Abstract There has always been an interest in the professional communities of libraries, archives and conservation science to find ways of estimating the rate of degradation of paper under archival conservation conditions. Previously we reported a number of considerations for developing a kinetic degradation model based on Whatman no.1 paper. In the present research, this model was extended to 10 different papers and validated. Various physical and chemical properties of acidic, neutral, and alkaline papers were measured, such as the degree of polymerization (DP), tensile strength, equilibrium moisture content (EMC), and pH, as well as alkaline fillers content when applicable. The activation energy (E_a) based on DP of cellulose and zero-span tensile strength were determined. E_a and pH had the most significant influence on the simulated decay of paper. Papers with a high E_a ($> 120 \text{ kJ mol}^{-1}$), alkaline such as those containing at least 2% CaCO_3 , and acidic –but good printing quality papers made of bleached chemical pulp– were found the most durable in ambient conditions. Papers with a lower E_a ($< 110 \text{ kJ mol}^{-1}$) such as lignocellulosic papers containing significant amount of mechanical pulp were much less stable over time. Whatman filter papers, used as models of pure cellulosic papers, were found to have low E_a despite the good quality cotton fibers. A generic isoperm equation based on E_a was developed to predict the changes in the state of papers under various climatic conditions, and was applicable independently of the pH of the paper. The model developed allows a better quantification of the deterioration rate of printing papers such as those that are currently, and will be in the future, found in our archival collections.

Introduction

In the mid-nineteenth century, papermaking technology underwent major changes. The fiber source went from being mainly linen rags to wood, and new additives such as alum-rosin size replaced the traditional gelatin size that had prevailed since the Middle Ages. A significant decline in the durability of a large proportion of the papers made from mechanical pulp during that period was later noticed (Clapp 1972), which is nowadays common knowledge. Soon enough, great progress was made by the papermaking industry in the pulp production technologies, and it became possible to purify the pulp from wood components such as lignin. Chemical pulps from sulfite (acid) and later kraft (alkaline) cooking became available to produce better quality printing papers. Nevertheless, the papers produced during that period are among the least stable. In the twentieth century and to this day, understanding the paper degradation processes as well as studying paper lifetime has raised the interest of conservation scientists. The first attempts for modeling the cellulose degradation were led by Kuhn (1930); Ekenstam (1936); Wilson et al. (1955); Barrow and Sproull (1959). Erhardt (1989) later refined the relationship between reaction rates and temperature. From the Arrhenius equation, a 5 °C reduction in temperature doubles the lifetime of paper based on an activation energy (E_a) around 105 kJ mol⁻¹. Sebera (1994) proposed the concept of isoperm (isopermanence), a graphical representation of several relative humidity and temperature coupled values as lines that represent equal rates of deterioration and produce an equivalent effect on the permanence of paper. Later, the concept was revised by Strang and Grattan (2009) who improved the relationship between relative humidity (RH) and the equilibrium moisture content (EMC) of paper at a given temperature.

Zou et al. (1996a) developed a model for the decay of paper including acids and water concentrations as constants in the frequency factor A in the Arrhenius equation of the decay rate. Zervos (2010) and Porck (2000) made a substantial review of the paper degradation and its modeling. Tétreault et al. (2019) compared the decay models developed by

56 Ekenstam (1936), Calvini (2005), and Ding and Wang (2008), and proposed a new model based on Whatman paper
 57 no.1 paper, a cotton cellulose model paper, which included the frequency factor proposed by Zou et al. Since the pH
 58 and EMC both decreased slowly as the paper degraded, these changes were incorporated in the Zou et al. equation.

59
 60 The need to model the decay of a wider range of paper types, representative of the past, present and future collections
 61 in libraries and archives, mostly printing papers with different compositions (fiber, sizing materials and mineral fillers)
 62 prompted this research. Ten papers chosen to cover this wide range were aged for different durations and at different
 63 temperatures in the presence of humidity in closed vials. Physico-chemical properties such as degree of polymerization
 64 (DP), zero-span tensile strength, pH, alkaline fillers, and equilibrium moisture content (EMC) were measured. They
 65 were used to develop a decay model based on DP, adapted to each type of paper. The aim was to achieve a better and
 66 more accurate prediction of paper decay to allow the optimization of the climate control in museums, libraries, and
 67 archives. This is particularly crucial considering the increasingly difficult challenges posed by climate change and the
 68 growing emphasis on energy efficiency of buildings housing heritage collections. These institutions are under pressure
 69 to adopt sustainable and cost-efficient practices. The output of the model developed in this research was also
 70 transposed into isoperms.

71
 72 This research does not consider deacidified papers, neither the effect of inks and pigments or external pollutants on
 73 the rate of paper degradation.

74 Kinetic model

75
 76 Some key equations used in the cellulose degradation model are summarized in this section. More detailed information
 77 on those equations can be found in Tétreault et al. (2019). The degradation of the cellulose follows first order kinetics.
 78 The most commonly used model is the one proposed by Ekenstam (1936). The non-simplified version is shown in Eq.
 79 1. Cellulose fibers being made of orderly (crystalline) and disorderly regions, the degradation reactions occur
 80 predominantly in the latter. Sharples (1971) reported that the reaction rate is 100 times faster in the amorphous regions
 81 than in the crystalline regions. Calvini (2005) introduced the notion of levelling-off average degree of polymerization
 82 (LODP) in the Ekenstam equation (Eq. 2). LODP is an asymptotic limit in the DP decay curve, which indicates a
 83 maximum degradation of cellulose in dilute acidic conditions. Calvini et al. (2008) later proposed the concept of
 84 classes of bonds with different scission rate constants in relation to an initial number of reacting glycosidic linkages
 85 in weak, amorphous, and crystalline regions. The glycosidic bonds in each region would thus have different reactivity:
 86 weak (easily accessible and degradable), amorphous (degradation is still rather easy), and crystalline bonds (very
 87 slow). The two latter are commonly accepted to explain the experimentally verified different reactivity in the
 88 amorphous and in the crystalline regions in the literature by most authors. As for the role of weak bonds, it is most
 89 often omitted because of the claim that they may not exist as they would not resist the chemical treatments during
 90 Kraft pulp manufacturing. Only the glycosidic links in the amorphous region are relevant in this work since
 91 degradation beyond LODP will not be considered.

$$92 \quad k = \frac{1}{t} \ln \left[\frac{\overline{DP}_{nt}(\overline{DP}_{n0}-1)}{\overline{DP}_{n0}(\overline{DP}_{nt}-1)} \right] \quad (1)$$

$$93 \quad k = \frac{1}{t} \ln \left[\frac{\overline{DP}_{nt}(\overline{DP}_{n0}-LODP)}{\overline{DP}_{n0}(\overline{DP}_{nt}-LODP)} \right] \quad (2)$$

94
 95
 96
 97
 98 k : rate constant for glycosidic bond breakage (year^{-1})

99 t : time (year)

100 \overline{DP}_{nt} : Number-average degree of polymerization at time t

101 \overline{DP}_{n0} : Number-average degree of polymerization at time zero

102
 103 For simplicity, henceforth “DP” is used as an abbreviation of \overline{DP}_n .

104
 105 The acid catalyzed hydrolysis reaction drives the activation energy (E_a) and frequency factor (A). Other reactions such
 106 as oxidation most likely play a secondary role and will not be considered in the present research. By using the
 107 Arrhenius empirical concept, it is possible to extrapolate accelerated ageing conditions at high temperature to long-
 108 term natural ageing at ambient temperature as shown in Eq. 4.

109

$$k = Ae^{-E_a/RT} \quad (3)$$

111
 112 A : frequency factor (year⁻¹)
 113 E_a : activation energy (kJ mol⁻¹)
 114 R : universal gas constant (kJ mol⁻¹ K⁻¹)
 115 T : temperature (K)

$$t_2 = t_1 e^{\left[\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)\right]} \quad (4)$$

118
 119 T_1 : ageing temperature (K)
 120 T_2 : temperature of interest (K)
 121 t_1 : time to reach a specific change of DP at T_1 (year)
 122 t_2 : time to reach a specific change of DP at T_2 (year)

123
 124 The parameter A in the Arrhenius equation (Eq. 3) is called the frequency factor, or the pre-exponential factor. It can
 125 be related to molecules collision and to the optimal molecular orientation for a reaction to occur. Zou et al. (1996a)
 126 decomposed the frequency factor in the cellulose degradation reaction by including in it both the concentration of
 127 hydrogen ions and the concentration of water in the paper (Eq. 5).

$$A = A_n + A_W[H_2O] + A_{WH}[H_2O][H^+] \quad (5)$$

130
 131 A : overall frequency factor (year⁻¹)
 132 A_n : frequency factor for reactions not associated to hydrogen ions or water (year⁻¹).
 133 A_W : frequency factor for reactions associated to water (year⁻¹).
 134 A_{WH} : frequency factor for reactions associated to water and hydrogen ions (l mol⁻¹ year⁻¹).
 135 $[H_2O]$: concentration of water in paper or equilibrium moisture content (weight fraction conditioned).
 136 $[H^+]$: concentration of hydrogen ions (mol L⁻¹).

137
 138 Zou et al. (1996b) determined that A_n was about 1000 times smaller than A_W and that A_W was 10000 times smaller than
 139 A_{WH} . Because of these orders of magnitude differences, A_n and $A_W[H_2O]$ can be neglected in Eq. 5. By isolating DP_t
 140 from Eq. 2 we obtain the decrease of DP as a function of time (Eq. 6). The frequency factor (A) (Eq. 5) is included in
 141 the rate constant (k) (Eq. 3) of Eq. 6.

$$DP_t = \frac{DP_0}{\left(\frac{DP_0}{LODP} - 1\right)(1 - e^{-kt}) + 1} \quad (6)$$

144
 145 Water Concentration

146
 147 The water concentration $[H_2O]$ in the paper has a direct impact on the chemical reactions. Moreover, it also has an
 148 impact on the physico-chemical processes that influence cellulose reactivity such as ion mobility, plasticity and
 149 swelling of microfibrils, which all play a role in the optimal access of the reactants to cellulose for chain scissions and
 150 are part of A . Sorption of water takes place mainly in the amorphous regions and the interfibrillar accessible regions.
 151 Water concentration in the paper depends on the equilibrium moisture content (EMC) of the paper, which is a function
 152 of the water vapor concentration in the surrounding environment. The Guggenheim-Anderson-de Boer (GAB) sorption
 153 equation, which represents the isotherm relation at equilibrium between the liquid and vapor phases of water was used
 154 to calculate EMC (Eq. 7) (Parker et al. 2006; Timmermann 2003).

$$EMC_{GAB} = \frac{Wm Km Cg RH}{(1 - Km RH)(1 - Km RH + Cg Km RH)} \quad (7)$$

157
 158 EMC_{GAB} : equilibrium moisture content based on GAB parameters (weight fraction: g H₂O/g dry sample weight)
 159 Wm : moisture content of the monolayer (weight fraction)
 160 Cg : Guggenheim constant related to heat of sorption
 161 Km : constant related to multilayer molecules properties
 162 RH : relative humidity (% x 10⁻²)

Experimental

The papers selected in this research covered a wide range in terms of fiber and non-fibrous constituents (fillers and sizing), pulping process, acidity, EMC, and DP. A code is used to identify them using letters, corresponding to the pulp type, and numbers, corresponding to the initial pH (pH₀). BKP is used for bleached kraft woodpulp, BSP for bleached sulfite woodpulp, BSGWP for the mixture of bleached sulfite and groundwood pulps, C for cotton linters pulp and TMP for thermomechanical woodpulp. To these codes, the aqueous extract pH₀ of the paper is added. Most papers were already 30 to 35 years old at the time of their use for this research and had been stored in clean (unpolluted) and T/RH controlled environment. The Whatman papers were only a few years old. The ten papers studied are described in Table 1.

Table 1 Pulp process, constituents (fibres and additives) and manufacturers of the papers studied

Paper code	Qualifier and pulp process	Fibres	Additives	Manufacturer
TMP4.7	Acid newsprint Thermomechanical pulp	Hardwood and softwood	Alum-rosin sizing	Fletcher Challenge Canada
BKP4.9	Domtar Windsor offset, acidic fine paper + Bleached kraft pulp	Hardwood and softwood	10% fillers (clay) Alum-rosin sizing	Domtar Inc.
BSGWP5.1	60% bleached sulphite pulp and 40% groundwood pulp	Softwood	20% fillers (kaolin) Alum-rosin sizing	Centre Technique du Papier
BKP5.1	Acidic fine paper Bleached kraft pulp	50% hardwood 50% softwood	4% fillers (clay) Alum-rosin sizing Starch	Domtar Inc.
C5.9	Whatman no.40, ashless quantitative filter paper	Cotton linters	none	Whatman plc (now Cytiva)
BSP6.2	Neutral fine paper Bleached sulphite pulp	Softwood	none	Swedish Pulp and Paper Research Institute
C6.5	Whatman no.1, qualitative filter paper	Cotton linters	none	Whatman plc (now Cytiva)
C8.5	AB Tumba Svenskt Arkiv 80, alkaline fine paper	80% cotton linters 20% cotton cambers	2-4% fillers (PCC) 0.5-1% TiO ₂ AKD sizing	Swedish Pulp and Paper Research Institute
C9.1	Domtar Cleartone alkaline fine paper	Cotton linters	8.5% fillers (PCC) AKD sizing	Domtar Inc.
BKP9.6	Domtar Krypton Parchment, alkaline fine paper Bleached kraft pulp	15% hardwood 85% softwood	15% fillers (PCC) AKD sizing Starch	Domtar Inc.

177 PCC precipitated calcium carbonate; AKD alkyl ketene dimer

178

179 The paper samples were hygrothermally aged in hermetically closed vials according to TAPPI T573 pm-09 for various
 180 durations. The tensile strength, grammage, pH, EMC, and the calcium carbonate (CaCO_3) fillers content (alkaline
 181 papers) were measured (methods are provided in Section 1 in Supplementary Information (SI)). Based on the EMC,
 182 the GAB parameters were determined. The DP of cellulose was determined from size-exclusion chromatography
 183 analyzes of all the papers, except for those containing mechanical pulp (TMP4.7 and BSGWP5.1), for which viscosity
 184 measurements were carried out due to their poor solubility in the chromatographic solvent. The different
 185 deconvolution methods of the molar mass distribution profiles applied to obtain the number-average degree of
 186 polymerization (DP_n in Eqs 1 & 2) of the cellulose have been explained in a previous article (Dupont et al. 2018) and
 187 will not be discussed in detail here. Details on the ageing conditions and methods used for the characterizations and
 188 DP calculations can be found in Section 1 of the SI as well as in Tétreault et al. (2019).

189
 190

191 Results

192

193 DP, zero-span tensile strength, expressed in terms of zero-span breaking length (BL), grammage, EMC, GAB
 194 parameters, pH and CaCO_3 content for each paper and ageing condition are reported in Table S1 in the SI. These
 195 parameters are considered one by one in the following. Note that the purpose of the present article was to determine
 196 E_a based on the experimental data and to study the relative differences between them.

197

198 Activation energy based on DP and zero-span tensile strength

199

200 Paper samples were aged at different temperatures and for various durations, their physico-chemical properties were
 201 measured, which allowed to determine their activation energy (E_a) in the Arrhenius equation. More precisely, E_a was
 202 determined based on two properties: the DP of cellulose and the zero-span breaking length (BL) of the paper. All the
 203 experimental data can be found in Table S1 (SI).

204

205 The first interesting result was that whether calculated using DP or BL, the E_a were similar within 1% to 7% ($r^2 =$
 206 0.999 (Table 2). $E_a(\text{DP})$ will be used in the following and abbreviated E_a .

207

208 The values of E_a of all the papers tested were in the range of 93 to 130 kJ mol^{-1} . Considering the papers' pH, all the
 209 papers with an alkaline fillers (4% to 10%) had E_a around 129 kJ mol^{-1} . However, the spread of values for the acidic
 210 papers ($\text{pH} \leq 6.5$) was larger, from 93 to 127 kJ mol^{-1} .

211

212 **Table 2** Activation energy (E_a) (kJ mol^{-1}) based on the DP and BL

Samples	$E_a(\text{DP})$	$E_a(\text{BL})$
TMP4.7	101 ± 3	109 ± 1
BKP4.9	124 ± 3	129 ± 2
BSGWP5.1	104 ± 2	104 ± 2
BKP5.1	127 ± 3	125 ± 2
C5.9	93 ± 6	91 ± 10
BSP6.2	113 ± 4	120 ± 5
C6.5	102 ± 3	96 ± 11
C8.5	129 ± 2	127 ± 5
C9.1	130 ± 3	126 ± 4
BKP9.6	127 ± 4	131 ± 9

213

214 Experimental E_a from various authors, based on different paper properties (obtained with different papers and ageing
 215 conditions) are reported to be in the range 84 to 126 kJ mol^{-1} (Rouchon et al. 2016). More precisely, Zou et al. (1996a)
 216 found an E_a range of 104 – 113 kJ mol^{-1} based on the DP_v (viscometric average DP) of three acidic papers aged in

217 glass jars at 75% RH, maintained with NaCl solution. Liu et al. (2017) reported also a large range of E_a , from 108 to
218 153 kJ mol⁻¹, for ten different papers aged in various conditions in climate chambers and ovens. They reported a value
219 as low as 37 kJ mol⁻¹ for papers with iron gall ink.

220
221 In Tétreault et al. (2019), only one paper was studied: Whatman paper no.1 (same paper as C6.5). As C6.5 degraded,
222 it was found that E_a decreased accordingly. A limit around DP 1100 was chosen as the boundary to distinguish two
223 degradation rates. E_a of 102 kJ mol⁻¹ was determined for the low degradation levels at DP higher than 1100 and E_a of
224 95 kJ mol⁻¹ for the high degradation levels at DP lower than 1100. In the present research, the same observation was
225 made with the two papers containing mechanical pulp, TMP4.7 and BSGWP5.1. For this reason and similarly as in
226 Tétreault et al. (2019), it was decided to exclude the longest ageing durations from the calculation of E_a for these two
227 papers. This progressively diminishing regime in E_a depending on the degradation state was however not found with
228 the other papers studied.

229
230 The result of the extrapolation of the decay in DP and BL with time from high temperature ageing (Table S1 in SI) to
231 ambient conditions (Eq. 4) are shown in Fig. 1. High initial DP or BL combined with a slow decay curve (E_a above
232 120 kJ mol⁻¹) yield the longest lifetimes. The time scale extends up to 1000 years on the graph but data for the three
233 alkaline papers allow projections of DP > 500 far beyond this limit. Interestingly, while moderate DP decays are
234 observed for the three alkaline papers, a stable zero-span tensile strength is relatively well-maintained. Papers having
235 an E_a below 110 kJ mol⁻¹ reach the LODP before 500 years (TMP4.7, C5.9 and C6.5). The half-life DP (reached at a
236 DP loss of 50%) of C6.5 is reached in 98 years. This is in good agreement with the half-life of 103 years obtained by
237 Jeong and Potthast (2021), which they calculated with an E_a of 88 kJ mol⁻¹. BSP6.2 shows a different decay pattern.
238 It has a low DP₀ and an intermediate E_a of 113 kJ mol⁻¹, so its DP remains above 200 even after 1000 years with BL
239 maintained above 7 km, for which it has the property of a durable paper.

240

241
242
243
244

Fig. 1 DP and BL decay over time obtained by the extrapolation of artificial ageing conditions to 21 °C and 50% RH

245 EMC

246

247 Water concentration in the paper depends on the water vapor level in the surrounding environment. As the paper
 248 degrades, the EMC tends to decrease as shown in Fig. 2. No specific correlation was observed in terms of fiber
 249 constituents or CaCO_3 content. TMP4.7 and BSP6.2 stand out clearly with the highest EMC, yet it was not exactly
 250 clear why. It is also observed that for most papers, in the high DP region a substantial DP decrease is accompanied by
 251 a slow decrease in EMC. Conversely, in the low DP region 500-800, the decrease of EMC is more significant. This
 252 low DP range seems to correspond to a critical point in the degradation beyond which the decay of the paper accelerates
 253 considerably (Tétreault et al. 2019, Kaminska et al. 2001) as shown in Fig. S1 (SI). EMC and GAB parameters of
 254 different chemical degradation states and temperatures for all papers are in Tables S2 and S3 in the SI.

255
 256 **Fig. 2** Correlation between EMC (% g H₂O/g conditioned sample weight) and DP at 21 °C and 50% RH

257
 258 pH

259
 260 Fig. 3 shows the correlation between pH and DP, with a small decrease at high DP and a somewhat sharper one at DP
 261 below 1000. The lowest pH found, around 3.8, was for TMP4.7. It has been long known that mechanical pulp papers
 262 sized with alum-rosin acidify with time considerably more than good quality ancient papers (Barrow 1974; Jablonsky
 263 et al. 2020). The extent of the problem was underlined by Hansen and Vest (2008) who found that among a
 264 representative pool of 394 documents dating 1800-1985, 93% were acidic, the lowest pH being about 3.5, which is
 265 close to the lowest pH measured here.

266
 267 Conversely, alkaline papers maintain a pH above 8 even when their DP is beyond half-life DP and has decreased from
 268 1500-2500 to below 500. Fig. 4 shows the correlation between the pH and CaCO_3 content. Only unaged papers and
 269 papers aged at 100 °C for different periods of time are included. The amount of CaCO_3 decreased slightly (from 5%
 270 to 13%), which went along with the pH decrease as alkaline papers degraded. The dotted lines frame this trend: the
 271 top dotted line indicates the trend for all the unaged samples and the bottom dotted line the trend for all the heavily
 272 degraded papers (23 days at 100 °C). The reduction of pH in alkaline papers naturally and artificially aged was also

273 observed by Mochizuki et al. (2020) and Vibert et al. (2023). Bigourdan et al. (1996) suggested that the neutralization
274 of the acids by the alkaline fillers is minor compared to their rapid generation. Bégin et al. (1998) and Hubbe et al.
275 (2017) point out the particle size and non-uniform distribution of the alkaline fillers in the sheets being a cause of its
276 partial inefficiency. As opposed to the results here, Vibert et al. (2022) did not detect an alkaline fillers consumption
277 that could explain the pH decrease found in permanent paper upon ageing, and consistently with the previous authors
278 proposed that the neutralization reaction between calcium carbonate and acids was either partial or slower than the
279 acids production.
280

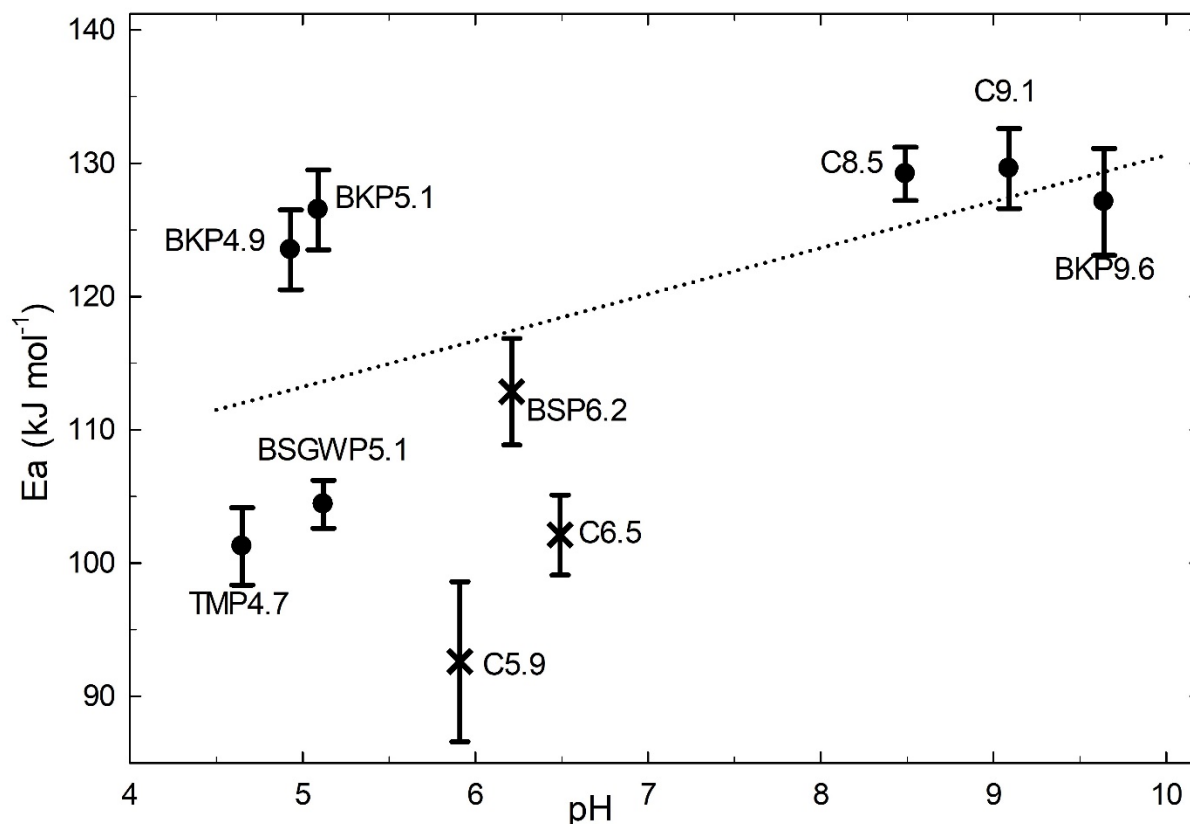

281
282 **Fig. 3** Correlation between pH and DP
283

284
 285 **Fig. 4** Correlation between pH and CaCO₃ content based on paper samples aged at 100 °C for different durations up
 286 to 23 days for C8.5 and C9.1 and, 72 days (BKP9.6). The neutral C6.5 paper is presented as reference
 287

288 The ISO 9706 (1994) specifies that permanent papers should contain at least 2% equivalent CaCO₃ as an alkaline
 289 fillers and should have a pH in the range of 7.5 to 10. Modern paper can contain up to 30% of fillers, among which
 290 kaolin and CaCO₃ are the most widely used (Bown 1996). A higher amount compromises fiber-fiber bonds and hence
 291 decreases the mechanical resistance. Based on Fig. 4 (dotted lines), alkaline papers should maintain a pH level at or
 292 above 7 throughout their lifetime. This supports the notion that papers containing approximately 2.5% CaCO₃, which
 293 is the minimum amount of alkaline fillers in permanent paper to ensure its durability, should indeed stay in a good
 294 condition over several centuries (effects of pollutants and other agents excluded).

295
 296

297 **Fig. 5** E_a of all papers tested in relation with pH. X symbols are excluded from the linear relationship since they
 298 may not be considered as printing papers due to their lack of additives such as fillers and sizing
 299
 300

301 No clear relationship between E_a and pH was found among the different papers, as shown in Fig. 5. The slope shows
 302 a weak correlation even when excluding three papers on the basis that they contain no sizing nor fillers (cross symbols).
 303 However, considering only the pulping process type, it can be observed that the E_a for BKP papers is in average 126
 304 kJ mol⁻¹ independently of the pH, which tends to indicate that the alkaline fillers do not improve significantly the
 305 lifetime of BKP papers. On the other hand, the E_a of cotton linters papers increase with the pH. However, it has to be
 306 noted that C5.9 and C6.5 are model filter papers (no sizing or fillers) and they may have a different chemical reactivity
 307 than printing papers. All the papers with a high initial pH have a high E_a , as explained earlier. Above pH 7, the three
 308 printing papers made of good quality pulp (cotton linters or bleached kraft pulp) have E_a around 129 kJ mol⁻¹. On the
 309 other hand, for papers with a pH lower than 7, E_a spreads in the range 93 to 127 kJ mol⁻¹. The two kraft pulp papers
 310 (BKP4.9 and BKP5.1) have a high E_a while the papers containing mechanical pulp (BSGWP5.1 and TMP4.7) have a
 311 low E_a . BSP6.2 shows an intermediate behaviour. It is a chemical pulp (sulfite) paper, but, as pointed out before, it
 312 has an intermediate E_a of 113 kJ mol⁻¹. This could be the result of its near-neutral initial pH, and/or low initial DP.
 313 The lack of additives, especially sizing, which may also allow an easier access of water and reactants (acids) to the
 314 core of the fibers. It could also relate more broadly to the pulping process. Several theories have been proposed to
 315 account for the mechanical and chemical differences of papers produced with alkaline kraft and acid sulfite pulping
 316 processes (Young et al. 1994).
 317

318 Fig. 5 also shows that for the acidic printing papers, *i.e.*, all besides C5.9, C6.5 and BSP6.2 (cross data points on Fig.
 319 5), E_a values can be divided in two groups. For the papers that are exempt of lignin, E_a is around 126 kJ mol⁻¹ and for
 320 the papers containing significant amounts of lignin (mechanical pulp), E_a is below 110 kJ mol⁻¹. This difference could
 321 be due to the lower activation energy for the hydrothermal depolymerization of lignin, which, depending on the
 322 multiple and complex reactions pathways, is reported to be in the range 32-94 kJ mol⁻¹ (Zhang et al. 2008, Forchheim
 323 et al. 2014).
 324
 325
 326

327 Isoperms

328
329 Isoperms were built for each paper, based on the time needed to reach a DP decay of 50% (half-life DP). The half-life
330 decay was chosen instead of end of lifetime (defined as LODP) due to larger uncertainties on the predictions at high
331 degradation states.

332
333 For example, according to our decay model, it would take 630 years for paper BKP5.1 to reach half-life DP at 50%
334 RH and 20 °C. The duration of 630 years defines the isoperm 1 for this paper as shown in Fig. 6. When the isoperm
335 moves from line 1 to 2, the decay rate decreases by a factor of 2 meaning that it will take twice as long to reach the
336 DP decay of 50%. All the papers studied follow similar isoperm plots. This notion is developed in another section
337 below. Isoperm curves in Fig. 6 are similar as reported by Strlič et al. (2015). Isoperm lines in Sebera's (1994) are
338 more vertical towards high RH. Despite this, and consistently with the isoperm of Strlič et al. (for papers having a pH
339 = 8) and Sebera (for papers with an enthalpy of activation of 105 kJ mol⁻¹), our data show the same shift from isoperm
340 1 to 25 when environmental conditions change from 50% RH and 20 °C to 20% RH and 5 °C.

347
348 Empirical equations for the kinetic model

349
350 Further correlations between the chemical parameters were needed for completing the model developed by Tétreault
351 et al. (2019). Different empirical mathematical correlations must be determined for each paper such as EMC, pH and
352 A_{WH} as a function of DP.

353
354

355 *EMC*

356

357 The GAB equation (Eq. 7) allows to determine the relationship between EMC and RH for a given paper at a specific
 358 temperature. The GAB parameters obtained at 10, 21 and 30 °C (Table S2 in SI) as a function of the temperature
 359 followed a second-degree polynomial fit defined with a curve fit program (TableCurve 2D v5.01). The parameters in
 360 Eq 7 could then be defined. Those results are shown in Table 3. GAB parameters as a function of temperature for C6.5
 361 and C5.9 had been already determined in Tétreault et al. (2019). Equations in Table 3 should remain valid slightly
 362 beyond the temperature range used due the smooth trends of the fitted curves.

363

364 **Table 3** GAB parameters as a function of the temperature T in Kelvin and the parameter moisture adjustment (Ma)

367

368

369 It was found that EMC decreases as the DP decreases, as shown in Fig. 2. The empirical equation developed for C6.5
 370 and validated in Tétreault et al. (2019) modelled the change in EMC as paper degrades. The Eq. 9 developed by
 371 Tétreault et al. (2019) integrates this evolution based on the number of broken glycosidic bonds (n) (Eq. 8). In Eq. 9
 372 the moisture adjustment parameter (Ma) is unique to each paper, and determined with the curve fit program. It replaces
 373 the value determined for C6.5 in Tétreault et al (2019). Ma for each paper is reported in Table 3. Fig. 7 represents the
 374 result of a simulation for the paper BKP5.1. It shows the importance of continuously adjusting the EMC input in the
 375 model. As the DP decreases (paper degrades or is exposed to high temperature), the isotherm is shifted downwards,
 376 which in turns affects the degradation rate. The two experimental data points shown in Fig. 7 (grey diamond symbols)
 377 fall exactly on the simulated curve and validate the Eq. 9

401
402
403
404

From the relationship between pH and DP (Fig. 3) a generic equation (Eq. 10) was determined that relates the concentration in hydrogen ions $[H^+]$ to DP_t . The parameters a, b, and c of the equation were determined with the curve fit program and are provided in Table 4. This equation fitted well all the papers, but less so the most degraded C6.5 (DP<400). Eq. 11, which had been developed in Tétreault et al. (2019), gives a better fit for C6.5, especially for DP below 400. The Eqs. 10 and 11 shown as trendlines in Fig. 3 fit well the experimental data.

414 ^a Eq.11 is used for C6.5415 A_{WH}

416 In Tétreault et al. (2019) it was observed that the predicted decay of C6.5 was faster than the degradation measured
 417 experimentally. The most likely explanation is that the concentration of hydrogen ions predicted by the model at low
 418 DP was too high. It was proposed that the contribution of the hydrogen ions in the depolymerization is less efficient
 419 as the paper becomes more degraded. An adjustment was applied for simplicity by decomposing A_{WH} as shown in Eq.
 420 12. This observation was confirmed with all the papers tested in this research, which indicates that this is a common
 421 phenomenon in the degradation of paper. Using the same approach as for C6.5, A_{WH_1} and A_{WH_2} were determined with
 422 a best fit method (Excel program) and are shown in Table 5. This adjustment allowed to fit the output that as DP
 423 decreases, A_{WH} is slowly reduced. This equation can be used until it becomes clearer what is or are the factors affecting
 424 the decrease in the degradation rate with the ageing of paper and can be refined further.
 425
 426
 427

432
433 *BL vs DP*

434 Both DP and BL show an exponential decay over time, but a linear correlation between BL and the number of broken glycosidic bonds (n) (Eq. 8) is found, as shown in Fig. 8. The conversion of DP to BL is then made easier through the number of broken glycosidic bonds as shown in Eq. 13. Parameters d (slope in km) and BL_0 are in Table S4 in SI. A deviation from the linear correlation was observed only for C5.9 because of the level-off degree of polymerization (LODP) being reached, as shown by the grey diamond symbols.

$$441 \quad BL = -d n + BL_0 \quad (13)$$

442

443
444 **Fig. 8** Correlation between BL and number of broken cellulose bonds (n)

445
446 *Isoperms*

447 A generic isoperm model based on the papers studied in this project was developed. Both the RH and temperature are included in the isoperm equation (Eq. 14). The exponential segment on the right refers to the change of temperature based on the Arrhenius equation (Eq. 4) and the exponential segment on the left, including the factor 2.46, refers to the change of RH. The change of RH is modelled with a best fit equation developed based on BKP4.9 data. BKP4.9 was chosen since its relationship EMC vs RH is average, hence a conservative representation of the different papers studied as shown in Fig. 2. At 50% RH and 20 °C, the isoperm (Eq. 14) of 1.0 is obtained. This is the reference point. As the RH and/or temperature change, the isoperm will reflect the new decay rate independently of the type of paper. The isoperm model closely fits the experimental data of the different papers tested with their respective E_a but independently of their pH. However, the difference between the experimental data and the modelled data increased up to 15% if extreme environmental conditions were applied such as cold and dry or warm and humid.

$$459 \quad \text{Isoperm} = 2.46 e^{-(0.00822T_2 - 0.572)RH} e^{\left[\frac{E_a}{R} \left(\frac{1}{T_2} - \frac{1}{T_1}\right)\right]} \quad (14)$$

463 T_2 : temperature of interest (Kelvin)

464

465 Hygrothermal degradation simulation

466

467 *DP Decay simulation*

468

469 The integration of DP, EMC and pH determined experimentally into each paper's respective equation allows to
 470 simulate their decay. This is shown in Fig. 1 where the decay curves drawn to fit the experimental data points are the
 471 result of the model simulation. Fig. 9 shows the results of decay simulations for TMP4.7, BKP5.1, BKP9.5 and C6.5
 472 in different climate conditions. These simulations are based on non-fluctuating temperature and RH. Indeed, the
 473 cycling of these parameters during accelerated ageing have been shown to have little impact. The fluctuation between
 474 55 and 75% RH or 84.2 and 95 °C have been shown to have no significant impact on the long-term decay of different
 475 papers (Menart et al. 2011). Shahani et al. (1995) and Bogaard and Whitmore (2002) had found an impact of RH
 476 fluctuations, yet over a larger RH span (40 % to 90% RH at 40 °C and 25% to 75% RH at 23 °C, respectively). The
 477 simulations also do not consider any additional adverse effect due to external or indoor air pollutants, which have been
 478 shown to degrade paper (Tétreault et al. 2013).

479

480

481 **Fig. 9** Decay simulations for TMP4.7, BKP5.1, C6.5 and BKP9.6 in different environmental conditions. Line 1:
 482 50% RH & 5 °C; 2: 50% RH & 10 °C; 3: 50% RH & 15 °C; 4: 40% RH & 20 °C; 5: 50% RH & 20 °C; 6: 60% RH
 483 & 20 °C; 7: 50% RH & 25 °C

484
485 The decay trends at the different ambient conditions support the recommendation for archives to store paper
486 documents in dry and cold environment for best preservation. The contributions of the temperature and RH in the
487 cellulose degradation are shown in the Arrhenius equation (Eq. 3) and the equation defining the frequency factor A
488 (Eq.5). Since the temperature is an exponent in the Arrhenius equation, at constant E_a , a small reduction in temperature
489 will result in a bigger reduction of the paper decay than the same small reduction of the RH. This is illustrated in Fig.
490 9 for TMP4.7 and BKP9.6.

491
492 Fig. 9 further demonstrates that papers with an E_a of 120 kJ mol⁻¹ or higher, such as those containing at least 2%
493 CaCO₃ alkaline fillers (BKP9.6) or other kraft quality papers (BKP5.1), would experience a very different loss of DP,
494 of about 10% and 50%, respectively, when stored under conditions of 60% relative humidity (RH) and 20-22 °C for
495 a period of 500 years. At the opposite end, papers with E_a lower than 110 kJ mol⁻¹ such as TMP4.7 and C6.5 or with
496 an initial DP lower than 1000 will need stricter environmental control to maintain their DP above the LODP over 500
497 years. For example, with E_a of 101 kJ mol⁻¹, TMP4.7 should be stored at or below 10 °C and 50% RH or 15 °C and
498 20% RH.

499
500 It is interesting to compare the simulated decay of BKP5.1 and TMP4.7. They have a similar pH₀ but different E_a (127
501 and 101 kJ mol⁻¹, respectively). In this case, after 250 years, the loss of DP for BKP5.1 and TMP4.7 is 48 and 82%,
502 respectively, showing that in this case E_a drives the durability property. The compared simulation decay of BKP5.1
503 and BKP9.6 indicating a different pattern. They have a have similar E_a (127 kJ mol⁻¹) but different initial pH₀. The
504 simulation revealed that the DP of BKP5.1 drops by 58% after 500 years in the least favorable environment conditions
505 (conditions 7: 50% RH and 25 °C) while DP of BKP9.6 dropped by only 28% as shown on Fig. 9. This points out that
506 pH also plays a role in the durability for those papers. This is explained by the respective contributions of E_a and pH₀
507 to the decay model. As shown in Eqs. 3 and 5, E_a and pH₀ are expressed as natural and decimal logarithms,
508 respectively. A small change in their values causes a great impact. For example, for TMP4.7, a 3% increase of the E_a
509 and pH₀ yields a DP difference of 71% and 28%, respectively. The impact of E_a errors on the decay simulation of
510 TMP4.7 can be viewed in the Fig. S2 in the SI.

511
512 TMP4.7 and C6.5 also have a similar E_a (101 and 102 kJ mol⁻¹) and different pH₀. However, after 250 years, they
513 show a rather similar loss of DP of 82% and 95%, respectively. Both approach their respective LODP, yet C6.5 has a
514 higher initial DP₀ of 2366, while DP₀ of TMP4.7 is 1458, i.e., 50% lower. With DP₀ and pH₀ higher than TMP4.7, a
515 better durability of C6.5 was expected. This lack of performance may be due to the absence of papermaking additives
516 (dry strength agents, sizing) compared to a printing paper. Of course, a paper with low E_a and low pH₀ will decay
517 much faster than any paper with higher E_a and/or pH₀. This is the case for instance with TMP4.7 and BSGWP5.1 as
518 illustrated in Fig. 1.

519
520 Based on the simulation and excluding the two Whatman model papers, the following observations can be made: both
521 E_a and pH₀ are critical parameters that determine the durability of paper but weigh differently depending on the paper.
522 Already in 1978, Gray (1978) supported that pH alone could not allow to estimate paper lifetime with confidence. A
523 decay model based on a unique E_a and different pH₀ may be valid, but only for the same type of papers (Strlič et al.
524 2015), and not for different types of papers with varied characteristics.

525
526 Of course, different parameters such as EMC, metal ions salts such as alum (Barański et al. 2004) and grammage (high
527 grammage tends to be associated with higher tensile strength) also affect the paper decay rate to some extent. It is
528 worth noting that although their individual contributions may contribute to the decay, their collective impact are most
529 likely integrated into the overall E_a value as determined here.

530
531 The model proposed is built using new papers, but it also allows the simulation of the decay over time of papers which
532 are already naturally aged and somewhere along their DP decay. For instance, if TMP4.7, which has a DP₀ of 1458
533 was aged naturally at 50% RH and 20 °C for 100 years, its DP would be expected to be 440, as illustrated in Fig. 9.
534 Using the age information, the simulation can start at a DP of 440, and the corresponding adjustments will be made
535 automatically with the relationships between DP, EMC, pH, and A_{WH} developed above. This ensures that the
536 simulation always accurately reflects the changes that occur in the paper as it ages.

537
538 Using Eq. 13 a simulated DP can allow to determine a respective BL for each paper, as shown in Fig. 8. When DP is
539 below about 300, BL becomes as low as 2.5 km, which also sets the limit of the linearity of the relationship between

540 BL and the number of broken glycosidic bonds. For C6.5 a good linearity is maintained until the DP reaches 150,
 541 which is close to its LODP of 100 (Tétreault et al. 2019). A physical strength threshold can be associated to DP close
 542 to LODP. A BL higher than 3 km could thus be considered best for safe handling of different type of papers.

543
 544 *Scenario based on isoperms*

546 Two scenarios based on the impact of the reduction of temperature and RH were investigated using the isoperm generic
 547 model (Eq. 14). Table 6 shows the impact of the decrease of 5 °C on the isoperm based on different E_a . A decrease of
 548 5 °C doubles the lifetime of papers with E_a of 95 kJ mol⁻¹. The higher the E_a , the better is the permanence. This means
 549 for instance that papers containing mechanical pulp would need to be stored at lower temperature than chemical pulp
 550 papers in order to significantly increase their lifetime. Table 7 shows the impact of reducing the RH by half on the
 551 isoperm. The isoperm almost doubles ($\times 1.9$) when the RH is reduced from 70% to 35%, and this was verified for any
 552 given E_a . Table 7 also shows that by halving RH in the lower RH range, the improvement in the isoperm is smaller.
 553 Moreover, the isoperm increase with the RH reduction was practically the same at any temperature. The data in Strlič
 554 et al. (2015) and Parsa Sadr et al. (2022) indicated a higher increase, by a factor of about 3.4 in the same conditions,
 555 i.e., when halving RH from 70% to 35%, independently of the pH of their paper. Even though the values are in the
 556 same order of magnitude, it is important to keep in mind that the approach of these authors differs from ours in several
 557 ways, including a different isoperm 1 setting and model used. It is worth noting that while the E_a and pH₀ values are
 558 crucial, the uncertainty on these values have a negligible impact on the two scenarios cited above, as this is a relative
 559 comparison. The Isoperm equation (Eq. 14) is a useful tool that can be applied to different papers, even in cases where
 560 the E_a is unknown. The impact of E_a on the isoperm is relatively small, which means that the average E_a for each type
 561 of paper can be used. For example, in the case of mechanical pulp papers, bleached kraft pulp papers, and papers with
 562 alkaline fillers, average values of 103, 125, and 129 kJ mol⁻¹, can be used respectively.

563
 564 **Table 6** Effect of E_a and temperature on isoperm at 50% RH

E_a (kJ mol ⁻¹)	Temperature (°C)	Isoperm
95	20	1.0
95	15	2.0
110	20	1.0
110	15	2.2
130	20	1.0
130	15	2.6

565
 566 **Table 7** Effect of RH on isoperm at 20 °C

RH reduction	Isoperm increase	Permanence increase
70% to 35%	0.7 to 1.3	1.9
60% to 30%	0.8 to 1.4	1.7
50% to 25%	1.0 to 1.6	1.6

567
 568 In Du Plooy (1981) the permanence of acid and alkaline papers was found to improve by a factor of 17 when the
 569 environmental conditions shifted from 50% RH and 20 °C to 30% RH and 10 °C. This projection is twice as optimistic.
 570 With the isoperm developed here, an improvement of about 8 times was obtained, and a similar result was obtained
 571 by Strlič et al. (2015). Du Plooy also claimed an improvement of the permanence of about 1000 and 500 for acid and
 572 alkaline papers, respectively, if the conditions shifted further down to 5% RH and 5 °C. Again, our isoperm shows a
 573 more modest improvement of 70 and 60, respectively. A slight extrapolation of the isoperm developed by Strlič et al.
 574 (2015) tends to a similar result.

575
 576 As with any prediction, the decay model developed is not without limitations and uncertainties. One such limitation
 577 is the relatively small number of papers studied (10), which restricts the projections made based on some of the
 578 observations. However, our results are consistent with previously published results which strengthens the confidence
 579 on their reliability. The relative change in decay rates resulting from variations in the environment conditions is likely
 580 to be more reliable than determining a DP value reached after an extended period of time.

Conclusion

The application of the decay model developed in Tétreault et al. (2019) to different types of paper allowed to confirm its validity beyond the proof of concept for a wide range of papers as well as making the following new observations.

The integration of DP, EMC, and pH into the Calvini kinetic model enables the prediction of the decay rate of different types of papers under different environmental conditions for an extensive period of time, i.e., over several centuries. If all the simulations in this research rely on new or quasi new paper, they also apply to naturally aged printing papers as long as their actual DP_t at the time of the simulation is taken into consideration. The time to reach their end lifetime is obviously shorter

.
A wide range of E_a was found for the papers, from 93 to 130 kJ mol⁻¹. Papers with alkaline fillers have an E_a around 129 kJ mol⁻¹. All the bleached kraft pulp papers also have an E_a around 126 kJ mol⁻¹ even those with low (acidic) pH₀. Their high E_a ensures their durability. However, the mechanical pulp papers have an E_a below 110 kJ mol⁻¹, which, as demonstrated threatens their lifetime. Two Whatman papers made of cotton linters, used as models, showed a low E_a of 93 and 102 kJ mol⁻¹ compared to the other papers. These two papers widely used as paper models in several paper ageing studies therefore show their limitations in terms of representativeness of printing papers and archival papers for durability studies.

Secondary to E_a , the simulations show that pH₀ is also a critical parameter that determines paper decay and hence its durability. However, the accurate determination of the end of lifetime remains a challenge for any decay model due to the uncertainty on E_a , which is inherent to the experimental parameters, as well as because of the hardly predictable future environmental conservation conditions.

The model allowed the development of a generic isoperm, based on E_a , valid for a wide range of papers made of different fibers and additives, and different pH₀, which represent the modern paper collections presently stored in libraries and archives and that will also be part of their collections in the future. The popular belief that a decrease of 5 °C doubles the permanence of paper remains valid as long as the E_a is close to 95 kJ mol⁻¹. The permanence increases with E_a , for instance by up to 2.6 times for E_a of 130 kJ mol⁻¹. In particular, alkaline buffered paper is extremely durable and hence a reliable information carrier and art medium, especially in protected and environmentally controlled infrastructures. The environmental control for the preservation of these papers in archival contexts can be minimal due their intrinsic durability, as opposed to acidic papers with a low E_a which would significantly benefit from small climate adjustments. The isoperm approach can provide a reasonable estimate of the rate of aging of paper and can help inform decisions related to their preservation.

The results of the simulations also confirm the importance of storing mechanical pulp papers in a dry and cold environment for optimal preservation and extension of their usability to more than 500 years.

Acknowledgements

The authors would like to dedicate this paper to our late friend Luc Bourbonnais. We have played with some equations together. The authors are grateful to Valérie Dupont for her insightful contribution during the editing of this article.
