<sub>5</sub>

and TaF<sub>5</sub>, NbOF<sub>3</sub> appears to be more hygroscopic than TaOF<sub>3</sub>, resulting in a higher OH substitution rate for these niobium compounds.

**Figure 2.** <sup>1</sup>H MAS NMR spectra of NbOF<sub>3</sub> (60 kHz) and TaOF<sub>3</sub> (50 kHz).

#### 4.2 Structural characterization: XRPD.

The crystal structures of NbOF<sub>3</sub> and TaOF<sub>3</sub>, determined by Köhler *et al.* (*I4/mmm* space group (no. 139)),<sup>15</sup> have been revised. The recorded RT PXRD diagrams have been refined by using the Rietveld method<sup>101</sup> implemented in the Fullprof software.<sup>102</sup> For both compounds, based on <sup>19</sup>F solid-state NMR, we assumed that the terminal X2 site is fully occupied by F atoms and that the bridging X1 site has an occupancy of 0.5 O and 0.5 F and we considered isotropic displacement parameters (IDP) for all atoms. The cell parameters, atomic coordinates and IDPs are gathered in **Table 3**. The observed, calculated and intensity difference patterns and reliability factors are given as SI (**Figures S7** and **S8** for NbOF<sub>3</sub> and TaOF<sub>3</sub>, respectively).

Crystal structures have been deposited via the joint CCDC/FIZ Karlsruhe deposition service. CSD<sup>103</sup> 2260474 and 2260475 (deposition number) contains the supplementary crystallographic data for NbOF<sub>3</sub> and TaOF<sub>3</sub>, respectively. These data can be obtained free of charge from FIZ Karlsruhe via [www.ccdc.cam.ac.uk/structures](http://www.ccdc.cam.ac.uk/structures).

The BVS calculations<sup>32,33</sup> (**Table 4**), despite slightly high bond valences for Nb and Ta, indicate quite clearly an occupation of the X1 sites by O and F and a preferential occupation of the X2 sites by F. Perspective views of the unit cell of NbOF<sub>3</sub> and of *cis*- and *trans*-NbO<sub>2</sub>F<sub>4</sub> octahedra are represented on **Figure 3(a)**.

**Figure 3.** (a) Perspective views of the  $NbOF_3$  unit cell (on the left) and of *cis*- and *trans*- $NbO_2F_4$  octahedra (on the right). (b) Perspective view of a  $2 \times 2 \times 1$  supercell. The  $NbO_2F_4$  octahedra are displayed in purple.

**Table 3.** Atom, site multiplicity and Wyckoff symbol (Wyck.), site symmetry (Sym.), atomic coordinates ( $x, y, z$ ), site occupancy factor (sof) and isotopic displacement parameters ( $U_{\text{iso}}$ ,  $\text{\AA}^2$ ) in  $\text{NbOF}_3$  ( $a = b = 3.9739(1) \text{\AA}$ ,  $c = 8.3612(2) \text{\AA}$ ) and  $\text{TaOF}_3$  ( $a = b = 3.9465(1) \text{\AA}$ ,  $c = 8.4454(2) \text{\AA}$ ).

#### 4.3 O/F correlated disorder.

As mentioned in the introduction, O/F correlated disorder has been previously highlighted in Nb<sub>3</sub>O<sub>5</sub>F<sub>5</sub>,<sup>30</sup> NbO<sub>2</sub>F<sup>29,31</sup> and TaO<sub>2</sub>F<sup>25,31</sup> resulting in one-dimensional O/F-ordered strings of atoms and out-of-center displacement of metal cations. For NbOF<sub>3</sub>, the presence of O/F correlated disorder in the  $\alpha$ (MOF<sub>3</sub>) layers, along <100> and <010> directions, has been predicted.<sup>30</sup> From our experimental results, in both MOF<sub>3</sub> compounds, the X1 site has an occupancy of 0.5 O and 0.5 F and the X2 site occupied only by F leading to either *cis*- or *trans*-MO<sub>2</sub>F<sub>4</sub> octahedra (**Figure 3(a)**). The former octahedral units are more favored, particularly when the cation is a d<sup>0</sup> transition metal. Indeed, having anions with similar Pearson hardness near each other maximizes the  $\pi$ -hybridization in the M-anion bonds by allowing atomic relaxations toward characteristic bond

lengths (*i.e.*, cation displacements toward the less electronegative anion).<sup>2</sup> This results in one-dimensional –F–M–O–M– chains along  $\langle 100 \rangle$  and  $\langle 010 \rangle$  directions.

#### **4.4 Possible models for NbOF<sub>3</sub> and TaOF<sub>3</sub> using 2×2×1 supercells**

Considering a 2×2×1 supercell (**Figure 3(b)**), there are only three ways to construct a  $\infty(\text{MOF}_3)$  layer with *cis*-MO<sub>2</sub>F<sub>4</sub> octahedra corner-connected by two O atoms and two F atoms (**Figure 4(a)**). Since each supercell consists of two stacked  $\infty(\text{MOF}_3)$  layers and excluding all symmetry equivalent combinations, ten different 2×2×1 supercells have been built (**Figure 4(b)**). These ten models were then geometry optimized. The structural characteristics of the ten non-optimized, APO\_DFT-D3 and FO\_DFT-D3 optimized supercells, for NbOF<sub>3</sub> and TaOF<sub>3</sub>, are summarized in **Tables 5** and **6** (details for each model are given as SI in **Figure S9** and **Tables S9–S22**). For NbOF<sub>3</sub> and TaOF<sub>3</sub>, each of the ten APO\_DFT-D3 and FO\_DFT-D3 models exhibits similar structural characteristics.

**Figure 4.** (Left) Representation of the three ways to construct a  $\infty(\text{MOF}_3)$  layer with *cis*- $\text{MO}_2\text{F}_4$  octahedra corner-connected by two O atoms and two F atoms, labeled as (a) diamond ( $\diamond$ ), (b) zigzag ( $>$ ) and (c) diagonal ( $\backslash$ ). (Right) Illustration of two successive  $(\vec{a}, \vec{b})$  planes, (001) and (002), for each of the ten constructed models. The rotational operation around  $\vec{c}$  involved for five of the models are indicated.

**Table 5.** Average cell parameters ( $a$ ,  $b$  and  $c$ , Å), average supercell volume ( $\text{Å}^3$ ), average M–O1, M–F1 and M–F2 bond lengths (Å) from the ten non-optimized (ES), and APO\_DFT-D3 and FO\_DFT-D3 optimized supercells of NbOF<sub>3</sub> and TaOF<sub>3</sub>.

Supercell	$a$	$b$	$c$	$V$	M–O1	M–F1	M–F2
<b>NbOF<sub>3</sub></b>							
<b>ES</b>	7.948	7.948	8.361	528.2	1.987	1.987	1.819
<b>APO_DFT-D3</b>	7.948	7.948	8.361	528.2	1.888	2.092	1.881
<b>FO_DFT-D3</b>	7.945	7.944	8.266	521.7	1.886	2.093	1.881
<b>TaOF<sub>3</sub></b>							
<b>ES</b>	7.893	7.893	8.445	526.1	1.973	1.973	1.823
<b>APO_DFT-D3</b>	7.893	7.893	8.445	526.1	1.880	2.073	1.892
<b>FO_DFT-D3</b>	7.945	7.945	8.351	527.1	1.888	2.091	1.890

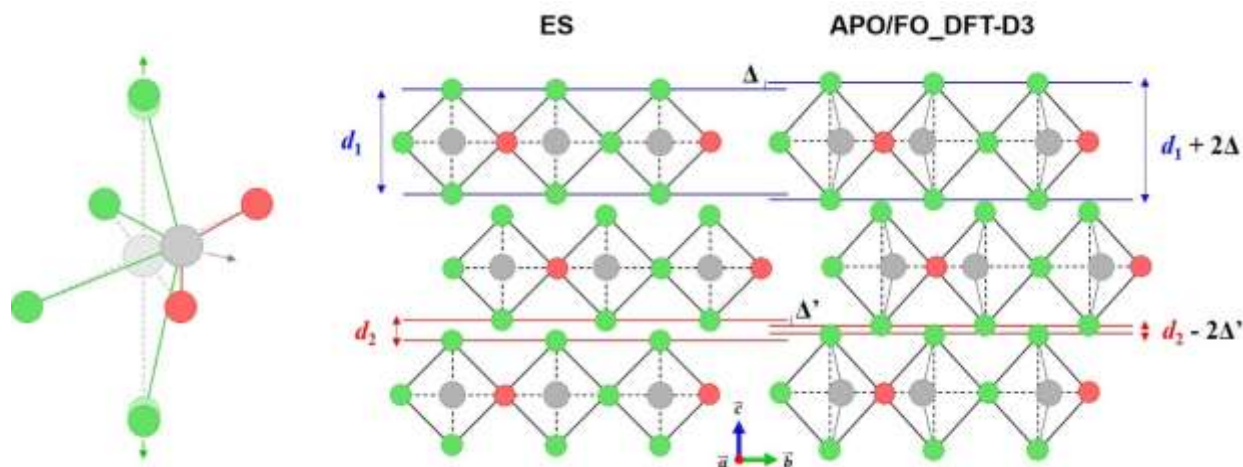

When the supercells are fully optimized, the cell parameters  $a$  and  $b$  are more or less constant for NbOF<sub>3</sub> and increase for TaOF<sub>3</sub>. For both,  $c$  decreases. The cell volume slightly decreases for NbOF<sub>3</sub> (1.2 %) and remains almost constant for TaOF<sub>3</sub> (+ 0.2%) which seems to demonstrate the effectiveness of the dispersion correction. We observe, after APO and FO, atomic relaxations towards characteristic bond lengths, *i.e.*, metal displacements towards oxygen, the least electronegative atom, as shown by the decrease of the average M–O1 (increase of the average M–F1) bond lengths ( $\sim 0.1$  Å, **Table 5**) and the increase of the average O1–M–O1 (decrease of the average F1–M–F1) angles ( $\sim 6^\circ$ , **Table 6** and **Figure 5**). The M–F2 bond lengths increase ( $\sim 0.06$  Å, **Table 5**) and the F2–M–F2 angles decrease (from  $180^\circ$  to  $\sim 163^\circ$ , **Table 6** and **Figure 5**). From the decrease of the F2–M–F2 angles, it can be estimated that, in the average structure, the M–F2

bond lengths are underestimated by about 0.02 Å.  $\infty$ (MOF<sub>3</sub>) layers are then getting closer in the optimized supercells since the decrease in angle values does not compensate for the increase in bond lengths. This is even more pronounced for the full optimized supercells for which the cell parameters *c* are smaller.

After optimization, the values for bond lengths and bond angles not only deviate from the average values determined by diffraction but are, as expected in disordered compounds, distributed.

**Table 6.** Average X–M–X Angles (°) between Adjacent (X1–M–X1) and Opposite (F2–M–F2)) M–X Bonds and Average M–O1–M and M–F1–M angles (°) of the 10 APO\_DFT-D3 and 10 FO\_DFT-D3 optimized supercells of NbOF<sub>3</sub> and TaOF<sub>3</sub>.

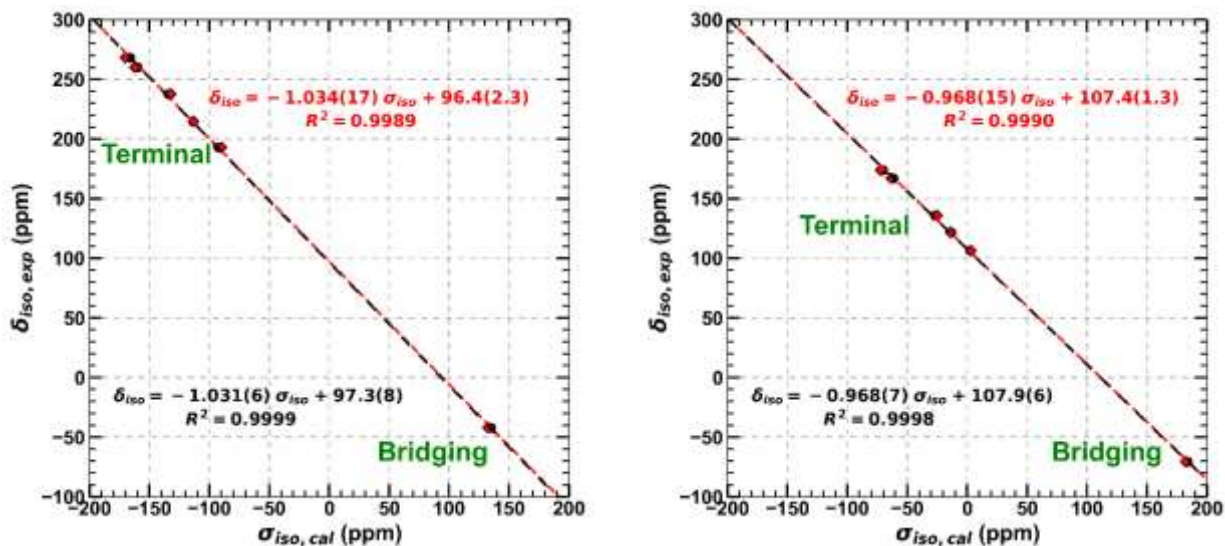

**Figure 5.** Illustration of the optimization effect on the  $\text{MO}_2\text{F}_4$  octahedra (left) and on the thickness  $d_1$  of the  $\infty(\text{MOF}_3)$  layers as well as the distance  $d_2$  between them (right). M, O and F are represented in grey, red and green, respectively.

#### 4.5 $\delta_{\text{iso}} = \sigma_{\text{ref}} - a \sigma_{\text{iso}}$ equations for $^{19}\text{F}$ from $\text{NbF}_5$ and $\text{TaF}_5$

The equations used to convert the  $^{19}\text{F}$   $\sigma_{\text{iso}}$  values into  $\delta_{\text{iso}}$  values were established from the two isomorph binary pentafluorides  $\text{NbF}_5$  and  $\text{TaF}_5$ . The calculations were done using the same conditions as for  $\text{NbOF}_3$  and  $\text{TaOF}_3$ , *i.e.*, on APO and FO structures, both including DFT-D3, for consistency and because  $\text{NbF}_5$  and  $\text{TaF}_5$  consist of tetrameric structural units  $[\text{M}_4\text{F}_{20}]$  ( $\text{M} = \text{Nb}, \text{Ta}$ ), built up from  $\text{MF}_6$  octahedra linked to each other by corners, in a *cis*-configuration, and held together by vdW interactions. They seem perfectly suitable for establishing such predictive equations since they present several F crystallographic sites, including, like  $\text{NbOF}_3$  and  $\text{TaOF}_3$ , bridging and terminal F atoms. The linear regressions between the calculated  $\sigma_{\text{iso}}$  values and experimental  $\delta_{\text{iso}}$  values<sup>83</sup> of  $^{19}\text{F}$  (**Table S23**) are reported in **Figure 6**. For  $\text{NbF}_5$ , the equations are:  $\delta_{\text{iso}}$  (ppm) =  $-1.031(6) \sigma_{\text{iso}} + 97.3(8)$  and  $\delta_{\text{iso}}$  (ppm) =  $-1.034(17) \sigma_{\text{iso}} + 96.4(2.3)$  for APO\_DFT-D3 and FO\_DFT-D3, respectively. For  $\text{TaF}_5$  the equations are:  $\delta_{\text{iso}}$  (ppm) =  $-0.968(15) \sigma_{\text{iso}} + 107.4(1.3)$  and  $\delta_{\text{iso}}$  (ppm) =  $-0.968(7) \sigma_{\text{iso}} + 107.9(6)$  for APO\_DFT-D3 and FO\_DFT-D3,

respectively. The slopes of the TaF<sub>5</sub> linear regressions, established using  $\sigma_{\text{iso}}$  values calculated with the VASP code, are closer to the theoretical -1 value in comparison to those ( $\sim -0.78$  for APO structures) established using  $\sigma_{\text{iso}}$  values calculated with the CASTEP code.<sup>83</sup> In contrast, the slopes of the NbF<sub>5</sub> linear regressions remain close whatever the code used to calculate the  $\sigma_{\text{iso}}$  values.

**Figure 6.** Calculated  $^{19}\text{F}$   $\sigma_{\text{iso}}$  values as function of the experimental  $^{19}\text{F}$   $\delta_{\text{iso}}$  values for NbF<sub>5</sub> (left) and TaF<sub>5</sub> (right). The red squares and the black dots correspond respectively to the values calculated from the FO\_DFT-D3 and APO\_DFT-D3 structures. The dash red and black lines represent the linear regressions when considering the calculated  $\sigma_{\text{iso}}$  values from the FO\_DFT-D3 and APO\_DFT-D3 structures, respectively. Their equations are given in red and black, respectively.

#### 4.6 Theoretical $^{19}\text{F}$ solid state NMR spectra of NbOF<sub>3</sub> and TaOF<sub>3</sub>

The structural features of the APO\_DFT-D3 and FO\_DFT-D3 models being similar for each compound, consistently, the calculated  $^{19}\text{F}$   $\sigma_{\text{iso}}$ ,  $\sigma_{\text{CSA}}$  and  $\eta_{\text{CSA}}$  values are similar as well (**Tables S24–S35**). Using the linear regression equations above (**Figure 6**), the calculated  $^{19}\text{F}$   $\sigma_{\text{iso}}$  values

were converted into  $\delta_{\text{iso}}$  values and the average  $\delta_{\text{iso}}$ ,  $\sigma_{\text{CSA}}$  and  $\eta_{\text{CSA}}$  values from each model are gathered in **Tables 7 and 8**. The  $\delta_{\text{iso}}$  values of the terminal F2 atoms decrease linearly as the F2–M bond lengths increase (**Figure S10**).

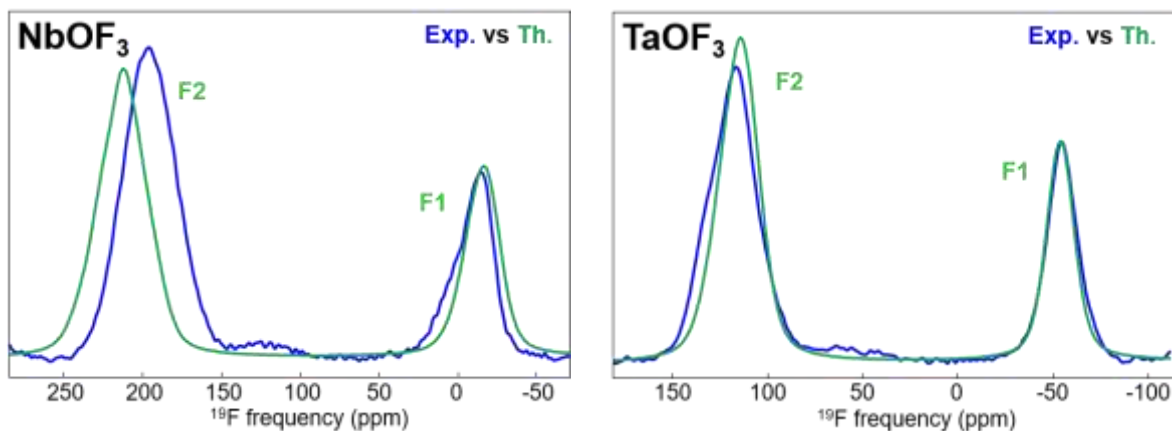

For both compounds, and in agreement with more intense spinning sidebands, the calculated  $\sigma_{\text{CSA}}$  values are higher for F2 atoms compared to F1 atoms. The  $\eta_{\text{CSA}}$  values show good agreement for both F1 and F2 atoms in TaOF<sub>3</sub>, and a less satisfying agreement for F2 atoms in NbOF<sub>3</sub> (**Tables 1, 7 and 8**). For TaOF<sub>3</sub>, the agreement between calculated and experimental average <sup>19</sup>F  $\delta_{\text{iso}}$  values is almost perfect for both F1 and F2 atoms. In contrast, for NbOF<sub>3</sub>, this agreement is less satisfying for the F2 atoms. Furthermore, the dispersion of the calculated  $\delta_{\text{iso}}$  values for each model is consistent with the widths of the NMR signals (**Tables S1-S4, and S24, S27, S30 and S33**). Therefore, since there is no significant difference between the total energy of each model (**Table S10**), there is no reason to rule out any particular model and we assume that they all contribute equally to the structural modeling of MOF<sub>3</sub>. Theoretical <sup>19</sup>F NMR spectra were then plotted considering the 240 (80 F1 and 160 F2) calculated  $\delta_{\text{iso}}$  values. These spectra being similar we present only those from the APO\_DFT-D3 models (**Figure 7**). The agreement between the experimental and theoretical spectra is excellent for TaOF<sub>3</sub>, but less satisfactory for NbOF<sub>3</sub> in particular for the NMR line corresponding to the F2 atoms (**Table 9**). Assuming that it is related to the higher OH group content in NbOF<sub>3</sub>, we have studied the effect of the substitution of F1 atoms by OH groups on the structure and on the NMR parameters.

**Table 7.** Average calculated  $^{19}\text{F}$   $\delta_{\text{iso}}$  (ppm),  $\sigma_{\text{CSA}}$  (ppm) and  $\eta_{\text{CSA}}$  values for each APO\_DFT-D3 and FO\_DFT-D3 optimized supercells of  $\text{NbOF}_3$ . The equations used to convert the calculated  $^{19}\text{F}$   $\sigma_{\text{iso}}$  values into calculated  $^{19}\text{F}$   $\delta_{\text{iso}}$  values are those established from the APO\_DFT-D3 and FO\_DFT-D3 structures of  $\text{NbF}_5$  (**Figure 6**).

The experimental spectra were processed by using the TOP procedure.<sup>71</sup> The theoretical spectra were built using the calculated  $^{19}\text{F}$   $\delta_{\text{iso}}$  values from the APO\_DFT-D3 models.

**Table 9.**  $^{19}\text{F}$  Experimental weighted average  $\delta_{\text{iso,exp}}$ ,  $\delta_{\text{CSA}}$  and  $\eta_{\text{CSA}}$  values, and calculated average  $\delta_{\text{iso,cal}}$ ,  $\sigma_{\text{CSA}}$  and  $\eta_{\text{CSA}}$  values from APO\_DFT-D3 and FO\_DFT-D3 models, of F1 and F2 atoms in  $\text{NbOF}_3$  and  $\text{TaOF}_3$  (ppm).

#### 4.7 Modeling hydroxylated NbOF<sub>3</sub>.

New supercells NbO1F<sub>1-x</sub>(OH)<sub>1-x</sub>F<sub>2</sub> were then built with two different OH substitution rates,  $x = 1/8$  and  $x = 1/4$ . For each of the ten models, the substitution of one or two F1 atoms by OH groups was performed using the “Supercell” program<sup>104</sup> and led to multiple possible configurations. Testing all possible configurations for all models is beyond the limits of our computational hardware. Therefore, only the supercell with the lowest coulomb energy was chosen for each NbOF<sub>3</sub> model and substitution rate. The atomic positions of the selected supercells were then optimized and the structural characteristics are gathered as SI in **Tables S36-S43**. The NMR parameters are then calculated and the <sup>19</sup>F  $\sigma_{\text{iso}}$  converted into <sup>19</sup>F  $\delta_{\text{iso}}$  values by using the linear regression equations established on NbF<sub>5</sub> (**Tables S44-S49**). Average values are gathered in **Table 10** and the two new theoretical <sup>19</sup>F NMR spectra are presented in **Figure 8**. The agreement between experimental and theoretical spectra is improved. Substituting F1 atoms by OH groups results in a decrease of the average F2  $\delta_{\text{iso}}$  value and thus of the gap between the calculated and experimental F2 resonances, without significant variation of the average F1  $\delta_{\text{iso}}$  values. Moreover, some F2 atoms have significantly lower  $\delta_{\text{iso}}$  values (**Figure 9** and **Table 10**) and they are distinguishable when plotted against F2–M bond lengths (**Figure S11**). A combined analysis of the structural data and calculated <sup>1</sup>H and <sup>19</sup>F  $\delta_{\text{iso}}$  values shows that each OH groups is involved either in one strong O–H···F bond or four O–H···F weak bonds or contacts (**Tables 11, S50 and S51**). Usually, O–H···F contacts with angles (°) larger than 115° and H···F distances (Å) smaller than the sum of H (1.20 Å) and F (1.47 Å) van der Waals radii are considered as H-bonds. The <sup>19</sup>F  $\delta_{\text{iso}}$  values of the F2 atoms involved in O–H···F weak bonds or contacts are only slightly lower than those of the remaining F2 atoms and contribute to the decrease of the  $\delta_{\text{iso}}$  value of the main F2 resonance. The calculated <sup>1</sup>H  $\delta_{\text{iso}}$  values of the H atoms forming weak O–H···F bonds or contact are only slightly

less than to those of H atoms forming a unique and strong H bond. Overall, the  $^1\text{H}$  calculated  $\delta_{\text{iso}}$  values are close to those of the NMR line assigned to H-bonded OH (**Table 2**). The experimental spectrum shows a second contribution assigned to non H-bonded OH. Indeed, at room temperature and in the course of time, the rotational movement of OH groups enables the formation and breaking of these H-bonds, whereas these effects cannot not be captured by the inherently static DFT optimized structure at 0 K.

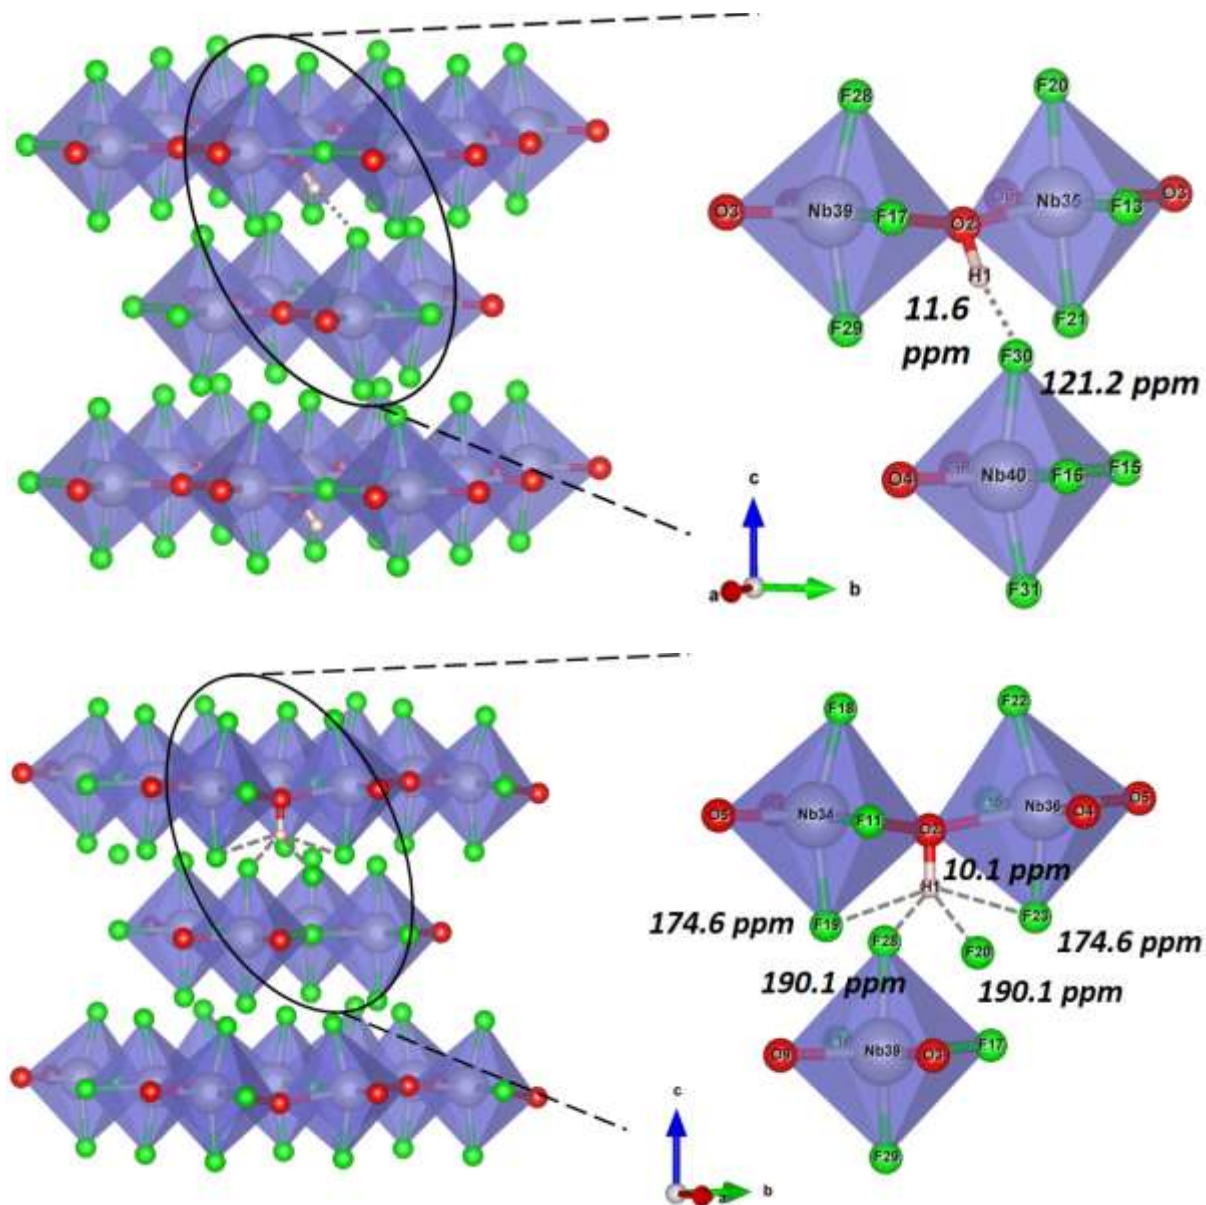

**Table 10.** Weighted average  $^{19}\text{F}$  experimental  $\delta_{\text{iso}}$  values (in italic) and average theoretical  $\delta_{\text{iso}}$  values for F2, strongly H-bonded F2 and F1 atoms ( $\langle\delta_{\text{iso}}\rangle$ , ppm) and corresponding relative intensities ( $I$ , %) from the studied sample and  $\text{NbOF}_{1-x}(\text{OH})_x\text{F}_2$  models.

## 5. Conclusion

The average crystal structures of NbOF<sub>3</sub> and TaOF<sub>3</sub>, especially the occupancy rates of the anion crystallographic sites based on a correct assignment of the <sup>19</sup>F NMR resonances, have been revised. The non-bridging site is fully occupied by F while the bridging site has an occupancy of 0.5 O and 0.5 F. The structure consists of stacked ∞(MOF<sub>3</sub>) layers along the  $\vec{c}$  direction, formed by MO<sub>2</sub>F<sub>4</sub> octahedra, corner-connected by two F and two O atoms. An O/F correlated disorder is then expected since *cis*-MO<sub>2</sub>F<sub>4</sub> octahedra are favored. Ten different 2×2×1 supercells per compound, fulfilling these characteristics, were built and DFT optimized, and the <sup>19</sup>F isotropic chemical shift values were determined. The agreement between the experimental and theoretical <sup>19</sup>F spectra is excellent for TaOF<sub>3</sub> but less satisfactory for NbOF<sub>3</sub> in relation with its higher OH group content. New supercells involving OH groups were then generated. A good agreement between the experimental and theoretical <sup>19</sup>F and <sup>1</sup>H calculated  $\delta_{\text{iso}}$  values is obtained for the supercells with the composition closest to that estimated, *i.e.*, NbOF<sub>2.85</sub>(OH)<sub>0.15</sub>. All these results confirm the O/F correlated disorder and show that the ten possible 2×2×1 supercells present a good structural model of NbOF<sub>3</sub> and TaOF<sub>3</sub>. The short-range structures deviate markedly from the average crystal structures to accommodate the different, by ~ 0.2 Å, M–O and M–F bond lengths. The building unit of MOF<sub>3</sub>, the *cis*-MO<sub>2</sub>F<sub>4</sub> octahedra, are especially distorted with average angle values between adjacent and opposite M–X bonds away from the values of the average structure. The values for bond lengths and bond angles not only deviate from the average values determined by diffraction but are, as expected in disordered compounds, distributed. Finally, the structural modeling of hydroxylated NbOF<sub>3</sub> highlights that each H atom is either strongly H bonded to one F2 atom or in contact with four F2 atoms. This study proves the efficiency of combining theoretical calculations

and solid-state NMR to model O/F correlated disorder in oxyfluorides as well as their hydroxylation.

## Table of Contents Synopsis.

MOF<sub>3</sub> (M = Nb, Ta) compounds were precisely modeled by combining powder X-Ray diffraction, solid-state NMR spectroscopy and semi-empirical dispersion corrected DFT calculations. *cis*-MO<sub>2</sub>F<sub>4</sub> octahedra are favored, resulting in O/F correlated disorder. Some of the bridging F atoms are substituted by OH groups, especially in NbOF<sub>3</sub>. Hydroxylated NbOF<sub>3</sub> was then successfully modeled highlighting that each H atom is either strongly H bonded to one F2 atom or in contact with four F2 atoms.
