## 37 **Abstract**

38 18 Martian gullies are surface features, typically composed of an alcove, a channel and a depositional apron.

39  
40 19 They have been extensively studied since their first observations in the 2000s and were initially  
41  
42 20 attributed to the action of liquid water. Later studies highlighted that their activity is spatially and  
43

44 21 temporally correlated with the seasonal presence of surface CO<sub>2</sub> ice, suggesting a link between seasonal  
45  
46 22 frost and gully activity. However, the exact mechanisms leading to gully formation are still under debate.

47  
48  
49 23 Establishing whether or not gullies are formed by liquid water has important implications for Mars  
50  
51 24 recent climate and habitability. Here, we study the evolution of seasonal frost and its connection to gully

52  
53 25 activity in Sisyphi Cavi, located in the southern circumpolar region (68°S - 74°S; 345°E - 5°E). The  
54  
55 26 high latitude of this site allows for detailed temporal monitoring, owing to the high frequency imaging

56  
57  
58 27 by spacecraft in polar orbits, largely unavailable for other martian gullies, hence this site has the potential  
59  
60 28 to reveal new insights on gullies in general. In particular, we used repeat images from MRO HiRISE  
61  
62  
63  
64  
65

29 (Mars Reconnaissance Orbiter, High Resolution Imaging Science Experiment) and TGO CaSSIS (Trace  
30 Gas Orbiter, Colour and Stereo Surface Imaging System). Our findings show that the general timing and  
31 characteristics of the defrosting patterns in Sisyphi Cavi follow seasonal patterns that are consistent from  
32 year to year. The timing of the start of defrosting and its temporal evolution are controlled by the overall  
33 orientation of the host hillslope, with equator-facing slopes defrosting before pole-facing ones and the  
34 steepest pole-facing slopes defrosting last. Gully alcoves defrost before channels and aprons located on  
35 the same hillslope independent of the orientation of the hillslope likely because the aprons have a lower  
36 thermal inertia than the alcoves that counteracts the orientation effect, which on pole-facing slopes  
37 would mean the alcoves should defrost last. We observe the presence of seasonal and ephemeral dark  
38 spots and flows which are interpreted to be a result of sediment deposition on top of the seasonal ice  
39 deposits, triggered by basal sublimation. Our observations suggest that the appearance of dark spots and  
40 dark flows can be spatially correlated with surface roughness, including presence of boulders, contrasts  
41 in material types, irregular lobes/levees and braiding caused by gully activity, and therefore could be  
42 used to help detect recently active gullies on Mars in areas with seasonal frost without the need of repeat  
43 imaging. Finally, we propose that presently observed gully activity in Sisyphi Cavi is driven by defrosted  
44 material flowing on to a frosted apron. We infer that the presence of a frosted apron could be common  
45 precursor for this type gully activity. We note that this activity only involves the mobilisation of loose  
46 materials and we have not observed any erosion of the wall rock present in Sisyphi Cavi.

## 42 48 **1. Introduction**

### 44 49 **1.1. Gullies and seasonal frost**

46 50 Martian gullies have been abundantly studied since they were first observed by Malin and Edgett (2000).  
48 51 Yet their formation mechanism is still under debate (e.g. Heldman and Mellon, 2004; Cedillo-Flores et  
50 52 al., 2011). Gullies are landforms typically composed of an alcove, a channel and a depositional apron,  
53 53 with a lengthscale of kilometres (Malin and Edgett, 2000; Harrison et al., 2015) and they are located on  
55 54 steep slopes spanning latitudes from 30° N/S to the polar caps (Conway et al., 2019a). They are generally  
57 55 present on crater walls and central peaks, fossae/valles walls or on sand dunes (Malin and Edgett, 2000;  
60 56 Dundas et al., 2012; 2015; 2019; Diniega et al., 2010; Hansen et al., 2011; Jouannic et al., 2012; Harrison

57 et al., 2015; Raack et al., 2015; Pasquon et al., 2019a), being particularly abundant in the southern  
1 58 hemisphere, where steep slopes are commonplace (e.g. Harrison et al., 2015). Gully morphologies are  
2 59 highly variable and include features which can have kilometre-wide alcoves and aprons as well as metres  
3 60 wide “linear” dune gullies (Dickson et al., 2007; 2012; Conway et al., 2011; Harrison et al., 2015;  
4 61 Pasquon et al., 2019a).

10 62 Many different hypotheses have been proposed for martian gully formation: liquid water from  
11 63 shallow groundwater aquifers (Malin and Edgett, 2000; Mellon and Phillips, 2001; Heldmann and  
12 64 Mellon, 2004; Heldmann et al., 2005; Malin et al., 2006), deep groundwater sources (Gaidos, 2001;  
13 65 Hartmann, 2001), melting of shallow ground ice (in the form of pore ice or excess ice; Costard et al.,  
14 66 2002; Reiss and Jaumann, 2003; Mangold et al., 2003, 2010; Miyamoto et al., 2004; Balme et al., 2006;  
15 67 Reiss et al., 2010; Conway et al., 2011a; Jouannic et al., 2012, 2015; Conway and Balme, 2016),  
16 68 snow/icemelt (Lee et al., 2001; Christensen, 2003; Dickson et al., 2007; Védie et al., 2008; Hauber et  
17 69 al., 2011; Williams et al., 2009; Khuller & Christensen, 2021), or dry mass wasting (Treiman, 2003;  
18 70 Shinbrot et al., 2004), brines (Knauth and Burt, 2002; Ojha et al., 2015; Massé et al., 2016), frosted  
19 71 granular flow (CO<sub>2</sub>, H<sub>2</sub>O) (Hugenholtz, 2008), CO<sub>2</sub>-supported debris flows (Hoffman, 2002; Ishii and  
20 72 Sasaki, 2004; Di Achille et al., 2008; Diniega et al., 2010; Cedillo-Flores et al., 2011; Dundas et al.,  
21 73 2012; 2015; 2019; Pilorget and Forget, 2016), and release of liquid CO<sub>2</sub> (Musselwhite et al., 2001). For  
22 74 a full review see Conway et al. (2019b).

23 75 Some gullies are active today, including at times of the year when the martian surface is at its coldest  
24 76 and CO<sub>2</sub> ice is condensed on the surface, suggesting that they are triggered by seasonal processes related  
25 77 to ice (e.g., Dundas et al., 2010; Diniega et al., 2013; Raack et al., 2015; Pasquon et al., 2019b). Such  
26 78 seasonal processes are generally attributed to CO<sub>2</sub> sublimation driven by solar radiation (e.g., Kieffer,  
27 79 2000; 2007; Kieffer et al., 2006; Hansen et al., 2011). The seasonal CO<sub>2</sub> and water ices start to  
28 80 accumulate on the surface during autumn and sublimate away the following spring. During winter, these  
29 81 deposits: i) cover all surfaces above ~ 60° latitude, ii) are discontinuous from 40° to 60° of latitude  
30 82 (Schorghofer and Edgett, 2006; Vincendon et al., 2010; Diniega et al., 2013), and iii) are limited to pole-  
31 83 facing slopes nearer the equator (Lange et al. 2022; Dundas et al., 2015, 2019, Vincendon et al., 2010;  
32 84 Khuller, et al., 2021; Piqueux et al., 2016). Ice deposits can be up to meters thick near the poles (Smith  
33

85 et al., 2001), to sub-centimetre in thickness at lower latitudes (Vincendon, 2015). Most ice deposits are  
1  
2 86 composed of CO<sub>2</sub> (~centimetres) (Diniega et al., 2013; Dundas et al., 2015), whereas H<sub>2</sub>O is a minor  
3  
4 87 component (~micrometres) (Kereszturi et al., 2009; Gardin et al., 2010; Vincendon et al., 2010a; 2010b).  
5  
6 88 To simplify terminology, in this paper we use the term “frost” to describe the seasonal ice deposits of  
7  
8  
9 89 Mars.

## 13 91 **1.2. Sisyphi Cavi and gully activity**

15 92 Sisyphi Cavi is a site with an anomalously high concentration of gullies for its latitude (Harrison et al.  
16  
17 93 2015) located in the southern circumpolar area (68°S - 74°S; 345°E - 5°E). This is likely caused by a  
18  
19 94 higher frequency of steep slopes than typical of this latitude (Conway et al. 2019a), due to the occurrence  
20  
21  
22 95 of numerous steep-sided, flat-floored depressions, generally several hundred kilometres across and more  
23  
24 96 than 1 km deep (Tanaka and Scott, 1987). Conway et al. (2019a) defined steep as being >20° at the ~1.5  
25  
26 97 km length scale allowed by the Mars Orbiter Laser Altimeter gridded data. Raack et al. (2020) showed  
27  
28 98 the slope at length scales of 100 m exceeds 30° at the top of the hillslopes in Sisyphi Cavi and that the  
29  
30 99 steepest portion of the hillslope was consistently located at the top. Hence, throughout this paper we  
31  
32  
33 100 make the assumption that the steepest part of the hillslope is located in the upper part. The formation of  
34  
35 101 these depressions, which are incised into Amazonian surfaces (Tanaka and Scott, 1987), is not  
36  
37 102 completely understood (e.g., Raack et al., 2020). Gullies are present over large continuous swathes of  
38  
39 103 the walls of these depressions (Raack et al., 2020).

42 104 Previous work by Raack et al. (2015, 2020) considered the timing of gully activity in Sisyphi  
43  
44 105 Cavi. They found that sediments were transported down the gully and deposited over the apron in 35  
45  
46 106 gullies (out of a total of 19,827 gullies). None of these observation revealed erosion of the wall rock  
47  
48 107 present in Sisyphi Cavi by these flows. Using spectral observations and numerical modelling, Raack et  
49  
50  
51 108 al. (2015) showed that the surface ice deposit during the period of gully activity consists of a translucent  
52  
53 109 slab of CO<sub>2</sub> ice with minor amounts of H<sub>2</sub>O ice. Gully activity occurs at the end of the spring, during the  
54  
55 110 final stages of defrosting when some surfaces are already fully ice-free. They suggested that activity is  
56  
57 111 driven by dry flows mobilised over a sublimating CO<sub>2</sub> ice slab, similar to the mechanism proposed by  
58  
59  
60 112 Cedillo-Flores et al. (2011). Raack et al. (2020) refined this model, suggesting an accumulation of

113 material within gully channels via small dry flows on top of the ice. When a critical mass sediment is  
 114 reached on top of the slab ice, the sediment flows down the still frosted gully on top of the sublimating  
 115 ice or as a mixture of dry material and sublimating ice as a flow. This accumulation phase means more  
 116 sediment would be mobilised, explaining the observable thickness of the flow deposits.

### 1.3. Dark spots and dark flows

125 Ephemeral dark spots were reported for the first time by Malin (1998). These are low albedo spots  
126 (generally circular) that can measure up to several metres in diameter (Kereszturi et al., 2009, 2010) and  
127 are linked to seasonal CO<sub>2</sub> ice deposits (Gardin et al., 2010; Kereszturi et al., 2009, 2010; Möhlmann  
128 and Kereszturi, 2010; Diniega et al., 2021). Dark spots usually appear between the middle of the winter  
129 and early spring and disappear each year in late winter/early summer (Kereszturi et al., 2009). The  
130 prevailing hypothesis for dark spot formation is the accumulation of material following the ejection of  
131 dust and sand from a CO<sub>2</sub> gas jet (Kieffer et al., 2006; Kieffer, 2000, 2007; Piqueux and Christensen,  
132 2008). These gas jets are thought to form as follows: In winter CO<sub>2</sub> frost is deposited on the surface,  
133 quickly sintering and producing an impermeable slab that becomes translucent to visible radiation. After  
134 mid-winter the sun's rays penetrate the translucent ice and heat the underlying substrate, causing the  
135 CO<sub>2</sub> ice to sublimate at its base. An over-pressure, due to the CO<sub>2</sub> gas that accumulates, occurs under  
136 the ice layer and cracks the ice (Piqueux et al. 2003; Kieffer et al. 2006; Piqueux and Christensen 2008;  
137 Portyankina et al., 2011). Degassing occurs through these cracks and particles are entrained by the gas  
138 and redeposited on the surface of the ice (e.g. Piqueux et al., 2003; Kieffer et al., 2006; Portyankina et  
139 al., 2011). When dark spots appear on a sloping surface, they can evolve into “dark flows” which are  
140 dark features that can incrementally elongate downslope (Kereszturi et al., 2009; 2010; Gardin et al.,  
141 2010; Jouannic et al., 2019). Dark spots and flows are not associated with measurable material transport,  
142 so it is inferred that only dust or very minor amounts of sand are mobilised. Dark flows have been also  
143 interpreted to result from flowing brines (Möhlmann and Kereszturi, 2010; Kereszturi et al., 2011).  
144 However, their consistent association with CO<sub>2</sub> spectral signatures (Pommerol et al., 2013) in a wide  
145 range of environments and observations of fast flow speeds inconsistent with viscous brine (Gardin et  
146 al., 2010) suggest they may simply be another type of gas supported flow.

147 Dark spots and dark flows are visible each spring on the slopes, gullies and dunes of Sisyphi Cavi.  
148 They preferentially occur on dunes and inside gully channels and aprons (Raack et al., 2015; 2020). No  
149 perennial morphological changes have been associated with the activity of dark spots and dark flows in  
150 Sisyphi Cavi (Raack et al., 2015; 2020). Here, we also document their occurrence because their link  
151 with active gullies is ambiguous.

#### 1.4. Objectives of this study

1  
2 154 Previous studies (Raack et al., 2015; 2020) showed that the activity of gullies in Sisyphi Cavi occurs  
3  
4 155 before the seasonal frost disappears from the surface, and thus suggest that a relationship likely exists  
5  
6 156 between gully activity and springtime defrosting. Here we perform a detailed study of seasonal frost  
7  
8 157 evolution on the slopes of Sisyphi Cavi (68-74°S; 345°-5°E) (Fig. 1A), exploring the relationship  
9  
10 158 between gully activity and frost occurrence. We focus on two main points: 1) Investigating the changing  
11  
12 159 appearance of the seasonal frost through the winter and spring before gully activity occurs, to build  
13  
14 160 intuition on the environmental factors leading to gully activity; and 2) the sequence of events and their  
15  
16 161 timing during defrosting, to better understand the potential triggers and conditioning factors for activity.  
17  
18  
19  
20  
21

#### 2. Methods

22 163  
23  
24 164 We based our study on the analysis of HiRISE (High Resolution Imaging Science Experiment; McEwen  
25  
26 165 et al., 2007) and CaSSIS (Colour and Stereo Surface Imaging System; Thomas et al., 2017) image data.  
27  
28 166 The HiRISE camera is aboard NASA's MRO (Mars Reconnaissance Orbiter) spacecraft, and acquires  
29  
30 167 images with a spatial resolution of 0.25-1 m/pixel and three filters (RED, BLU and NIR centred on 694,  
31  
32 168 536 and 874 nm respectively) (McEwen et al., 2007). The CaSSIS camera is on board ESA's TGO  
33  
34 169 (Trace Gas Orbiter) spacecraft. CaSSIS acquires images with a resolution of ~4.6 m/pixel and four  
35  
36 170 possible colour filters (BLU, PAN, RED and NIR centred on 497.5, 677.4, 835.4 and 940.2 nm  
37  
38 171 respectively) (Thomas et al. 2017).  
39  
40  
41

42 172 Given the large dimensions of our study area (68°-74°S; 345°-5°E) we divide the region into  
43  
44 173 "sites", with smaller "areas" defined within each site (Fig. 1). Image data available for Sisyphi Cavi  
45  
46 174 have a spatially discontinuous time coverage with some sites having only one or two images. We divide  
47  
48 175 the region in 3 sites, each containing between 4 and 20 gullies, located at: 1) 68.5°S and 1.3°E (Fig. 1B),  
49  
50 176 2) 70.92°S and 1.2°E (Fig. 1C) and 3) 69.4°S and 347°E (Fig. 1D). Although these sites form the  
51  
52 177 majority of our data analysis, we also use images located elsewhere in Sisyphi Cavi as illustrative  
53  
54 178 examples. A summary of the images used is provided in Supplementary Table S1.  
55  
56  
57

58 179 To describe the timing of events in this paper, we use the solar longitude (Ls) of the first image  
59  
60 180 where we observe the feature/ activity appear and the Ls when we observe it for the last time. So, the  
61  
62  
63  
64  
65

181 disappearance of the feature occurs after the last Ls provided, but before the Ls of the next image in the  
182 sequence (all sequences are visible in the Supplementary Table S1) for the same Mars Year. As  
183 interannual variability in the timing of defrosting (Piqueux, et al., 2015) is less than the typical time gap  
184 between images, we sometimes group data from different Mars years to form more complete datasets.  
185 The events documented in this paper include: appearance of dark spots, appearance of dark flows, and  
186 the assessment of the continuity of frost cover.

187         Assessing frost/ice cover from optical images is challenging because of the transparency of slab  
188 CO<sub>2</sub> ice in visible wavelengths and up to 25 cm of CO<sub>2</sub> ice can accumulate before the surface is masked  
189 in the visible wavelengths (Singh and Flanner, 2016). We address this by using features/patterns in  
190 optical data observed by other researchers, where these researchers used spectral datasets to confirm the  
191 presence of frost. We infer the presence of transparent ice, by the fact that surface features such as ripples  
192 and boulders can be weakly observed on the surface, and the surface shows dark spots and flows  
193 indicative of the presence of slab ice (Andrieu et al. 2018; Kieffer et al., 2006; Kieffer, 2000,  
194 2007; Piqueux and Christensen, 2008). Brightening of the seasonal ice cover at a given location just  
195 prior to its retreat has been noted in previous publications (e.g. Langevin et al. 2007; Calvin et al. 2017)  
196 and is thought to represent break-up of the CO<sub>2</sub> to smaller grainsizes or deposition of water ice frost cold  
197 trapped by the CO<sub>2</sub>. We infer that on partially defrosted surfaces, the remaining CO<sub>2</sub> ice acts as a cold  
198 trap for water vapour which in turn presents a highly visible, bright surface frost, which contrasts with  
199 the lower albedo of the defrosted surfaces. We classify images as completely defrosted when no  
200 remaining bright patches can be observed on any surface. We are reasonably confident with this  
201 interpretation as these images are always towards the end of spring in our time series and these images  
202 which occur later than the time of retreat of the seasonal cap at this latitude as detected by other  
203 researchers using thermal and/or spectral data (Brown et al., 2010; Piqueux, et al., 2015).

204         We highlight that site n°1 has the best coverage, with 59 HiRISE and 11 CaSSIS images available,  
205 so we focus most of our analysis on this site. As Supplementary Table S1 shows, there is good temporal  
206 sampling of this region spanning from mid-winter to summer (from Ls 158.4° to Ls 349.5°). However,  
207 the lack of images from the middle of summer to the start of winter (from Ls 349.5° to 158.4°) prevented

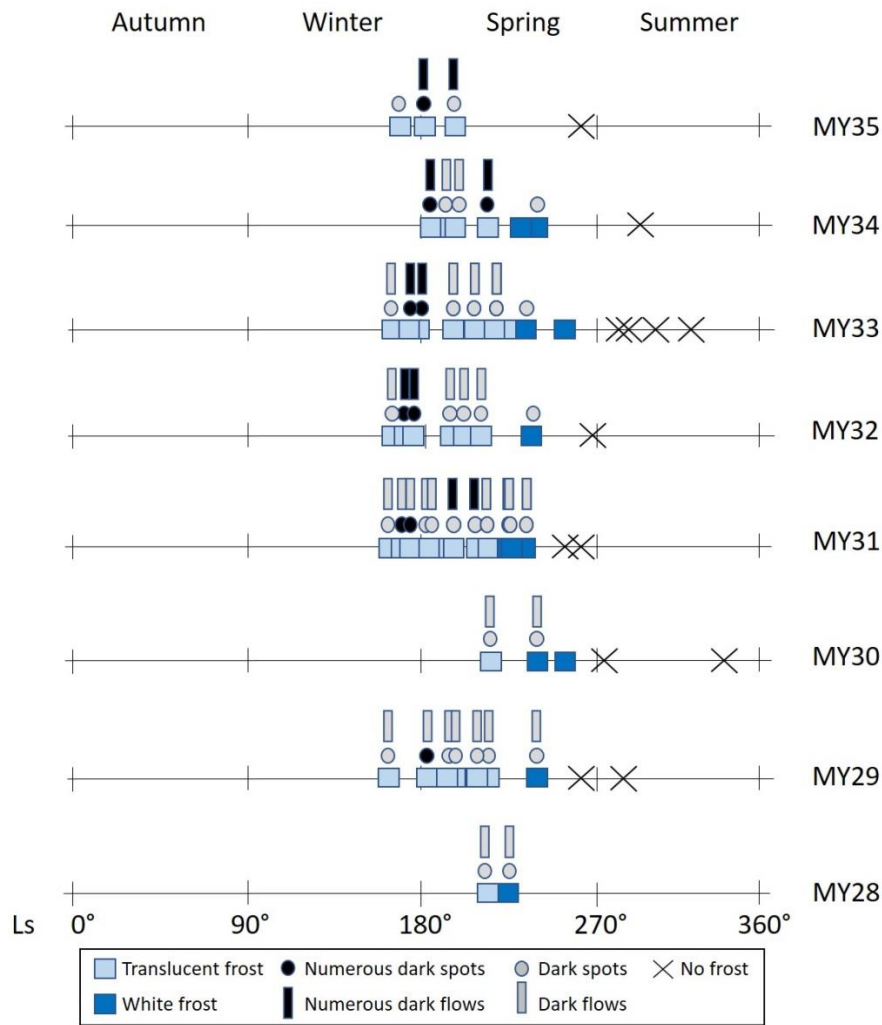

208 us from studying the emplacement of the seasonal frost. We further divide the site n°1 into several areas,  
 209 (A to D, Fig. 1B) to distinguish different parts with different hillslope orientations.

210

### 211 3. Results and interpretations

#### 212 3.1. Patterns in seasonal defrosting

213 In this section, we only report results from site n°1 (68.5°S and 1.3°E, Fig. 1B) due to the better multi-  
 214 temporal image coverage (Supplementary Table S1), unless otherwise indicated.

### 3.1.1. General patterns in seasonal defrosting

230 We first focus our analysis on areas C and D within region 1, which have the highest temporal and  
231 spatial availability of image data. Regions C and D (Fig. 1B) contain 59 and 57 HiRISE images  
232 respectively, spanning Martian Years (MY) 28 to 35, with 7-13 images available for each year.

233 In each martian year, we consistently observe the following sequence of events leading to defrosting,  
234 with area C lagging tens of Ls behind area D (Supplementary Table S2):

- 235 - We observe numerous dark spots and dark flows on top of the translucent frost, around Ls 160-  
236 230° (Figs. 2, 3AB; Supplementary Table S2). The frost is considered as translucent, because  
237 underlying features (e.g., boulders, alcoves, or channels) can still be seen.
- 238 - After this, the frost becomes “brighter” with fewer or absent dark spot(s) and dark flow(s) (Figs.  
239 2; 3CDEF; Supplementary Table S2). This brightening has been noted in previous publications  
240 (e.g. Langevin et al. 2007), but could be attributed to changes in overall image contrast. In either  
241 case it indicates the break-up of the translucent frost (Fig. 3C-F).
- 242 - From Ls 170° to 225°, the frost becomes visually patchy and discontinuous and only some small  
243 patches are visible by Ls 225° (Figs. 2, 3 DEF; Supplementary Table S2).
- 244 - Defrosting is complete at around Ls 250-300° (Fig. 2; Supplementary Table S2).

245 Dark spots and dark flows never appear when frost becomes patchy. They are first visible only when  
246 frost seems to be continuous.

### 3.1.2. Defrosting patterns of gullies

252 Here, we report on the frost occurrence and distribution within gullies, including the alcoves, channels,  
253 and aprons, during winter and spring in areas C and D (region 1). We observe a consistent sequence of  
254 events across martian years, as shown in Supplementary Table S3:

- 255 - All surfaces are frosted until Ls  $\sim 220^\circ$  (Figs. 2; 3AB; Supplementary Table S3),
- 256 - Then, alcoves begin to defrost, while areas surrounding the gullies begin to defrost starting at  
257  $\sim Ls 230^\circ$  (Supplementary Table S3). At the same time or just afterwards the channels and aprons  
258 begin to defrost.
- 259 - The areas around gullies become completely defrosted as early as Ls  $210^\circ$  and as late as Ls  $247^\circ$   
260 (Supplementary Table S3),
- 261 - The alcoves are completely defrosted. Then the channel and aprons are the last to defrost at  $\sim Ls$   
262  $250^\circ$  (Supplementary Table S3), where some patches of late persistent frost remain visible at  
263 the bottom of alcoves and inside the channels (Fig. 3F),
- 264 - All surfaces are defrosted around Ls  $240-300^\circ$  i.e., between the middle of spring to the beginning  
265 of summer (Fig. 2; Supplementary Table S3).

266 Within this sequence, gully alcoves defrost before channels and aprons on areas C and D (Fig. 3DE;  
267 Supplementary Table S3). Yet some patches of frost persist inside the channel and at the bottom of the  
268 alcove (Fig. 3F). In general, gullies defrost later than their surrounding terrain (Fig. 3DE; Supplementary  
269 Table S3), with the notable exception of sandy areas, such as dunes.

### 281 3.2. Effects of slope orientation on defrosting

282 We now report the results of studying the timing of defrosting for gullied slopes with differing  
 283 orientations and different orientations of slope facets within their alcove and channels. We include  
 284 observations from MY31 for site n°1 (68.5°S, 1.3°E; Figs. 4, 5 and 6), and site n°2 (69.5°S, 347°E; Fig.

285 7). For site n°1, area A has a slope orientation of 80°-85°N, area B: 95°-105°N, area C: 130°-140°N,  
 286 and area D: 0° - 10°N (Fig. 1B). For site n°2 (Fig. 7), we divide the gullies observed into two groups  
 287 according to their slope orientation. Slopes in gully group 2A are oriented 225° with respect to north,  
 288 on average, whereas group 2B has an orientation of 200°.

291 *Fig. 5: Defrosting sequence for areas A, B, C and D which have different orientations - site n°1 (68.5°S;*  
 292 *1.3°E, MY31). Blue lines highlight the inter-site variability of the timing of the end of translucent frost*  
 293 *(dark blue lines) and of the end of defrosting (light blue lines), which is most extreme between equator-*  
 294 *facing area D and slightly pole-facing area C. Each symbol represents the timing of the image given in*  
 295 *Supplementary Table S1.*

296 For each slope orientation, we observe the same sequence of seasonal defrosting and associated  
 297 features for each of the areas A, B, C and D, as already described in section 3.1.1, with the detailed time  
 298 intervals reported in Supplementary Table S4 and on Fig. 5. However, the onset of events in each area  
 299 is offset in time. For example, there is a lag of 37° solar longitude between the appearance of “bright”  
 300 frost in area C compared to area D (Fig. 5; Supplementary Table S4), and we observe a lag of 18° solar  
 301 longitude in the complete defrosting of area C compared to area D (Fig. 5; Supplementary Table S4).

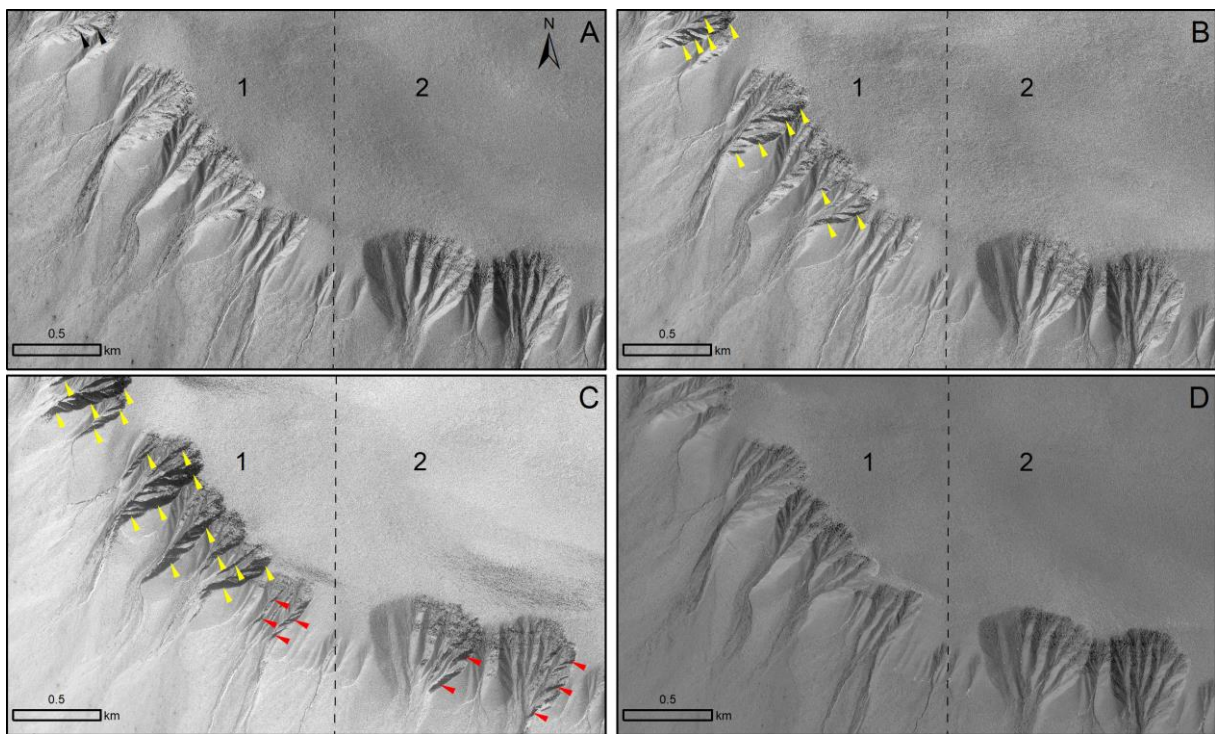

302 We also observe differences in seasonal frost patterns within gullies (e.g., on the channel flanks)  
1  
2 303 that are related to the orientation of these slope facets, as shown in Fig.6 and Supplementary Table S3  
3  
4 304 for areas A, B, and C in MY31 and in Figure 7 for site n°2. In summary, equator-facing alcove facets  
5  
6 305 start to defrost first, followed by equator-facing channel facets and parts of the surrounding terrain.  
7  
8 306 Equator-facing alcove facets can be completely defrosted while pole-facing ones are only starting to  
9  
10 307 defrost. On the contrary, pole-facing alcove and channel facets are the last to defrost. Slight east (or  
11  
12 308 west) deviations on an equator-facing slope facet delay initial and complete defrosting, and conversely  
13  
14 309 advance pole-facing slope facet defrosting.

15  
16  
17 310 In general, the timing of defrosting depends on slope orientation (Supplementary Table S4), and  
18  
19 311 the sequence of events and the distribution of remaining frost remains consistent across regions. (Figs.  
20  
21 312 4, 7; Supplementary Table S4). An equator-facing slope always defrosts before a pole-facing slope for  
22  
23 313 the same material type and slope angle (Figs. 6, 8; Supplementary Table S5). Yet, the orientation of  
24  
25 314 slope facets inside an alcove or a channel causes differences in the relative timing of defrosting (Figs.  
26  
27 315 6, 8; Supplementary Table S5). Finally, gully-alcoves always defrost before channels and aprons  
28  
29 316 regardless of gully orientation (Supplementary Tables 3, 4 and 5).

### 345 3.3. Effect of surface type on defrosting

346 We next interrogate the relationship of dark spots and dark flows with surface roughness and gully  
347 activity using HiRISE and CaSSIS data. We find that surface roughness at the meter scale may influence  
348 the number of dark spots, and possibly dark flows present on the surface. We find that surface roughness  
349 is present in the form of boulders, depositional and erosional elements including braiding; levees, lobes.  
350 For this analysis we focus on the 3 sites shown in Fig. 1, located at: 1) 68.5°S and 1.3°E, 2) 70.92°S and

1.2°E and 3) 69.4°S and 347°E. Before considering the effect of surface roughness, we describe our general observations of dark spots and dark flows in Sisyphi Cavi.

### 3.3.1. Evolution of dark spots and dark flows in Sisyphi Cavi

We studied the presence and distribution of dark spots and dark flows in MY31 for areas A, B, C and D in site n°1. Dark spots and dark flows do not appear in gully alcoves in areas A, B or C, whereas both features are present in the channels from Ls 158.4° to Ls 228.8°, on the gully-apron from 158.4° to 235.9°, on the gully apron terminations from 167.2° to 185.5° and on the terrain around gullies from Ls 158.4° to 185.5° (Fig. 9; Supplementary Table S6). In contrast, dark spots appear on the terrain surrounding gullies and on gully aprons in area D at Ls 158.4° ( Fig. 9; Supplementary Table S6). At Ls 167.2°, dark spots that were clearly visible in the previous image appear faded, whereas new dark spots appear on the smooth apron surfaces ( Fig. 9; Supplementary Table S6). At Ls 173.3° nearly all dark spots appear faded, and at Ls 182.6° all dark spots have disappeared ( Fig. 9; Supplementary Table S6).

Dark spots and dark flows are visible between the middle/end of winter to the middle/end of spring in Sisyphi Cavi (Figs. 2, 3ABCD, 9; Supplementary Tables 2 and 6). They are distributed non-homogeneously on all surfaces, with a spatial distribution that appears roughly similar from one martian year to the next, hinting at their preferential emplacement in given locations. Timing-wise, the appearance of dark spots and dark flows does not follow a reproducible pattern from year to year, and they do not have the same morphology, size, or lifetime (Fig. 3ABC, 9; Supplementary Tables 2 and 6). For a given slope with gullies sharing all the same overall orientation, several generations of dark spots may appear throughout the same martian year (Fig. 3ABC, 9; Supplementary Tables 2 and 6).

### 3.3.2. The role of surface roughness and substrate on the onset of dark spots and flows

Boulders are common on slopes in the Sisyphi Cavi region (Fig. 10), sourced from a layer that appears at the same elevation as gully alcoves. These boulders measure from 1 m<sup>2</sup> (the limit of HiRISE resolution) to nearly 30 m<sup>2</sup>. These decametre-scale boulders are preferential locations for dark spot

378 formation (Fig. 10), and their occasional evolution into dark flows (Figs. 10CD). In our study region,  
1  
2 379 the majority of visible boulders are associated with dark spots.

380 Dark spots (and sometimes dark flows) cluster on the floor of alcoves, in the channel, and/or on  
381 the apron as shown in Fig. 11. These surfaces are rougher than the surrounding terrain, having more  
382 boulders, but also having braided sections with metre-scale scarps and irregularities where aeolian  
383 smoothing seems to be less prevalent and we interpret this as being representative or more recently  
384 active areas (following Dundas et al. 2019).

386 *Fig. 10: Relation between boulders and dark spots/dark flows for site n°2 (70.7°S, 1.5°E). A) The west*  
387 *part of the image has few boulders, and correspondingly few dark spots, on the east part of the image*  
388 *there are more boulders and more dark spots. HiRISE image: ESP\_028868\_1090, Ls 176.2°, B) Zoom*  
389 *in on panel A which shows that each boulder correspond (on average) to a dark spot, C) Boulders and*  
390 *associated dark spots/dark flows concentrated along gullies are visible, HiRISE image:*  
391 *PSP\_003353\_1090, Ls 249.1°, D) Zoom in on part of panel C which shows the relation between the*  
392 *position of boulders and the presence of dark spot/dark flows. Image credit: NASA/JPL/UofA. Note that*  
393 *each image was individually contrast-stretched.*

394 Contrasts in surface roughness as well as substrate composition and physical properties seem to  
1  
2 395 facilitate the onset of dark spots. For example, the transition between apron and hillslopes host numerous  
3  
4 396 dark spots (Fig. 12CD), which aids in the identification of this transition without having to zoom-in.  
5  
6 397 Another example where dark spots concentrate is at the boundary between a sandy surface and the  
7  
8 398 surrounding terrain, where they also sometimes evolve into dark flows if the terrain is sloping (Fig.  
9  
10 12AB).

11 399  
12  
13 400  
14  
15 401 In summary, we observe that the presence of metre-scale surface roughness produces a higher number  
16  
17 402 of dark spots and dark flows in winter and spring (Figs. 10, 11 12). In Sisyphi Cavi, this roughness  
18  
19 403 takes the form of: 1) boulders (Fig. 10), 2) braided gully surfaces (Fig. 11) and 3) contrasts in substrate  
20  
21 404 properties (Fig. 12).

#### 4. Discussion

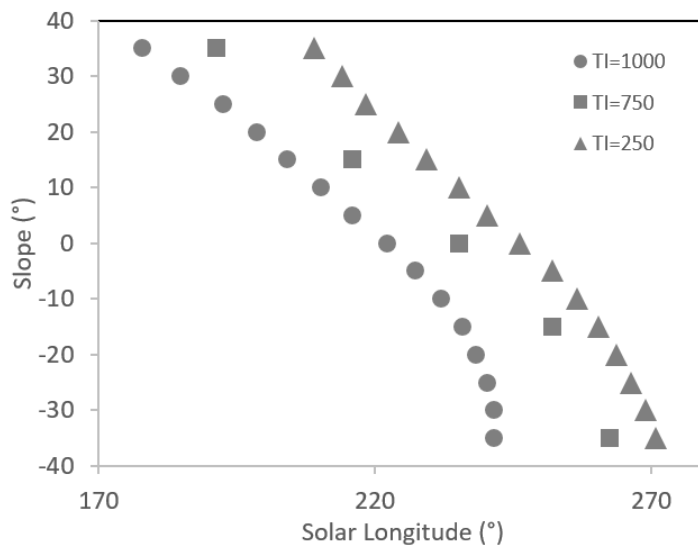

425  
 426 The aim of this work is to better understand the relationship between gully activity and seasonal frost  
 427 deposits in Sisyphi Cavi and to investigate if we can draw wider conclusions about this relationship for

gullies in general. We place our results into context with previous, related results from the literature. We discuss the significance of our findings regarding the sequence and timing of defrosting first, and the influence of gully activity on the presence of dark spots and dark flows second. Finally, we discuss the possible factors leading to gully activity and the possible effects of inhomogeneous frost distribution on gully morphology.

#### 4.1. Frosted aprons as a precursor to gully activity?

Raack et al. (2015,2020) inventoried the gully activity of the Sisyphi Cavi area and showed that it occurs on area C between Ls 234° and Ls 252° (Raack et al., 2020) and in area D, between Ls 218° and 226° (Raack et al., 2015). Neither activity involved the erosion of material from the wall rock of the gully. This timing corresponds to a period when the alcoves have already begun to defrost, when frost is brighter and just before the surface becomes ice free (Fig. 5). For area D, we observe that a new and relatively dark deposit overlies an apron that is covered in brighter frost in both instances of documented gully activity (Fig. 14 B, C, Ls 226° and 227° respectively). In area C, the image acquired prior to the change documented by Raack et al. (2020) shows that the gully is completely covered in frost at Ls 235 (Fig. 14A). The following image, ESP\_048107\_1115 shown in Figure 3 of Raack et al. (2020), acquired 20° of solar longitude later, shows the new deposit. However, the apron could have been covered in frost when the activity occurred. Hence, it seems that a frost covered apron could be an important precursor to some gully activity – a possibility we expand on below.

447 *Fig. 13: Solar longitude of when defrosting of CO<sub>2</sub> occurs on slopes with different angles, where negative*  
 448 *values represent pole-faing (south-facing) slopes and positive values equator-facing slopes. The results*  
 449 *are obtained from 1D climate model simulations for different thermal inertias (TI).*

464 The fact that the gully alcoves defrost first in Sisyphi Cavi (Fig. 15; Supplementary Tables 3, 4  
1  
2 465 and 5) independent of orientation means that a factor other than solar insolation controls the onset of ice  
3  
4 466 loss. The expected defrosting sequence starts at steep equator-facing slopes, then progresses towards  
5  
6 467 shallower equator-facing slopes to flat surfaces, afterwards onto shallow pole-facing slopes and finally  
7  
8 468 steep pole-facing slopes defrost. Making the assumption that the steepest slopes are found at the top of  
9  
10  
11 469 the hillslope consistent with the topographic measurements by Raack et al. (2020), this should result in  
12  
13 470 the top of the pole-facing hillslope, where the alcoves are located, defrosting last. Instead we observe  
14  
15 471 that it is the pole-facing aprons that are the last to defrost. We think this could be a key feature that could  
16  
17 472 explain present-day activity in some martian gullies. From an informal survey of HiRISE images of  
18  
19 473 typical mid-latitude gullies taken during the final stages of defrosting, we found several other examples  
20  
21  
22 474 where aprons remained frosted while the alcoves had already defrosted (Fig. 16). However, this does  
23  
24 475 not seem to be a universal pattern in all gullies - for example, for linear gullies in the southern  
25  
26 476 hemisphere (Pasquon et al., 2016) the channel and apron defrost before the alcove. The difference in  
27  
28 477 behaviour is likely related to the substrate properties. In some gully systems, including those in Sisyphi  
29  
30 478 Cavi the alcoves are comprised of rough rocky materials, whereas the aprons are presumably finer  
31  
32  
33 479 unconsolidated materials (as supported by studies of the thermal inertia of gully systems - Harrison et  
34  
35 480 al., 2019; Khuller et al. 2021), so there are different materials on the same slope. Dune gullies in contrast  
36  
37 481 have rather uniform substrate properties throughout, so follow the expected defrosting pattern (i.e. the  
38  
39 482 steepest pole-facing slopes, defrost last).

42 483 In order to investigate this further we used surface temperature data from the 1D climate  
43  
44 484 model runs presented in Conway et al. (2018). We extracted half-hourly surface temperature data for  
45  
46 485 present day obliquity and position of perihelion for surface thermal inertia values of 250, 750 and  
47  
48  
49 486 1000 Jm<sup>-2</sup>K<sup>-1</sup>s<sup>-0.5</sup> (referred to as thermal inertia units or tiu) and slopes of 0-35° in the north- and  
50  
51 487 south-facing orientations for 72°S. Thermal Emission Spectrometer (TES) data for the region suggests  
52  
53 488 the average surface thermal inertia varies between 130 and 250 tiu. However, the TES footprint is  
54  
55 489 >2 km, hence cannot capture local variations on the hillslopes which have a smaller spatial extent.  
56  
57  
58 490 Bedrock is expected to have values higher than 1200 tiu (Edwards et al., 2009), but is likely mixed  
59  
60 491 with other materials in this area because it does not appear as continuous outcrop, hence we choose

intermediate values of 750 and 1000 tiu for illustrative purposes. From these data we extracted the solar longitude at which the surface temperature exceeds the condensation temperature of CO<sub>2</sub> as shown in Fig. 13. From these data it can be seen for a constant thermal inertia the expected defrosting sequence starts at steep equator-facing slopes, then progresses towards shallower equator-facing slopes to flat surfaces, afterwards onto shallow pole-facing slopes and finally steep pole-facing slopes defrost last. Assuming aprons have a thermal inertia of 250 tiu and that alcoves are generally steeper than 30°, a pole-facing alcove with a thermal inertia of 750 tiu would defrost at the same time as a pole-facing apron. In contrast, a pole-facing alcove with a thermal inertia of 1000 tiu would defrost nearly 20° Ls before the pole-facing apron. Therefore, we infer the alcoves likely have a thermal inertia between these two extremes to explain the observations. The elevated thermal inertia of the gully alcoves with respect to gully fans could be due to a number of factors including, higher near-surface ice content, higher rockiness, larger grainsizes, or lower dustiness.

Other examples of gullies where mobilised material superposes a frosted apron exists. Dundas et al. (2015) observed dark flows over a frosted surface inside two gullies located at 37.4°S; 229°E; and in the northern hemisphere at 58.2°N and 89.7°E. On the dunes of Kaiser crater (47.2°S; 19.5°E), a gully shows an apron covered in frost just before the new gully deposits are observed (Fig. 14D; Dundas et al., 2012; Pasquon et al., 2019a). For the large sinuous gully on the Matara dunefield (49.5°S; 34.7°E), material from the alcove is mobilised over a frosted channel and apron (Fig. 14F; Dundas et al., 2012; Pasquon et al., 2019b). New gully deposits are usually not first imaged/detected during the defrosting season, and therefore we do not know if they were emplaced while the aprons were covered in frost. However, other observations suggest that the activity occurs primarily during the defrosting season (Dundas et al. 2019), meaning it is not unreasonable to assume that the deposits are commonly mobilised over a frosted surface. The only notable exception is for linear gullies, where frost is still present in the alcoves (generally) when activity occurs (Fig. 14E; Dinwiddie and Titus 2021; Jouannic et al., 2012; 2019; Pasquon et al., 2016). We note that for gullies on sand dunes, discrete scars in the sandy alcoves are often associated with activity (e.g., Pasquon et al., 2019b), yet in gullies with bedrock alcoves, none of the observed activities had detectable erosion of the wall rock in the alcoves (Dundas et al. 2012; 2019). This lack of erosion, could mean that CO<sub>2</sub> related processes are not responsible for the formation

520 of the whole gully landform or could simply reflect that the temporal baseline of observation is not long  
521 enough to detect erosion into these presumably more durable materials (Levin et al. 2022).

#### 4.2 Dark spots and flows as an indicator of recent gully activity

43

 64  
 65

We observe that boulders, rough surfaces inside channels and on the aprons of gullies, and contrasts in surface type (e.g. the edge of a dune field) are preferential locations for dark spots (and sometimes dark flows) (Figs. 8-10). Boulders have been noted previously as initiation points for dark spots and fans (Thomas et al. 2010). In this context, our observed strong spatial correlation between the appearance of dark spots/flows and surface roughness could be explained by the following hypotheses:

- 1) Surface roughness, in particular non-homogenous thermal inertia, should cause spatial heterogeneities in the temperature field of the substrate and thus also in the sublimation of the

1  
2 545 ice layer. More gas may be produced on the sun-facing side of a boulder, for example, causing  
3 preferential pressure build-up at that location, as warmer surfaces defrost faster.

4 547 2) Surface roughness (e.g. boulders or levees), in particular gradients in normal stresses caused by  
5  
6 548 variable overburden thicknesses or densities, could cause bending moments and mechanical  
7  
8 549 weakness in the overlying CO<sub>2</sub> ice slab. This would pre-condition that location for failure when  
9  
10  
11 550 the gas pressure builds up.

12  
13 551 3) Both of the aforementioned factors could be at play.

14  
15 552 The fact that surface roughness promotes more numerous dark spots and flows can be combined with  
16  
17 553 the fact that recently active gullies tend to have rougher surfaces (Dundas et al. 2019). For this reason  
18  
19 554 they could assist in detecting recently active sites without the need for repeat imaging. Repeat images  
20  
21  
22 555 could then be targeted at this zone as active sites are often repeatedly active.

23  
24 556 We now interrogate what role is played by the dark/spots flows in gully activity. Surface  
25  
26 557 modification events in gullies in Sisyphi Cavi are less frequent compared to gullies on sand dunes or  
27  
28 558 sandy surfaces on Mars, which are generally active annually (e.g. Dundas et al., 2012; 2015; 2020;  
29  
30 Pasquon et al., 2019b). Activity of gullies on dunes is accompanied by a similar sequence of defrosting  
31  
32 559 patterns to those we report for Sisyphi Cavi, including the appearance of dark spots followed by their  
33  
34 560 transformation into dark flows as the surface warms (Jouannic et al., 2012; 2019). The activity of gullies  
35  
36 561 occurs generally during the final stages of defrosting. The frequency of activity on Sisyphi Cavi is  
37  
38 562 comparable and consistent with gullies on non-sandy surfaces e.g., crater walls (Dundas et al., 2019),  
39  
40 563 but in contrast observations of dark spots and flows are rather rare in these systems. For both areas  
41  
42 564 studied in detail in Sisyphi Cavi (areas C and D at 68°S; 1.3°E) only 2 out of 33 gullies are active  
43  
44 565 between MY28 and MY35 (Raack et al., 2015; 2020). One gully on area C is active and just once over  
45  
46 566 a period of 8 MY. Only one gully is active in area D in MYs 29 and 31. So, material movement in these  
47  
48 567 two areas seems to be relatively sparse. The disconnect between the widespread presence and annual  
49  
50 568 occurrence of dark spots and dark flows and the low spatial and temporal frequency of activity in gullies  
51  
52 569 might suggests that dark spots and dark flows are not a primary agent in triggering gully activity. .  
53  
54 570  
55  
56 571

57  
58 571  
59  
60 572 **5. Conclusion**

1  
2 574 In this paper we explored the process of defrosting in gully-incised slopes in Sisyphi Cavi. We explored  
3  
4 575 the sequence, timing, and duration of events that occur during seasonal defrost, and their connection to  
5  
6 576 gully and dark spot/dark flow activity. We find that the general timing and characteristics of the seasonal  
7  
8 577 defrosting patterns in Sisyphi Cavi are very consistent from year to year, and similar to the general trend  
9  
10 578 observed at a global scale for the seasonal frost deposits. Our observations show that the absolute timing  
11  
12 579 of the different stages of the defrosting sequence is influenced by the overall orientation of the host  
13  
14 580 hillslope, with equator-facing slopes generally defrosting earlier than the pole-facing ones. Gully alcoves  
15  
16 581 defrost first before channels and aprons and independently of orientation. This is unexpected because  
17  
18 582 based on incoming solar radiation the defrosting should progress from the top of equator-facing slope  
19  
20 583 down towards the flat floor and up the pole-facing slope, terminating at the top. We argue that this could  
21  
22 584 be due to the dominant effect of contrasting substrates between alcove (rocky materials) and aprons  
23  
24 585 (finer unconsolidated materials) over the role of solar insolation and orientation during the early stages  
25  
26 586 of defrost. We also observe that gullies defrost later than their surrounding terrain, with some frost  
27  
28 587 patches remaining in the interior of channels and alcoves at the end of defrosting, likely due to  
29  
30 shadowing.

31  
32  
33 588 We also find that dark spots and flows concentrate in areas of increased surface roughness. This  
34  
35 589 suggests that gully activity, which creates surface roughness via contrasts in material types, deposition  
36  
37 590 of boulders levees and lobes and erosion to form braiding, can facilitate the appearance of dark spots  
38  
39 591 and dark flows over the affected area the following winter. We therefore infer that dark spots and dark  
40  
41 592 flows could be used to help to detect recently active gullies on Mars without repeat imaging, but they  
42  
43 593 themselves are not a precursor to gully activity.

44  
45  
46 594 Finally, we note that a prerequisite for gully activity in Sisyphi Cavi is a frosted apron surface. We show  
47  
48 595 that such a configuration is found in gully-sites elsewhere on Mars, raising the possibility that this is a  
49  
50 596 common precursor for gully activity, where seasonal frost is present. We note that this type of activity  
51  
52 597 is not associated with detectable erosion of the wall rock in the alcoves, which could mean erosion by  
53  
54 598 CO<sub>2</sub> related process is too small to be detectable in these durable materials or that another process is  
55  
56 599 responsible for the initial formation of gullies.  
57

## 6. Acknowledgments

We'd like to thank Ginny Gulick and Aditya Khuller whose detailed and helpful reviews increased the quality of the manuscript. The HiRISE data used in this study can be accessed from the Planetary Data System <https://pds-imaging.jpl.nasa.gov/volumes/mro.html> or at or the PI website at <https://www.uahirise.org/> and the CaSSIS data can be accessed via the PSA at <https://archives.esac.esa.int> or the PI website at <https://observations.cassis.unibe.ch/>. The authors are grateful for the financial support from Région Pays de la Loire, project étoiles montantes METAFLOWS (convention N° 2019-14294) and also the financial support of CNES in support of their CaSSIS work. The authors thank the spacecraft and instrument engineering teams for the successful completion and operation of CaSSIS. CaSSIS is a project of the University of Bern funded through the Swiss Space Office via ESA's PRODEX programme. The instrument hardware development was also supported by the Italian Space Agency (ASI) (ASI-INAF agreement no. I/018/12/0), INAF/ Astronomical Observatory of Padova, and the Space Research Center (CBK) in Warsaw. Support from SGF (Budapest), the University of Arizona (LPL) and NASA are also gratefully acknowledged. Operations support from the UK Space Agency under grant ST/R003025/1 is also acknowledged. SRL is supported by UK Space Agency grants ST/W002949/1, ST/V005332/1, and ST/T002913/1. Thanks goes to Valentin Bickel and Candy Hansen for informal comments that improved the manuscript.

## Supplementary material

Supplementary Table S1: CaSSIS and HiRISE images used for this study for the 3 sites 1) 68.5°S and 1.3°E (Fig. 1B), 2) 70.92°S and 1.2°E (Fig. 1C) and 3) 69.4°S and 347°E (Fig. 1D). x = image covers the area/site indicated. Ls = Solar Longitude. MY= martian year.
