Key Points:

- Radiance simulations can help characterize two essential inputs of climate services, satellite data records and reanalyses
- Uncertainties in observations collected by the Spektrometer Interferometer-1 flown on a Soviet satellite in 1979 were estimated
- Radiance simulations of satellite instruments can provide information on the quality and realism of climate reanalyses

30 **Abstract**

31 Climate services are largely supported by climate reanalyses and by satellite Fundamental
32 (Climate) Data Records (F(C)DRs). This paper demonstrates how the development and the
33 uptake of F(C)DR benefit from radiance simulations, using reanalyses and radiative transfer
34 models. We identify three classes of applications, with examples for each application class. The
35 first application is to validate assumptions during F(C)DR development. Hereto we show the
36 value of applying advanced quality controls to geostationary European (Meteosat) images. We
37 also show the value of a cloud mask to study the spatio-temporal coherence of the impact of the
38 Mount Pinatubo volcanic eruption between Advanced Very High Resolution Radiometer
39 (AVHRR) and the High-resolution Infrared Radiation Sounder (HIRS) data. The second
40 application is to assess the coherence between reanalyses and observations. Hereto we show the
41 capability of reanalyses to reconstruct spectra observed by the Spektrometer Interferometer (SI-
42 1) flown on a Soviet satellite in 1979. We also present a first attempt to estimate the random
43 uncertainties from this instrument. Finally, we investigate how advanced bias correction can help
44 to improve the coherence between reanalysis and Nimbus-3 Medium-Resolution Infrared
45 Radiometer (MRIR) in 1969. The third application is to inform F(C)DR users about particular
46 quality aspects. We show how simulations can help to make a better-informed use of the
47 corresponding F(C)DR, taking as examples the Nimbus-7 Scanning Multichannel Microwave
48 Radiometer (SMMR), the Meteosat Second Generation imager, and the DMSP Special Sensor
49 Microwave Water Vapor Profiler (SSM/T-2).

50 **1 Introduction**

51 Recognizing increased inter-relations between human activities, impacts, and evolving
52 climate phenomena, the World Climate Conference-3 (WCC-3, 2009a) fostered a substantial
53 expansion and enhancement of climate services worldwide. Although several World
54 Meteorological Organization (WMO) members already operated climate services before 2009,
55 this conference was a milestone in the establishment of the Global Framework for Climate
56 Services (GFCS). In coordination with several other organizations, including the United Nations
57 Educational, Scientific and Cultural Organization (UNESCO), the United Nations Environment
58 Programme (UNEP), the Food and Agriculture Organization of the United Nations (FAO), and
59 the International Council for Science (ICSU), the GFCS was established to complement and
60 support the work of the Intergovernmental Panel on Climate Change (IPCC) and the United
61 Nations Framework Convention on Climate Change (UNFCCC) (WCC-3, 2009b).

62 More than ten years later, climate services have evolved beyond the scope of classical
63 climatology. Moving on from the classical form of climate means, compiled and served to the
64 public by national weather agencies, climate activities today embrace a bundle of relationships
65 and exchanges between the climate data and actors and societal applications (e.g., Brasseur &
66 Gallardo, 2016). Furthermore, environmental observations are no longer the exclusive remit of
67 selected public agencies: observations are now collected, assembled, curated, and served by a
68 variety of actors including, e.g., space agencies, universities, research programs and
69 organizations involved in environmental monitoring, but also associative or private initiatives,
70 and structural elements such as cloud-computing platforms (e.g., Thorpe & Rogers, 2018). These
71 actors operate alongside traditional national weather agencies that remain, in most cases,
72 ultimately responsible for key properties of climate data record monitoring (Mahon et al., 2019).

73 Climate monitoring is only one component of climate services (World Meteorological
74 Organization (WMO), 2018). Other components, of which some of them are related to
75 monitoring, include climate reanalyses, climate indicators and indices, longer-term forecast
76 elements that include predictions and projections, and attribution of climate phenomena. This last
77 component is crucial to understand the causes of, and later better project or predict, selected
78 climate phenomena and their impacts, and develop relevant mitigation or adaptation measures.
79 Enabled by methods such as developed by Hasselmann (1997), attribution is a preliminary step
80 before further climate adaptation or mitigation measures may be taken. Attribution is also called
81 to play a role in the UNFCCC Warsaw International Mechanism (WIM) to deal with loss and
82 damage due to climate change (Parker et al., 2015). Beyond this, without an underlying
83 understanding of the causes of important climate phenomena (such as ‘extremes’) and their inter-
84 relations with human activities, the risks run high of counter-productive societal measures that
85 can worsen the issues at stake (e.g., Schipper, 2020).

86 Even if climate services are not limited to climate monitoring and the corresponding
87 preparation and provision of observation-based Climate Data Records (CDRs), these data records
88 remain the necessary physical basis for all other components of the climate services. As such,
89 observation-based products underpin the outcomes of IPCC’s First Working Group that
90 examines the physical science of climate change (Masson-Delmotte et al., 2021). Similarly,
91 observations are often depicted at the onset of the weather and climate value chain (e.g., Ruti et
92 al., 2020).

93 The present paper focuses on a method to accelerate the development and uptake of
94 satellite-based CDRs. These are optimally based on satellite sensor data in the form of
95 Fundamental Climate Data Records (FCDRs), or else on Fundamental Data Records (FDRs),
96 also referred to as Sensor Data Records (SDRs) (Privette et al., 2023). Hereafter we evaluate the
97 quality of F(C)DRs by comparing them with simulated observations. While the use of
98 simulations to survey the quality of satellite-based observations and products over the long-term
99 is not a novelty (e.g., Jackson & Soden, 2007; Newman et al., 2020), their use to support the
100 CDR development is rather recent.

101 The outline of this paper is as follows. Section 2 presents the data and methodology.
102 Sections 3 to 5 showcase three different classes of applications, namely, Class-I: validating
103 assumptions (section 3), Class-II: assessing coherence between observations and reanalyses
104 (section 4), and Class-III: informing users (section 5). Section 6 discusses the results. Finally,
105 section 7 presents conclusions and prospects for future work.

106 **2 Data and methodology**

107 Satellite observations considered in this paper come from several instruments. The
108 radiative transfer simulations use reanalysis fields as input, and provide in return brightness
109 temperatures (or reflectances), for microwave channels and visible, near-infrared, shortwave
110 infrared, and thermal infrared channels. The differences between the observations and
111 simulations are hereafter called departures. The methods and data used in the paper are presented
112 below.

113 **2.1 Radiative transfer simulations**

114 Since the early days of satellite meteorology, the accurate and faithful numerical
115 simulation of satellite measurements has been a topic of research and active development (e.g.,

116 Gordon, 1962). From early on, the simulation methods for radiative transfer have involved a mix
117 of exact solutions and numerical methods (e.g., Hunt & Grant, 1969; Rodgers & Walshaw,
118 1963). A representation of the so-called direct (or forward) model is an essential tool to exploit
119 the measurements and map the signals into useful information (e.g., Rodgers, 1990). Also, by
120 allowing physical quantities to be estimated from the measurements, such as inversion or
121 retrieval process (e.g., Stephens, 1994), any improvement to the forward models further helps to
122 enhance the understanding of the observed natural phenomena (e.g., Houborg & McCabe, 2016).

123 Simulations of satellite observations have proven to bring about additional benefits, in
124 line with the continuous development in Earth sciences. This is an iterative process where the
125 lessons learnt from the confrontation of simulation results with actual observations enhance our
126 understanding of important effects affecting the quality the observations, thereby allowing to
127 repeat the data processing or simulations with improved algorithms, or to improve future
128 instrument design. This was shown, in particular, for the physical interactions between the
129 observed phenomena and the measurement process (e.g., Bell et al., 2010; John & Buehler, 2004;
130 Joiner & Poli, 2005). These iterative improvements enable researchers to continue extracting
131 ever-increasing value from these observations for societal applications, such as Numerical
132 Weather Prediction (NWP) (e.g., Shahabadi et al., 2018). Furthermore, such enhanced
133 understanding also helps to refine the design of new-generation instruments or data records. This
134 allows, for example, better understanding instrument ageing processes (e.g., Munro et al., 2016;
135 Quast et al., 2019), detecting the impact of imperfections that were previously thought negligible
136 (e.g., Lu & Bell, 2014), or releasing new versions of the data records that correct for observation
137 sampling effects (e.g., Mears & Wentz, 2017). Another benefit is to enhance our understanding
138 of discrepancies between models and observations, especially for data assimilation, whose remit
139 is to exploit these differences to extract information, even when a bias correction procedure is
140 necessary (e.g., Joiner & Rokke, 2000). On longer timescales, quantifying discrepancies between
141 models and observations can also help pinpoint effects that are important to consider in models,
142 such as anthropogenic effects (e.g., De Vrese & Hagemann, 2018).

143 Alongside all these applications sits also research towards using novel technology
144 instruments (e.g., Doutriaux-Boucher et al., 1998) or to revisit early satellite data records (e.g.,
145 Poli et al., 2017). However, climate research presents several distinct challenges when it comes
146 to observation data simulators. First, the time-series covered by climate model and by related
147 satellite-based CDR products are necessarily long. This makes running a full data assimilation
148 system (with underpinning Earth-system models and covering many observation types) an overly
149 computationally-expensive and inadequate venture. This is also partly unnecessary in the face of
150 the efforts already deployed by large modelling centres to create model-gridded global decadal
151 datasets, such as reanalyses, which gradually widen their remits to exploit (and hence simulate)
152 an increasing diversity of satellite-based data records. Secondly, the variety of observation data
153 that are available exceeds the variety of data encountered in a single data assimilation window
154 that covers a few hours of a given date. Furthermore, a thorough and relevant assessment of
155 reprocessed satellite data mandates to use state-of-the-art simulators that can be applied to the
156 latest versions of the data records quickly. This timing is not compatible with the planning of
157 reanalyses productions, which take years to prepare and execute. Finally, such assessments
158 require efficient and traceable simulation tools, while maintaining a strong link to community-
159 driven efforts that continually improve such simulation tools, based on the latest science (e.g.,
160 Swales et al., 2018).

161 Owing to these specificities, data simulators can be beneficial in at least three different
162 points of the climate value chain. The first possibility is to use them during the F(C)DR
163 development phase, to validate the assumptions made. A second possibility is to use them after
164 the production of a F(C)DR, but before data release, to assess the realism and coherence between
165 a new F(C)DR and state-of-the-art Earth system reanalyses. A third possibility is post-
166 production, even possibly after a F(C)DR release, to inform the data users about likely sources of
167 variability present in the data (e.g., natural variability versus instrumental or sampling artefacts).
168 These represent many feed-back opportunities. Note this paper does not discuss the issue of
169 using simulators as integral part of the F(C)DR production chain.

170 All these potential benefits have contributed to the development of a standalone
171 RADiance SIMulator (RADSIM) (Hocking, 2022), able to simulate all the satellite sensors
172 supported by the Radiative Transfer for Television Infrared Orbiting Satellite (TIROS)
173 Operational Vertical Sounder (TOVS) (RTTOV, Saunders et al., 2018). It must be recalled that
174 both elements, RADSIM and RTTOV, benefit from a long-term support of the EUMETSAT
175 climate services and development plan, with activities distributed between the EUMETSAT
176 central facility and its Satellite Applications Facility (SAF) network, including the NWP-SAF,
177 for these simulators. The results shown in this manuscript build on an implementation of
178 RADSIM and RTTOV in the EUMETSAT infrastructure, with massively parallel computations
179 carried out on a multi-node cluster computing system.

180 In the present study, we use RADSIM interfaced with RTTOV version 13.0, except for
181 simulating data from the Medium-Resolution Infrared Radiometer (MRIR) where we used
182 RTTOV version 12.2. Additional details about the radiance simulation configuration are given in
183 Supplement Text S1.

184 2.2 Reanalysis data

185 Reanalyses are used for their ability to provide temporally and spatially complete fields
186 of key atmospheric properties. Several global comprehensive reanalyses of the atmosphere have
187 been produced in the recent past. The following are considered in the present work, cited in the
188 order they were released: ERA-Interim (Dee et al., 2011; ECMWF, 2009), JRA-55 (Shinya
189 Kobayashi et al., 2015; Japan Meteorological Agency, 2013), ERA-20C (Poli et al., 2016;
190 ECMWF, 2014), ERA5 (Hersbach et al., 2020; Copernicus Climate Change Service, 2018), and
191 JRA-3Q (S. Kobayashi et al., 2021; Japan Meteorological Agency, 2022). Among these, only
192 ERA5 provides hourly analyses. For all others, the radiative transfer simulator uses 6-hourly
193 analyses. The reanalyses are used at $0.5^\circ \times 0.5^\circ$ (latitude, longitude) horizontal resolution, except
194 for MRIR simulations that used ERA5 data at $1^\circ \times 1^\circ$ resolution. The geophysical parameters
195 include temperature, humidity, and ozone (for all available model levels), as well as near-surface
196 wind speed, temperature, and humidity, and surface air pressure, surface geopotential, skin
197 temperature, land-sea mask, and sea-ice cover. The reanalysis cloud and precipitation
198 information is not used in the simulations.

199 2.3 Satellite data

200 This work uses data records from 8 different satellite instruments:

- 201 • Meteosat Visible Infra-Red Imager (MVISI), flown on Meteosat First Generation (MFG)
202 satellites, Meteosat-2 to -7 (EUMETSAT, 2020),

- 203 • Spinning Enhanced Visible and InfraRed Imager (SEVIRI), flown on Meteosat Second
204 Generation (MSG) satellites, Meteosat-8 to -11 (EUMETSAT, 2015)
- 205 • Medium-Resolution Infrared Radiometer (MRIR), flown on several TIROS and Nimbus
206 satellites, noting that this study only uses data collected by Nimbus-3 (McCulloch, 2014),
- 207 • Spektrometer Interferometer (SI-1), flown on Soviet weather satellites Meteor-28 and -
208 29, noting that this study only uses data collected by Meteor-29 (Poli et al., 2023),
- 209 • High-resolution Infrared Radiation Sounder (HIRS), flown on NOAA Polar Operational
210 Environmental Satellites (POES) TIROS/N, NOAA-6 to -19 and EUMETSAT polar-
211 orbiting satellites, Metop-A and -B (EUMETSAT, 2022),
- 212 • Advanced Very High Resolution Radiometer (AVHRR) flown on the same satellites as
213 HIRS as well as Metop-C (EUMETSAT, 2023),
- 214 • Scanning Multichannel Microwave Radiometer (SMMR), flown on satellites Seasat and
215 Nimbus-7, noting that this study only uses data collected by Nimbus-7 (Fennig et al.,
216 2017),
- 217 • Special Sensor Microwave Water Vapor Profiler (SSM/T-2), flown on U.S. DMSP
218 satellites F-11, -12, -14, and -15 (EUMETSAT, 2021).

219 The first 2 instruments are visible and infrared imagers on geostationary satellites, the
220 next 4 are visible and/or infrared imagers or infrared sounders on polar-orbiting satellites, and
221 the last 2 are microwave radiometers on polar-orbiting satellites. Several instruments are
222 historical sensors, given their early data record.

223 While it would take too long to expand all details of these instruments, as well as their
224 detailed configurations, Table 1 provides a summary of some of their key characteristics. Other
225 references, such as the WMO Observing Systems Capability Analysis and Review tool
226 (OSCAR) Space database (<https://space.oscar.wmo.int>), provide further information for these
227 instruments. Additional instrument information is given later, as relevant, when presenting the
228 simulation applications.

229 Table 1 indicates if the data records have been used in one way or another in global
230 reanalysis, indicating here the situation only for the data sources assimilated in ERA5 (Hersbach
231 et al., 2020), because it is the only reanalysis used for all comparisons. There are several cases of
232 indirect data use in ERA5, as indicated in Table 1. There are only three cases of direct
233 assimilation of the radiance data considered in the present study into ERA5 (Hersbach et al.,
234 2020): (1) MVIRI after 2001, (2) SEVIRI, and (3) HIRS.

235

Sensor	Years of operation	IFOV size ^b	Scanning pattern	Nb. of channels (wavelengths or frequencies)	DOI ^c
MVIRI a *	1977-2017	4.5 km	Earth disc, every 30 minutes	2 (6.4, 11.5 μm) ^d	10.15770/EUM_SEC_CLM_0009
SEVIRI a * +	2002-2023	3 km	Earth disc, every 15 minutes	8 (3.9—13.4 μm) ^d	10.15770/EUM_SEC_CLM_0008

236 **Table 1.** Overview of selected characteristics for instruments considered in the present study.
237 Several instruments still operate at the time of writing. +Radiance data from this instrument
238 were assimilated in ERA5. *Radiance data from this instrument were indirectly used in ERA5, as
239 follows, *via* assimilation of atmospheric motion vector (MVIRI, SEVIRI, AVHRR), or as input
240 to the sea-surface temperature forcing (AVHRR) or the sea-ice forcing (SMMR). §The
241 information given here pertains only to Nimbus-3. ^aMore information about this instrument is
242 accessible from WMO OSCAR at <https://space.oscar.wmo.int>. ^bInstantaneous Field-Of-View
243 (IFOV), at the sub-satellite point. ^cDigital Object Identifier (DOI) for the data used in the present
244 work, accessible at <https://doi.org/<DOI>>. ^dVisible channels from this instrument are not
245 simulated in the present work. ^eThis is the DOI reserved for future publication of the entire data
246 record, noting that the subset of data used in the present work are available from
247 DOI:10.5281/zenodo.7912742. ^fExcept for HIRS/4 (10 km), noting also HIRS on Nimbus-6 is
248 not covered here. ^gNote that AVHRR Global Area Coverage (GAC) data used in the present
249 work present a lower resolution.

250 Taking note of this inter-relation between reanalysis and the radiance data records, the
251 following remediation steps are taken. (1) For MVIRI we only show results before the date when
252 MVIRI radiances started being assimilated in ERA5. (2) For SEVIRI we do not simply consider
253 departures (differences between observed radiances and simulations), but consider how they vary
254 by changing the simulation setup. (3) For HIRS we do not consider the departures alone but
255 along with AVHRR, and we also exploit the departures at a time-scale for which we believe
256 there is independence between the satellite data record and the reanalysis.

257 2.4 Quality controls

258 2.4.1 Observations

259 Observations with missing geolocation, brightness temperatures, or reflectances (in the
260 case of AVHRR visible and near-infrared channels) are excluded from further analysis. In
261 addition, specific quality controls are applied to the data records of each instrument, using the
262 information available. For completeness, the details are reported in Supplement Text S1.

263 2.4.2 Simulations

264 The performance of radiative transfer simulations can be degraded in several situations.
265 These are indicated in this sub-section, along with measures to mitigate these degradations.

266 Performance degradation of the simulations may occur in situations of Non-Local
267 Thermal Equilibrium (NLTE) if this effect is not specifically accounted for. Such degradations,
268 which arise during daytime in modelling short-wave infrared channels, are excluded from the
269 analysis; for the corresponding HIRS, AVHRR, and SEVIRI channels (with wavelengths in the
270 region 3—4 μm), we follow a conservative approach, retaining only cases when the sun is below
271 the horizon by at least 10 degrees. Similarly, the performance of RTTOV may be degraded for
272 situations of specular reflections. Consequently, in the AVHRR visible and near-infrared
273 channels simulations, cases in which the sun is low on the horizon are discarded from the
274 analysis (we retain only cases when the sun is above the horizon by more than 10 degrees).

275 The performance of radiative transfer simulations is also degraded when the presence of
276 clouds (infrared and visible) or precipitating clouds (microwave) is not accounted for. As all
277 simulations are carried out assuming clear sky conditions, we need to apply a filtering to exclude
278 cloudy situations (infrared and visible) or precipitating clouds (microwave). For simplicity, we
279 use the generic term ‘cloud mask’ in all cases, even if there are distinct differences in the
280 implementations. These implementations are described now.

281 In the absence of a single cloud mask for all instruments at all dates and times, the cloud
282 filtering approach depends on the instrument. The presence of clouds and/or precipitation is
283 filtered in three cases in this study.

284 In the first case, a cloud mask is available for the instrument’s data record. This applies to
285 AVHRR (Karlsson et al., 2023), MVIRI (Stöckli et al., 2019), SEVIRI (EUMETSAT, 2015), and
286 SSM/T-2 (EUMETSAT, 2021). In the case of SSM/T-2, the cloud mask uses information
287 retrieved from SSM/I observations by the EUMETSAT Climate Monitoring SAF (CM-SAF)
288 (Andersson et al., 2017), albeit only available over oceans.

289 In the second case, the availability of a window channel (i.e., a channel affected only
290 weakly by atmospheric absorption) enables use of the departure window method check, similar
291 to the approach typically employed by data assimilation (Krzeminski et al., 2009). In this
292 method, a departure outside a predefined range is indicative of the presence of cloud. This
293 method works better over ocean than over land, affected by greater uncertainties in sea-surface
294 temperature and emissivity, and is applied over ocean region for filtering out clouds from SI-1
295 observations. The range of allowed window channel departures is set to $[-2 \text{ K}, 3 \text{ K}]$, as the SI-1
296 instrument operated before the well-observed satellite era, and when the quality of reanalyses is
297 known to be poorer (e.g., Bell et al., 2021). The SI-1 channels considered for this check are
298 between 882 cm^{-1} and 916 cm^{-1} .

299 In the third case, when neither of the two approaches above is applicable, but the effects
300 of clouds or rain need to be filtered out, we devise proxy criteria to identify pixels affected by
301 these situations. These criteria are presented afterwards, for MRIR and SMMR.

302 Additional details on the application of the cloud masks are presented in the relevant
303 sections hereafter as relevant.

304 2.5 Departure analysis

305 The general philosophy for analyzing the results is to follow the split-apply-combine
306 method (Wickham, 2011), preceded by the quality control steps mentioned previously. Hereafter,
307 we consider two statistics of the departures (observations minus simulations): the mean (noted μ)
308 and the standard deviation (noted σ). Both quantities are in K for brightness temperatures, or in
309 % for reflectances (for visible or near-infrared channels).

310 3 Class-I applications: Validating an assumption

311 When developing a dataset or an application, it is common to be faced with the issue of
312 validating an assumption used in the methodology. The assumption could, for example, relate to
313 the data themselves, or how to use them. However, a common difficulty is the impracticality of
314 proving the assumption. One can then revert to demonstrating that the assumption is not violated,
315 based on the evidence available. If the results obtained violate the assumptions, then the
316 assumption is proven wrong. If they do not, then the assumption cannot be rejected, and is hence
317 considered to remain valid.

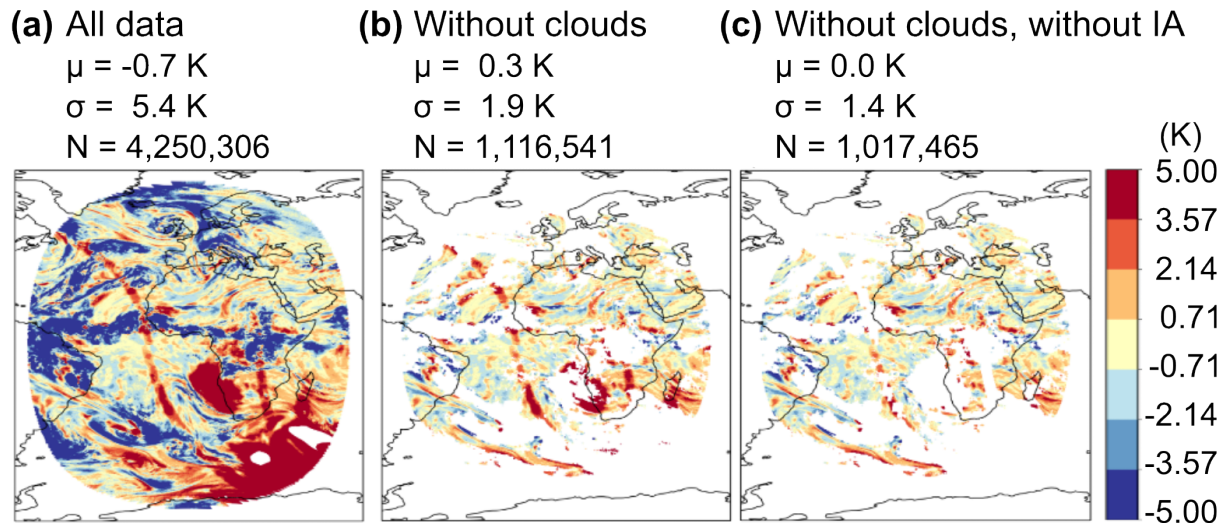

318 3.1 Advanced image quality control, example with Meteosat geostationary imagers

319 The Meteosat First Generation (MFG) satellites started the first series of continuous
320 imaging over Africa and Europe (e.g., De Jong, 1978). The resulting images brought about new
321 understanding of the weather patterns, but also uncovered a number of challenges for image
322 processing that were unforeseen when the instruments were designed. The analysis of the
323 resulting data record is impacted by so-called “image anomalies” (IA), which, for example, lead
324 to under- or over-estimation of the radiance at the scene. This term is to be understood distinctly
325 from its climate counterpart, where an anomaly is defined as the difference of a quantity with
326 respect to some climatology. In the case of instrument operations, IA refers to an unexpected
327 behavior that would cause improper interpretation of the image. As there is no reason to expect
328 that such effects should cancel out, it is important to identify data affected by instrument issues,
329 to avoid introducing spurious signals into long-term series. Several IA issues were not foreseen
330 when the MVIRI instrument was initially designed. Methodologies to detect geostationary IA
331 were developed over the years (e.g., Liefhebber et al., 2020) and cover a wide range of
332 situations, from simple cases of complete image data corruption to more complex situations of
333 regional over-illumination.

334 If these image anomalies are correctly detected, masking out such problematic areas or
335 images should lead to an improved agreement between images and other sources of information,
336 such as radiative transfer from simulations. We verify this here in Figure 1 for a randomly picked
337 date (1996-10-16) among dates when images anomalies were detected, from the MFG data
338 record of Meteosat-5. Figure 1(a) shows a map of all the departures before any cloud or image
339 anomaly filtering. Figure 1(b) shows the results after applying a cloud mask (Stöckli et al.,
340 2019). It can be seen that cloud masking improves the agreement between observations and

341 simulations significantly, by reducing the standard deviation of differences over the full image
 342 from 5.4 K to 1.9 K and by bringing the mean of differences closer to zero, from -0.7 K to 0.3 K.
 343 Figure 1(c) shows the results after filtering out scenes affected by an IA. In this case, the IA
 344 filtered out is direct stray light and over-illumination as defined by Liefhebber et al. (2020). The
 345 results indicate that this reduces the data count over the entire image by around 10%, but the
 346 agreement between observations and simulations is improved, with a standard deviation of
 347 differences reduced from 1.9 K to 1.4 K, and a mean reduced to near-zero.

348 In summary, the radiative transfer simulations help us validate the assumption that an
 349 advanced image quality control should improve exploitation of the MVIRI data record.

350

351 **Figure 1.** Maps of differences (in K) between observations and radiative transfer simulations
 352 using ERA5 for Meteosat-5 MVIRI water vapor channel, 1996-10-16 00 UTC: (a) all data, (b)
 353 results after excluding scenes believed to be cloudy, and (c) results after excluding in addition
 354 the scenes affected by image anomaly (IA). Overall statistics are reported at the top.

355 3.2 Cloud mask, example with HIRS and AVHRR

356 An important objective of the assessment of the quality of satellite data records is to
 357 determine the quality of representation of climate time-scales. Such decadal products are of
 358 interest to users to study possibly small-scale variations over a long timeframe. There is a wide
 359 body of literature on data assessment (e.g., National Research Council (U.S.), 2004). However,
 360 from infra-red sounders and imagers, most retrievals schemes are restricted to clear-scenes only.
 361 For this reason, cloud mask validation is important.

362 Such activities are already performed routinely by cloud mask data producers. We show
 363 an example of how radiative transfer simulations can further assist in this fashion. To this end,
 364 we consider the infra-red and visible data records of two polar-orbiting instruments, the AVHRR
 365 and HIRS instruments, operated both on NOAA and EUMETSAT polar-orbiting satellites, and
 366 compare with clear-sky radiative transfer simulations.

367 The effects of clouds and aerosols are not included in the radiative transfer simulations
 368 considered here. Consequently, a large disagreement is expected around and after the time of the

369 volcanic eruptions that generated considerable amounts of aerosols in the atmosphere. However,
370 the effects of volcanic eruptions alone may not necessarily stand out because of other effects,
371 such as spatial variability and clouds (ignored in the simulations). For this reason, we focus the
372 evaluation on small geographical regions, to avoid potential issues of large-scale
373 inhomogeneities within the region. The regions are as defined in the IPCC 6th Assessment Report
374 (Iturbide et al., 2020).

375 Figure 2 shows, for the Equatorial Pacific Ocean region, the results of differences for the
376 mode of differences (maximum of the departure distribution within a month) between
377 observations and clear-sky radiative transfer simulations. The results are shown without any
378 prior filtering for clouds. To obtain these timeseries, we first construct monthly histograms of
379 departures, for each satellite and each channel, with a resolution of 0.1 K for brightness
380 temperatures (HIRS and AVHRR infra-red channels) and of 0.1 % for reflectance (AVHRR
381 near-infrared channel). For each histogram, we then estimate the mode of the distribution.
382 Finally, we look on either side of the peak for values that delimit the 88% of the peak maximum.
383 This allows us to quantify a peak width, which would approximate the standard deviation of
384 departures if the distributions were normal. This metric is shown with bars around the mode.

385 We present here window channels, (respectively) HIRS channel 8 (thermal infrared at
386 11.1 μm), HIRS channel 18 (shortwave infrared at 4.0 μm), and AVHRR channel 4 (thermal
387 infrared at 11.0 μm). For these channels, the departures generally feature negative biases, as
388 expected, owing to the presence of clouds. Figure 2(a,b,c) shows the agreement between these
389 observations and ERA5 improves from 1991 onwards, thanks to Sea-Surface Temperature
390 information of high quality obtained from the well-calibrated sensors (Advanced) Along Track
391 Scanning Radiometer ((A)ATSR) on European Remote Sensing satellites ERS-1/2 (and Envisat),
392 as well as subsequent sensors, such as the Sea and Land Surface Temperature Radiometer
393 (SLSTR) on Sentinel-3. For the AVHRR near-infrared channel 2, the departures in Figure 2(d)
394 are generally within 0.5 %, except for some satellite-dependent and volcanic eruptions episodes
395 indicated by dashed vertical lines.

396 If the cloud mask is correct, we expect that its application would yield departures that are
397 possibly closer to zero, depending on the reanalysis intrinsic biases, but also with a reduced
398 standard deviation. Figure 3 shows this is indeed the case. Outside the volcanic eruption events,
399 the standard deviations of departures (height of individual bars) are reduced from 0.6-0.8 K to
400 0.4-0.6 K. The modes of departures for the HIRS channel 8 in Figure 3(a) feature a declining
401 trend in the 1980s, not seen with the channels shown in Figure 3(b,c). If the root cause of the
402 trend was only with a trend in biases in the reanalysis (ERA5) used for the simulations, then a
403 similar behavior would show on the other channels, too, but it is not the case. This would suggest
404 that the recalibration of HIRS channel 8 may benefit from further refinements. Note the effects
405 of volcanic eruptions stand out in all timeseries.

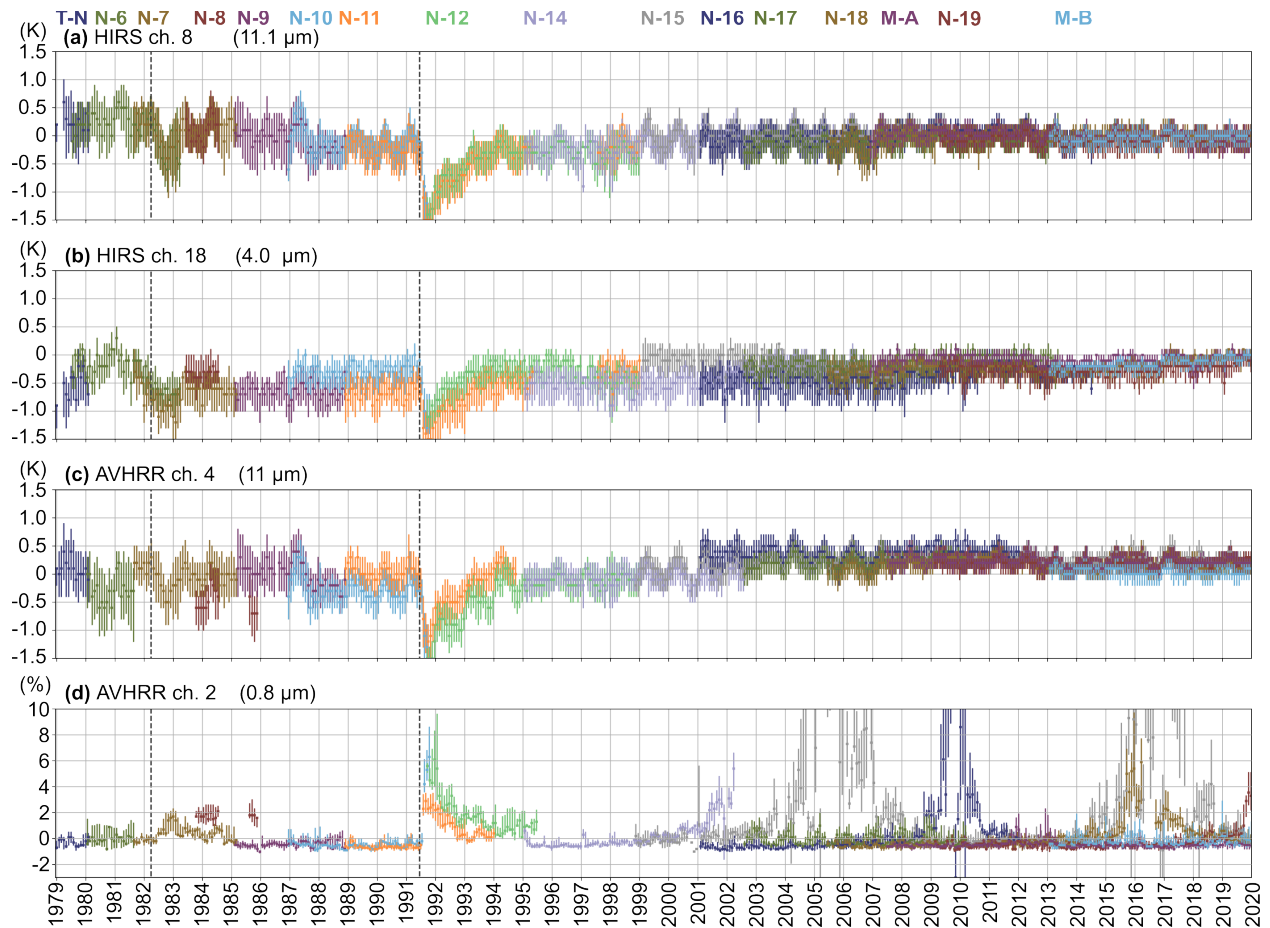

406 The relevance of a cloud mask needing not to be demonstrated further, we now
407 investigate the departures around the time of the Mount Pinatubo eruption in more details. The
408 use of AVHRR to monitor volcanic ash is well-established (e.g., Watkin, 2003). For all the
409 window channels, increased negative departures are observed in Figures 2 and 3 panels (a)-(c)
410 around the time of the El Chichon and Pinatubo eruptions, as expected, with aerosols scattering
411 radiation and emitting radiation from above the surface (hence at a colder temperature). For
412 Pinatubo, the cooling anomaly in terms of brightness temperatures is on the order of 1 K, for

413 short-wave and thermal channels alike, although the signatures differ somewhat between
414 channels.

415 For the AVHRR near-infrared channel 2 (0.8 μm), reflectance departures are positive for
416 2 to 3 years after the event, between 2 and 5%, in Figure 2(d). This is also as expected, due to
417 scattering caused by the aerosols (and not simulated here). Unfortunately, the combination of
418 rejection of high solar zenith angles with the selection of only clear scenes leads to discard most
419 of the data for AVHRR channel 2, resulting in the prevalent absence of results for clear-scene
420 reflectances in Figure 3(d). We now turn to the spatial variability of this global event, by
421 considering other IPCC regions.

422 Zooming in over a shorter time period (December 1990 – January 1994), Figure 4 shows
423 that the plume of aerosols took several months to propagate away from its origin in South-East
424 Asia. Considering the minimum observed in brightness temperature departures by the infrared
425 window channels (rows (a) to (c)), the effect of the eruption was most pronounced over the
426 Tropical Indian Ocean 3 months after the eruption (column (i)), and then over the Tropical
427 Pacific 4 to 5 months after the eruption (column (ii)), and again later in the southern latitudes (6
428 to 8 months, columns (iii),(iv)), with a further delay in the Mediterranean (up to a year, column
429 (v)). Considering the maximum observed in reflectance departures by the near-infrared channel,
430 the effect of the eruption was most pronounced over the Tropical Indian Ocean, and was felt in
431 southern latitudes 2 to 3 months later, or in the Mediterranean 5 to 6 months later. The effects of
432 this eruption were analyzed in detail previously (Stenchikov et al., 1998). However, the results
433 shown here quantify the relevance of this episode with respect to the HIRS and AVHRR data
434 records.

435 To summarize, this example validates the hypothesis that the CLARA-A3 cloud mask
436 can help to a) filter out cloudy scenes, and b) quantify the radiative effects of the Mount Pinatubo
437 eruption in the HIRS and AVHRR data records, with a separation between regional and temporal
438 variations, at the wavelengths covered by the channels selected here.

439

440 **Figure 2.** Monthly departures (modes as squares \pm vertical bars to indicate spread estimates, see
 441 text) between HIRS, AVHRR and clear-sky radiative transfer simulations using ERA5, for the
 442 Equatorial Pacific Ocean region, between 1979 and 2020. Note two important volcanic
 443 eruptions: El Chichon (Mexico, 1982) and Mount Pinatubo (Philippines, 1991), with onsets
 444 indicated by vertical lines. Departures are shown for brightness temperatures (in K) for three
 445 infrared channels (a-c), and for reflectances (in %) for one visible channel (d). There is one color
 446 per satellite (from left to right, see top: T-N: TIROS-N, N-6 to N-19: NOAA-6 to -19, M-A and
 447 M-B: Metop-A and Metop-B).

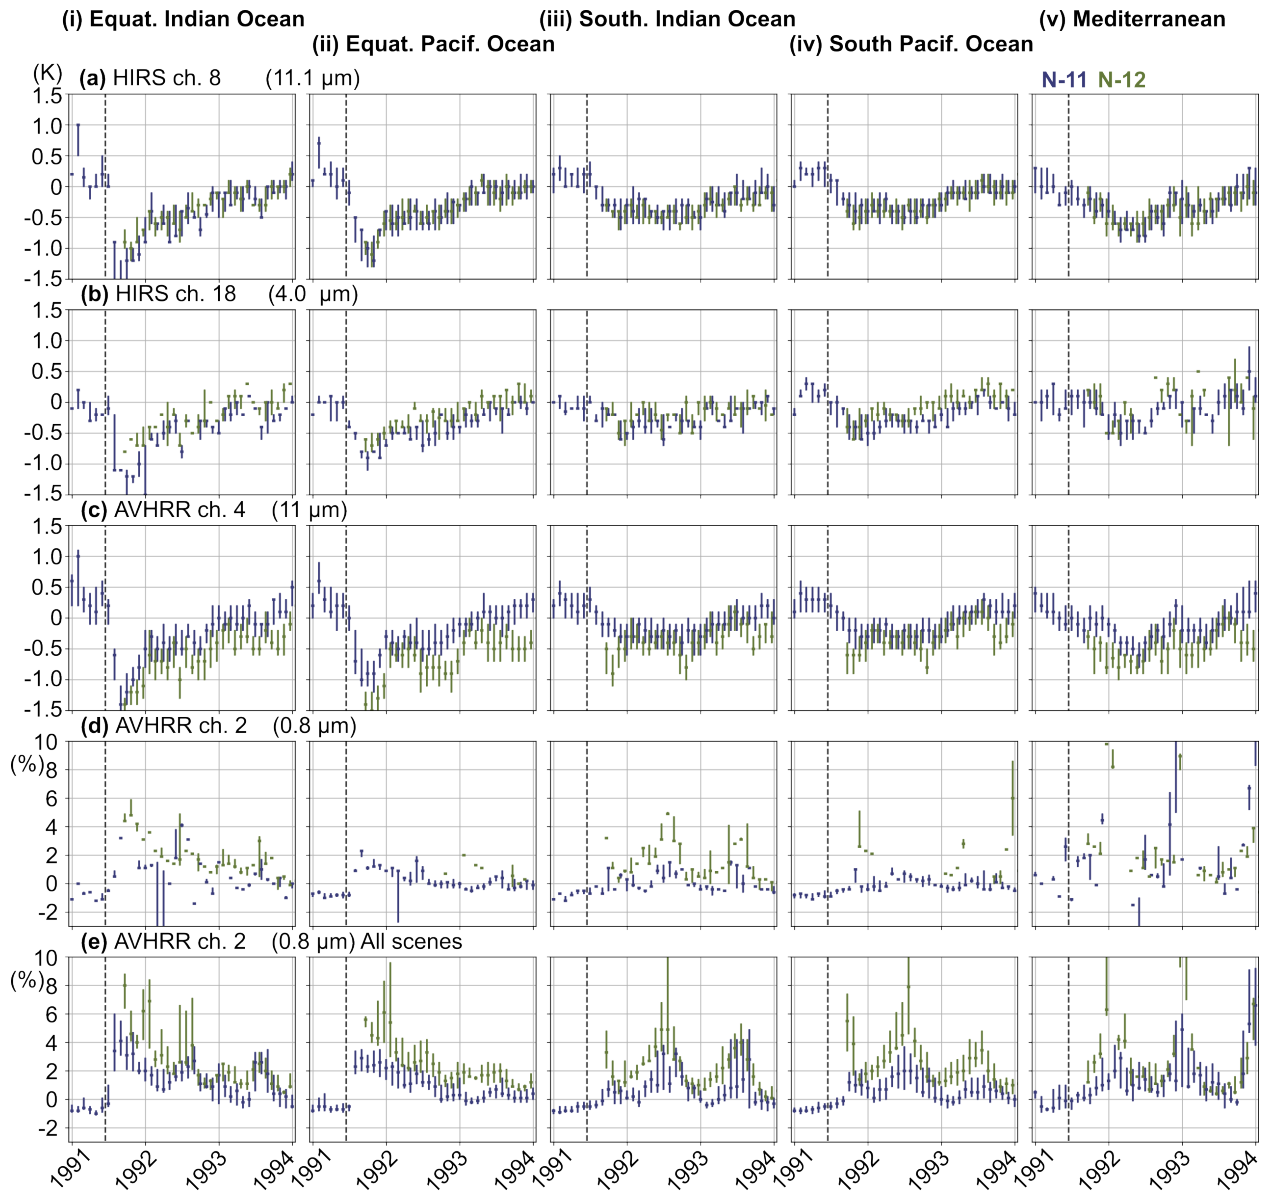

448

449

450

Figure 3. Similar to the previous figure, but restricting to scenes that are clear according to the cloud mask.

451

452

453 **Figure 4.** Similar to the previous figure, but showing several IPCC regions (see top, columns (i)
 454 to (v) from left to right) and zooming in on a time period starting six months before the Mount
 455 Pinatubo eruption (timing indicated by a vertical dotted line) and ending approximately 2.5 years
 456 after it. Note row (e) shows similar information as row (d) but for all scenes (i.e., without
 457 application of the cloud mask). There is one color per satellite (see top right, N-11 and N-12 for
 458 NOAA-11 and -12).

459 4 Class-II applications: Assessing coherence between reanalyses and observations**460 4.1 Synoptic timescales coherence, example with SI-1**

461 The SI-1 instrument was a Michelson interferometer developed in the former German
462 Democratic Republic, pursuing similar scientific objectives as the Infrared Interferometer
463 Spectrometer (IRIS) instruments on-board Nimbus satellites covering the wavenumber range
464 from 400 cm^{-1} to 1600 cm^{-1} (Hanel et al., 1970, 1972). The first IRIS instrument was launched a
465 few years earlier than the SI-1 instrument. More particularly, the SI-1 instrument was designed
466 to allow identification of atmospheric constituents, clouds, as well as temperature sounding
467 (Kempe, 1980; Kempe et al., 1980) as well as planetary exploration, as a similar instrument was
468 deployed in the atmosphere of Venus (Oertel et al., 1985).

469 Most of the 579-channel data record from this instrument has been rescued by
470 EUMETSAT (Théodore et al., 2015), and the comprehensive data record is being prepared for
471 public data release with support from the European Union Copernicus Climate Change Service
472 (C3S) at the time of writing. Figure 5 shows the spectral range covered by the instrument, and
473 the vertical sensitivity of the channels to atmospheric information. The SI-1 instruments operated
474 discontinuously in time and the resulting data record is too sparse to support consistent data
475 assimilation in a global reanalysis. However, high-resolution spectral features are potentially
476 useful to better understand subtle changes in the climate (e.g., Brindley & Bantges, 2016).

477

478 **Figure 5.** SI-1 wavelengths (top horizontal axis), wavenumbers (bottom horizontal axis), and
 479 RTTOV channel numbers (from left to right, in increments of 20). Each bar shows, horizontally,
 480 the nominal spectral resolution, and, vertically (bottom and top) the 5th to 95th percentiles
 481 (respectively) of the integrated weighting function, to help visualize where most of the
 482 atmospheric information comes from, for each channel, assuming clear-sky radiative transfer.
 483 Colors indicate the simulated brightness temperatures (in K, see scale). Calculations carried out
 484 from ERA5 data for a profile in the Spring over the Atlantic at the location (30°N, 30°W).

485 Another potential application of the SI-1 brightness temperatures is to use these to
 486 validate different reanalyses. We show an example here by considering a subset of the data
 487 record. Figure 6(a,b) shows the comparison of brightness temperature between observations and
 488 different reanalyses, for data at wavenumbers 400—1200 cm^{-1} collected by Meteor-29 over sea
 489 during the month of February 1979, for scenes to be believed free of clouds (123 spectra in
 490 total). The two panels separate between spectra that feature sharp departures (spikes) at
 491 wavenumbers 840—860 cm^{-1} and 765—810 cm^{-1} , across all reanalyses considered here. The
 492 reanalyses are ERA5, ERA-20C, JRA-55, and a preliminary version of the JRA-3Q reanalysis (a
 493 newer reanalysis as compared to JRA-55). For a fair comparison of the results, the ERA5
 494 reanalysis profiles are considered every 6-hours, with a validity time window of ± 3 hours, like
 495 the other reanalyses (hourly ERA5 profiles at non-synoptic hours are ignored). The lower panels
 496 in Figure 6 show these departures. In a given column, the use of the same color across plots
 497 enables to appreciate that some degree of agreement exists sometimes between the reanalyses.

498 Considering all the spectra shown in Figure 6, Figure 7(a) shows mean differences
 499 between SI-1 brightness temperatures and the reanalyses. The standard deviations of departures
 500 are shown in Figure 7(b). The dotted lines in these figures show statistics of departures between

501 observations and simulations in radiance space, converted from difference radiance to equivalent
502 difference brightness temperature at a nominal temperature of 280 K. Small differences with
503 brightness temperature statistics are mostly visible where the brightness temperatures vary
504 notably from this nominal temperature (see Figure 5), i.e., for the top-peaking channels in the
505 middle of the 1041 cm^{-1} ozone absorption line or 667 cm^{-1} CO_2 absorption line, both sensitive to
506 stratospheric temperatures. In this region, we find an agreement around $0.7\text{--}0.8\text{ K}$ in terms of
507 equivalent difference brightness temperature (at 280 K) standard deviation.

508 Spikes are believed to be due to improper assumptions for trace gas concentrations in
509 1979 in our simulations. This is the case in particular near 845 cm^{-1} , an absorption line of
510 trichlorofluoromethane, also known as CFC-11 (e.g., Harrison, 2018). Similarly, a bulge in
511 standard deviations is visible between 765 and 810 cm^{-1} . Zenith absorption spectra, such as
512 reported in the Atmospheric Infrared Spectrum Atlas (King & Dudhia, 2017), indicate strong
513 absorption features near 775 cm^{-1} (COF_2), 780 cm^{-1} and 810 cm^{-1} (ClONO_2), 785 cm^{-1} (CClF_3 ,
514 also known as CFC-13), 795 cm^{-1} (CCl_4), 810 cm^{-1} (CHClF_2 , also known as HCFC-22), and
515 $780\text{--}805\text{ cm}^{-1}$ (peroxyacetyl nitrate, $\text{CH}_3\text{C}(\text{O})\text{OONO}_2$, also known as PAN). All these
516 chemical constituents have seen large changes in concentrations over past decades owing to
517 industrial emissions. Differences between present-day concentrations and those actually present
518 in 1979 may be responsible for the departures reported here. Additional radiative transfer
519 simulations, varying the absorber amounts, would help support investigations of such an
520 hypothesis.

521 If the quality of JRA-3Q reanalysis improved as compared to the prior JRA-55 reanalysis,
522 one would expect to see a better agreement with the simulations. The JRA-3Q improvements
523 relative to JRA-55 in stratospheric ozone and stratospheric temperatures are clearly visible in
524 Figure 7(a,b) around wavenumber 1041 cm^{-1} (sensitivity to stratospheric temperature and ozone)
525 and wavenumber 667 cm^{-1} (sensitivity to stratospheric temperature). The standard deviations of
526 departures in the region $600\text{--}700\text{ cm}^{-1}$ in Figure 7(b) also show that ERA-20C is an outlier, as
527 compared to the other reanalyses, in terms of its fit to stratospheric-peaking channels located
528 near the center of the line.

529 Having noticed in Figure 6 that spectral departures are sometimes similar across
530 reanalyses, we apply similar concepts as those that underlie common uncertainty diagnostics
531 (Desroziers et al., 2005). Assuming that all random uncertainties are independent from one
532 another, we can estimate random uncertainties (see Supplement Text S2). Figure 7(c) shows the
533 combined random uncertainties in the observations and radiative transfer (or representativeness),
534 with a floor level in the range $0.8\text{--}1.0\text{ K}$ for most channels between 600 cm^{-1} and 1200 cm^{-1} .
535 We interpret spectral sharp departures above that floor level as deficiencies in the radiative
536 transfer assumptions (e.g., incorrect absorber concentration, which yields departures that are
537 correlated across all reanalyses, even though departures differ between different profile locations
538 and dates and times).

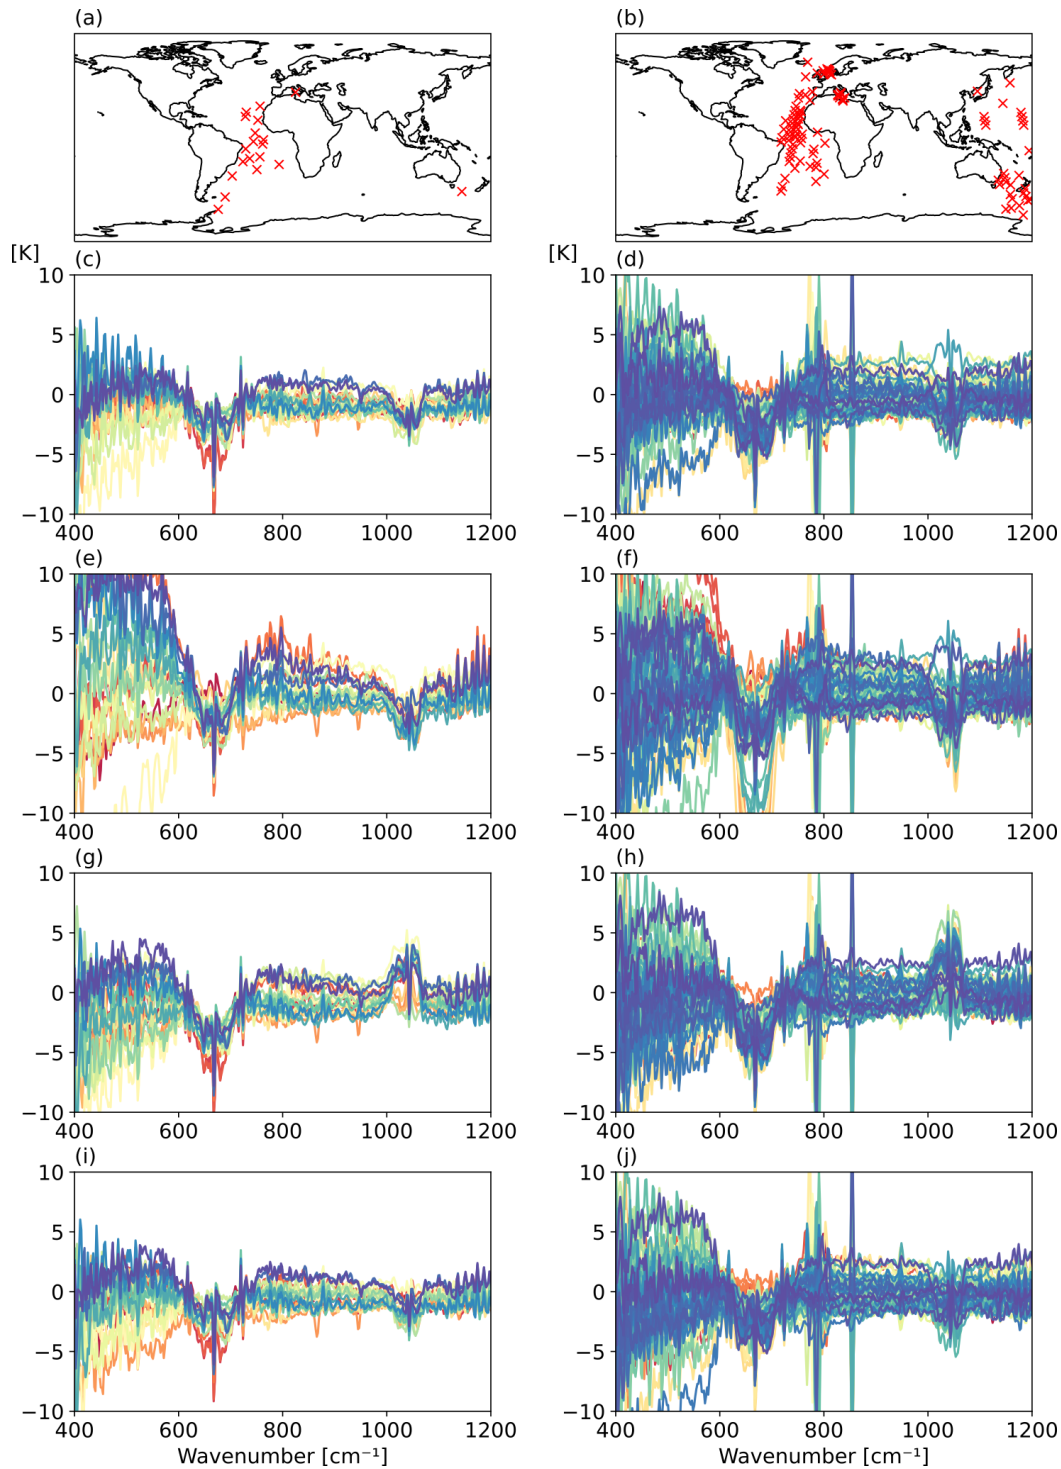

539 Going from high to low wavenumbers, we observe an increase of the combined random
540 uncertainties in the observations and radiative transfer (or representativeness). One may postulate
541 that this increase is related to instrument noise. However, our random uncertainty estimation
542 method does not separate between random instrument noise and random uncertainties in the
543 radiative transfer model. Consequently, it could also be that the radiative transfer model is
544 deficient in this region of the spectrum. There is indeed far less experience with observations of
545 this far-infrared region of the spectrum than at wavenumbers in the range $650\text{--}1600\text{ cm}^{-1}$. This

546 situation should improve in future years with the Far-infrared Outgoing Radiation Understanding
547 and Monitoring (FORUM) (Pachot et al., 2021). The FORUM instrument will indeed cover the
548 spectral range between 100 and 1600 cm^{-1} (wavelengths between 6.2 and 100 μm) at 0.3 cm^{-1} of
549 spectral sampling (5001 spectral elements).

550 Regarding the reanalyses, the estimates of random uncertainties are marked with crosses
551 when the sum of squared uncertainties does not match the observed departure variance within a
552 margin of 1% (this only occurs for some wavenumbers, in the region 620—750 cm^{-1}). Overall,
553 we note that in most cases the findings agree with the considerations above, i.e. the expectation
554 that the ERA-20C reanalysis contains much less pertinent information in terms of thermal
555 vertical structure than the other reanalyses shown here, and that JRA-3Q made significant
556 improvements regarding stratospheric representation quality as compared to JRA-55.

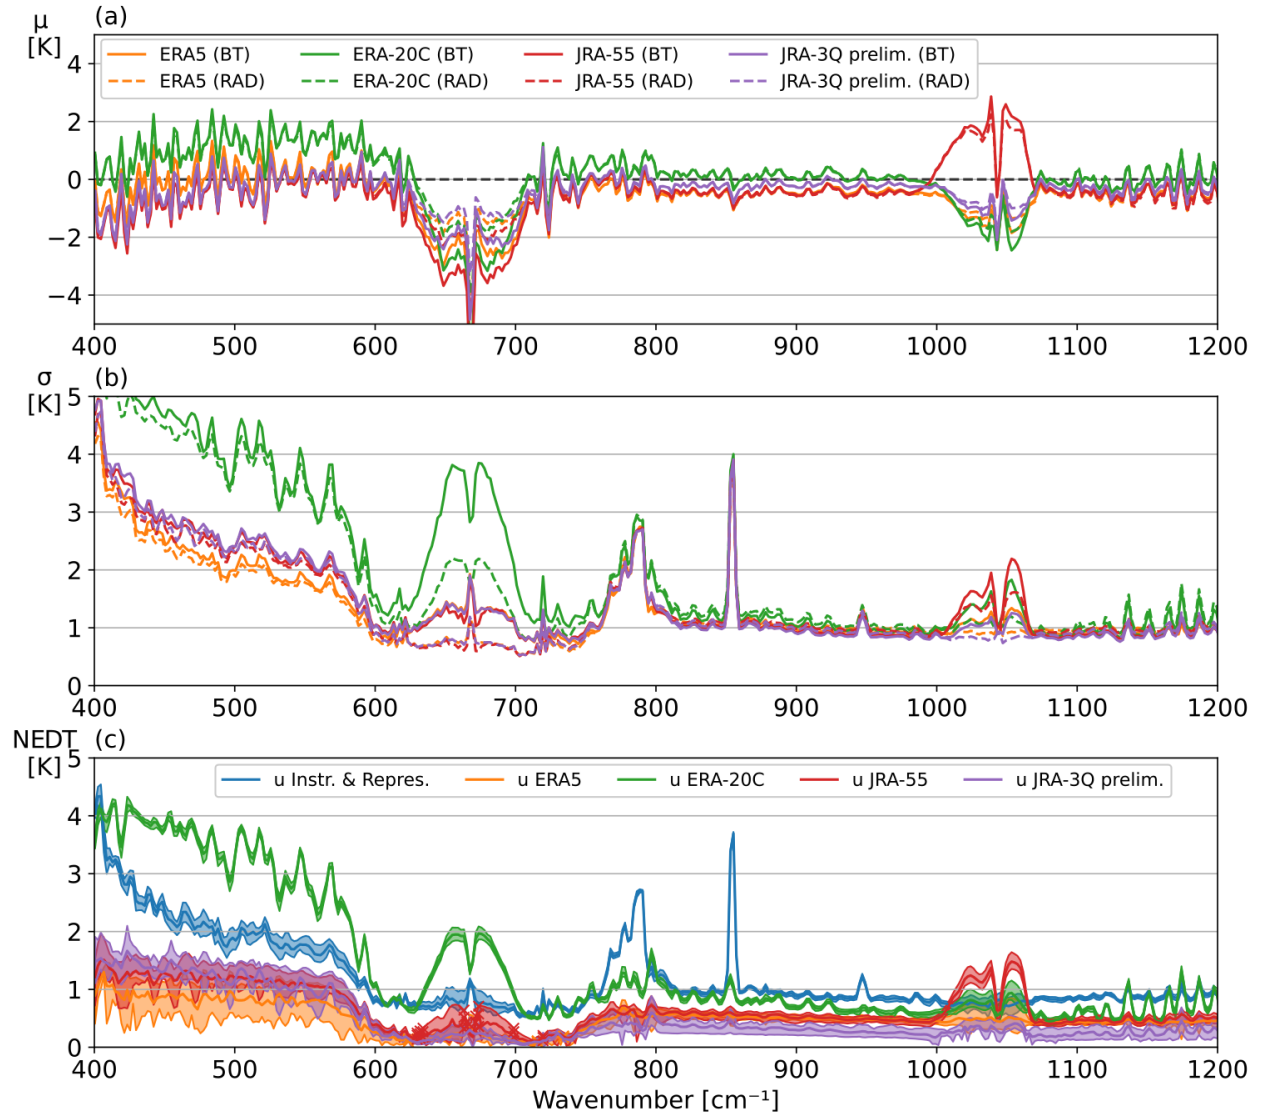

557 An important caveat of our method is the assumption of independence of random
558 uncertainties, i.e., that cross-correlations between different uncertainty sources are zero. This
559 may not be the case for a number of reasons, explained in the Supplement Text S2. In particular,
560 the small spread between reanalyses may not reflect the true uncertainty but rather that these
561 reanalyses share common uncertainties. For this reason, we believe that departures from this
562 assumption are responsible for the very low level of random uncertainties (sometimes under 0.5
563 K) found for reanalyses. Conversely, some the uncertainties attributed to observations and
564 radiative transfer (blue curve in Figure 7(d)) may actually come from uncertainties that are
565 shared across the reanalyses, and hence may be over-estimated. Overall, we acknowledge that
566 our method is not perfect but it still provides some initial insight into the uncertainties, which is a
567 first for data collected by this early interferometer.

568 To summarize, this example illustrates how a high spectral resolution record, even when
569 it is only short, can assist to measure progress in reanalyses.

570

571 **Figure 6.** (a) Map of 19 Meteor-29 SI-1 observations in February 1979 without significant
 572 spectral spikes in regions 840—860 cm⁻¹ and 765—810 cm⁻¹, and (b) map of 104 other Meteor-
 573 29 SI-1 observations presenting such spectral features. Bottom plots show corresponding
 574 differences in brightness temperature between observations and simulations, using (c,d) ERA5;
 575 (e,f) ERA-20C; (g,h) JRA-55; (i,j) a preliminary version of JRA-3Q.

576

577 **Figure 7.** Departure (a) means (μ) and (b) standard deviations (σ) of Brightness Temperature
 578 (BT) differences between 123 Meteor-29 SI-1 spectra shown in the previous figure and
 579 corresponding radiative transfer simulations using ERA5, ERA-20C, JRA-55, and a preliminary
 580 version of JRA-3Q (see legend). Dotted lines show similar statistics but based on radiance
 581 (RAD) differences, converted from difference radiance to difference brightness temperature at a
 582 nominal temperature of 280 K. Bottom plot (c) shows estimates of random uncertainties (u),
 583 separating between each reanalysis random uncertainty, and combined observation and
 584 representativeness random uncertainty (see legend, and refer to text for details).

585 4.2 Understanding differences via bias correction linear predictors, example with MRIR

586 Bias correction methods aim at removing low-frequency variability in differences
 587 between observations and models, believed to be caused by systematic errors, for example, in the
 588 radiative transfer model or the instrument calibration (e.g., Dee & Uppala, 2009). In data
 589 assimilation, where radiance simulations are based on atmospheric profiles provided by a
 590 background, the methodology for such bias correction is now well-established. The bias is

591 modelled as a linear combination of a set of predictors. Based on linear regression models, i.e.,
592 one of many methods used in machine learning (e.g., Mitchell, 1997), bias corrections are thus
593 effective tools to understand patterns of differences between observations and simulations.

594 For the infrared channels of the MRIR instrument, we investigate here the performance of
595 extending the predictor set to include parameters believed to be at least in part related to
596 instrument error. This analysis is restricted to daytime and ocean data only. Observations of the
597 visible channel of MRIR are used to screen clouds, by excluding observations with an albedo
598 greater than 0.1.

599 We compare the bias correction performances of three different bias predictor sets. The
600 first predictor set is similar to that used in ERA-Interim and ERA5. This set includes four air
601 mass predictors, in the form of geopotential layer thicknesses (1000—300 hPa, 200—50 hPa,
602 10—1 hPa, and 50—5 hPa). One notes that corrections related to air mass are unlikely to be
603 instrument-related, and may more closely relate to errors in the simulations (i.e., reanalysis in the
604 present case). This predictor set also includes an offset, as well as the satellite viewing angle and
605 its squared and cubed values. These four additional predictors are all expected to capture
606 instrument and simulation errors, although noting the cubed value may capture foremost
607 simulation errors. Note, the viewing angle is a parameter which may partly absorb calibration
608 errors (e.g., Buehler et al., 2005).

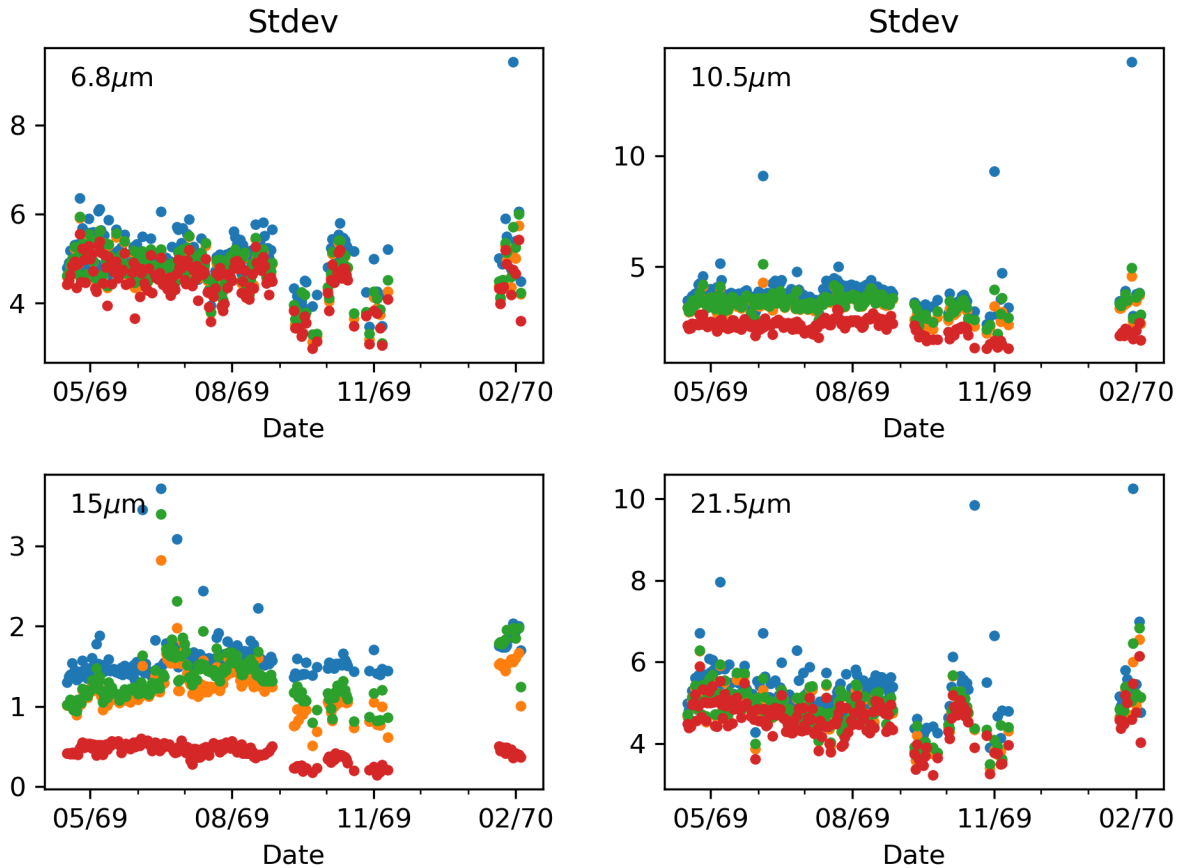

609 The second predictor set is the so-called instrument predictor set. It excludes some of the
610 predictors mentioned above that are believed to capture mostly simulation errors (layer
611 thicknesses and satellite viewing angle cubed). However, it adds scene brightness temperature
612 and instrument internal temperature. These two additional predictors are introduced to account
613 for instrument errors due to uncertainties in gain and non-linearity effects, and instrument-
614 temperature-related errors (respectively). Note, the scene brightness temperature is also expected
615 to absorb some of the simulation errors.

616 Finally, the third predictor set considered combines all predictors of the first and second
617 predictor sets.

618 Figure 8 shows the effects of applying the three bias predictor sets. The metric that is
619 chosen for this assessment is the standard deviation of the Nimbus-3 MRIR departures (σ). The
620 mean departures, not shown, are reduced to near-zero in all cases, by design of the bias
621 correction. The figure shows results without bias correction (blue), after applying the ECMWF
622 predictor set (orange), the instrument predictor set (green), and the combined predictor set (red).
623 As might be expected, all bias-corrected results fare better than the uncorrected case. In addition,
624 the ECMWF and instrument predictor sets have similar impacts. The combined predictor set
625 performs best of all. Especially for 10.5 μm and 15 μm channels there are significant
626 improvements to the standard deviations (note the factor two improvement for the 15 μm
627 channel). This indicates that both simulation and observation errors are significant. This also
628 suggests that further studies of instrument-related departures should provide useful insights into
629 the state of the instrument calibration.

630 In the case of the MRIR it is difficult to go beyond the bias correction models shown in
631 Figure 8 as we lack the low level telemetry data (Level 0 data) that are needed to correct for
632 instrument calibration errors at source.

633 In summary, this example shows that improvements may be made for MRIR to the bias
 634 correction models generally used in data assimilation, by considering likely instrument sources
 635 of uncertainties.

636

637 **Figure 8.** Time-series of daily Nimbus-3 (1969-1970) MRIR departure standard deviations (σ , in
 638 K), for four different channels, without bias correction (blue dots), and with different bias
 639 correction schemes applied: ECMWF predictor set (orange dots), instrument predictor set (green
 640 dots) and combined predictor set (red dots). See text for details.

641 5 Class-III applications: Informing users

642 5.1 Unexplained observation variability, example with SMMR

643 The microwave radiometer SMMR was a pioneering instrument for several fields in the
 644 Earth sciences. Two flight models were launched in 1978. The satellite carrying the first SMMR
 645 unit, Seasat, malfunctioned a few months after launch. The second SMMR unit, on Nimbus-7,
 646 operated for nearly 9 years, until August 1987. It offers an overlap, albeit limited, with the SSM/I
 647 (from July 1987). This particular time period is often looked at to enable inter-calibration of the
 648 two instruments' data records (e.g., Dai et al., 2015).

649 The SMMR instrument collected measurements at five microwave frequencies and two
 650 polarizations (vertical and horizontal). The complexities of this instrument and the resulting data

651 record stem from the use of six radiometers to monitor ten channels. This prevented continuous
652 monitoring of all ten channels for all footprints. Instead, the instrument used four radiometers to
653 monitor the lower frequencies (6.6 GHz, 10.7 GHz, 18 GHz, and 21 GHz), by alternating
654 polarization at each half-scan, while two other radiometers continuously monitored the 37 GHz
655 frequency, at vertical and horizontal polarizations. However, most physical retrieval schemes
656 were devised assuming data available from all channels. For this reason, the data processing
657 includes a re-sampling of the data to cover all footprints.

658 NASA carried out the first and only full SMMR reprocessing within the Pathfinder
659 project that was completed in the late 1990s (Njoku, 2003). This reprocessing included
660 corrections for antenna pattern and polarization mixing. The reprocessing also revisited
661 important components of the processing and applied lessons learnt from the mission. This effort
662 also unveiled new elements to address, such as a sharp change in Nimbus-7 spacecraft attitude in
663 1984, unaccounted for in this first reprocessing, as this issue was detected afterwards.

664 The CM-SAF (Fennig et al., 2017) further attempted to reprocess the SMMR data.
665 However, they could not start from the original low-level sensor data, as these data could not be
666 located at the time. This means that several of the benefits expected from a full reprocessing
667 could not be realized.

668 In this section, the reprocessed SMMR data from the CM-SAF are compared against
669 radiative transfer simulations from two reanalyses, ERA-Interim and ERA5. Figure 9 shows that
670 all frequencies present mean departures that are similar for ERA-Interim and ERA5, on the
671 monthly timescales shown here, for the horizontal polarization. The data counts differ from
672 ERA-Interim and ERA5 as approximately 4 times more data are being assessed in the case of
673 ERA5 (hourly) than in the case of ERA-Interim (six-hourly).

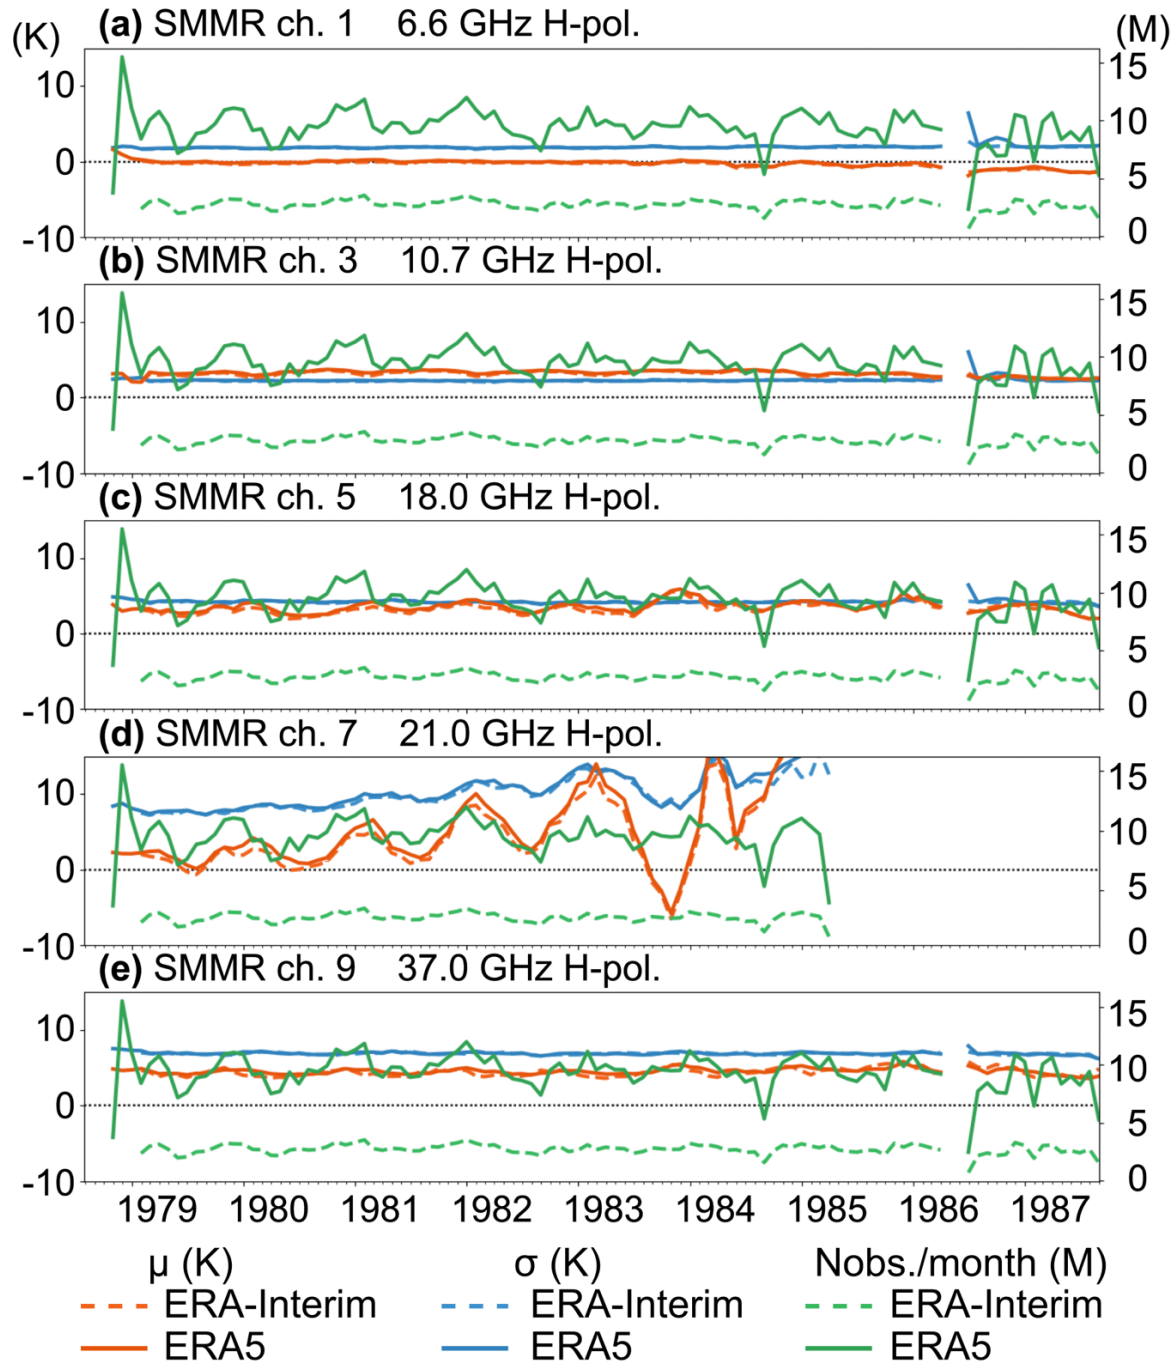

674 Over oceans, SMMR data with rainy situations are excluded by checking distributions of
675 departures (heuristic approach). Observations are considered rainy if the difference between
676 horizontally polarized channels 37 GHz minus 18 GHz is outside the range [30 K, 50 K], if the
677 difference between horizontally polarized channels 6.6 GHz minus 10.7 GHz is outside the range
678 [-15 K, -5 K], if the polarization difference (vertical minus horizontal) at 37 GHz is less than 35
679 K, or if the brightness temperature at 18 GHz (6.6 GHz), horizontal polarization, exceeds 160 K
680 (95 K, respectively). Data over land are not further analyzed here.

681 Figure 9(d) indicates spurious oscillations in the mean departures with respect to both
682 reanalyses, before the 21 GHz radiometer (channel 9) failed in 1985. The magnitude of these
683 oscillations grows over time, as well as the standard deviations of departures. Until such a
684 behavior can be explained, these features can be interpreted as symptoms of a degradation over
685 time of the horizontally-polarized 21 GHz channel.

686 During a Special Operations Period (SOP) that lasted from 3 April to 6 June 1986, the
687 SMMR instrument was operated in a different mode. Instead of functioning every other day, the
688 instrument was switched on and off more frequently, up to several times per day. The statistics
689 indicate that it took some time after the SOP for the instrument to recover to its pre-SOP status.
690 The exact cause for this behavior is unknown, but is suspected to be related to the SOP. The
691 observed degradation is reported by Njoku (2003) to have lasted “during and for some time after
692 the Special Operations Period”. This element is apparent for all channels as shown in Figure 9.
693 The difference in statistics before and after the SOP is indeed evident for most channels shown.
694 This points to a change in the calibration performance of the instrument after the 1986 SOP. In

695 other terms, the data collected in 1987 may not be taken as representative of the instrument
696 performance beforehand. Yet, the data from 1987 remain important as they are compared with
697 SSM/I in order to inter-calibrate both records, as indicated above.

698 To summarize, we find issues of channel performance degradation, large oscillating
699 biases, and changes in calibration performance after the 1986 SOP. This information is
700 potentially important information for users interested in climate applications. These issues are
701 however difficult to address at the level of retrieval into geophysical quantities. This would
702 rather need addressing with a new recalibration and reprocessing activity.

703

704 **Figure 9.** Time-series of monthly mean departures (μ , orange) and standard deviations (σ , blue)
 705 between SMMR brightness temperatures and simulations using 6-hourly ERA-Interim and
 706 hourly ERA5 fields (see legend), for horizontally-polarized channels at frequencies (a) 6.6 GHz,
 707 (b) 10.7 GHz, (c) 18.0 GHz, (d) 21.0 GHz, and (e) 37.0 GHz, in K (left-hand-side vertical axis).
 708 The data counts per month (green) are reported (in millions, M) on the right-hand-side vertical
 709 axis.

710 5.2 Explained observation variability, example with MSG

711 The SEVIRI instruments on-board MSG satellites extend the data records started by
712 MVIRI instruments on-board MFG satellites for the 3 heritage channels, i.e., the water vapor,
713 infrared, and visible channels. Furthermore, SEVIRI includes 6 additional channels in the
714 infrared region as compared to MVIRI. When the MFG and MSG satellites are positioned near
715 0-degree longitude, the field of view of the instruments covers Africa and Europe. Thus, the
716 observed radiances of these satellites allow patterns of variability to be inferred over areas with
717 important societal applications (e.g., Barbosa et al., 2019; Harrison et al., 2019).

718 Satellites in geostationary orbit are subject to small displacements around their nominal
719 positions around the Equator. These satellites are affected by gravity pulls from the Earth and the
720 Moon. This so called three-body system, or Lissajous track, results in figure-of-eight
721 displacements (e.g., Hubert & Swale, 1984). In addition, geostationary satellites may see
722 displacements during their lifetime when the nominal longitude changes. This section shows the
723 importance for climate applications of these displacements (even if seemingly small), through an
724 analysis of subsequent satellite data records that appear as originating from a single longitude
725 position at the Equator.

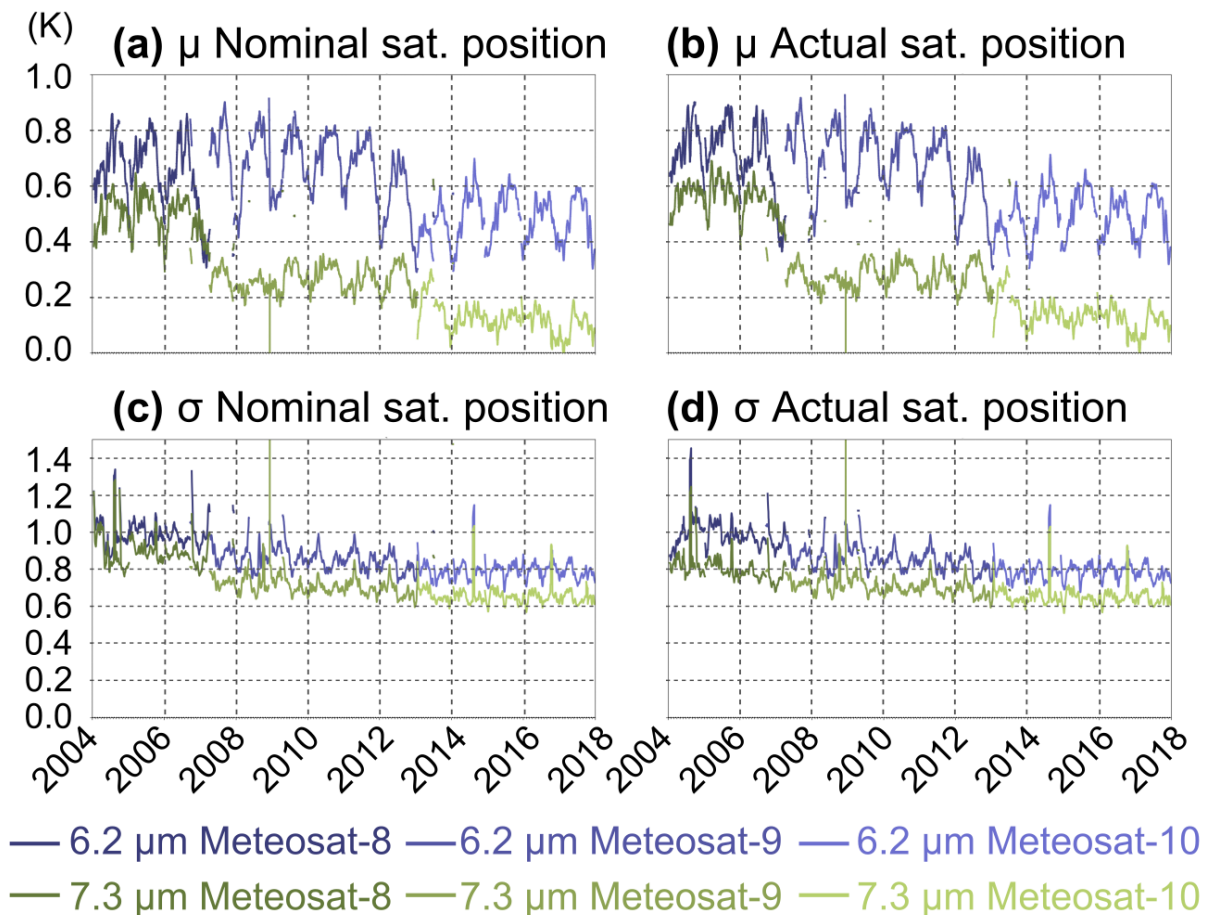

726 The 15-minute MSG All-Sky Radiances (ASR) products are simulated here only for the
727 two observation times closest to the hour (i.e., two images per hour are simulated, and two
728 images are not). The quality controls applied selects only pixels that are believed to be free of
729 clouds (so-called Clear-Sky Radiances, CSR), and for which the radiances are computed from an
730 average of at least 10 pixels. These radiances are indeed horizontal averages of higher-resolution
731 measurements.

732 The mean differences per month, as well as the standard deviations, between the MSG
733 SEVIRI observations and the simulations based on ERA5, are shown for the whole observation
734 area and for the two water vapor channels in Figure 10. In a first set of simulations, the nominal
735 satellite position, at 0-degree longitude, is assumed. The resulting departures vary over time.
736 Without any further indication to the contrary, a large part of these variations may be attributed
737 to variations in the quality of the ERA5 reanalysis. In a second set of simulations, the radiative
738 transfer simulations use as input the actual satellite position, as reported in the data, and thus can
739 account for the effect of changing the viewing angle. This accounting has little impact on
740 window channels (transparent to the atmosphere), but has some impact for channels measuring at
741 the water vapor wavelengths. At these wavelengths the transmission is affected by the
742 atmospheric optical depth. The comparison between Figure 10(c) and Figure 10(d) indicates that
743 the actual satellite position gives a slightly better agreement with the data record. However, the
744 magnitude of the changes may appear negligible at first sight.

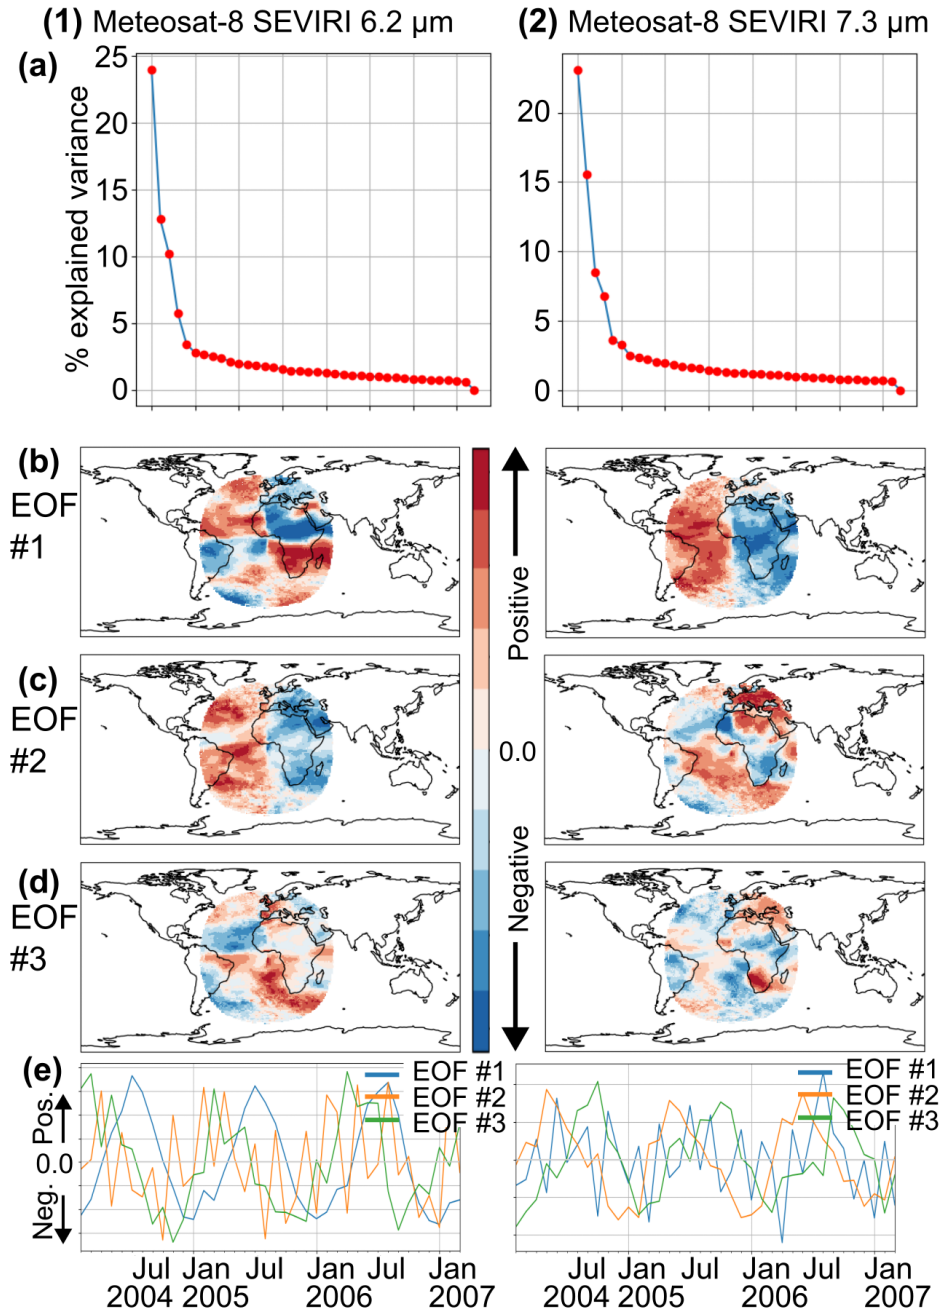

745 For this reason, it is important to investigate in more detail how these changes manifest
746 themselves. To this end, we compute mean differences per month between the two sets of
747 simulations, at a resolution of $1^\circ \times 1^\circ$ latitude, longitude. This enables a Principal Component
748 Analysis (PCA) to be carried out, using the differences between the two simulations. Prior to this
749 analysis, these differences are normalized to zero-mean and unit standard deviation for each
750 given satellite and each given channel (e.g., Aires et al., 2002). Figure 11(a) indicates that the
751 first eigenvectors (EOFs) explain most of the variability in the differences. The maps of these
752 differences in Figure 11(b,c,d) for the first three EOFs show the patterns of the differences. The
753 temporal variations are also shown in Figure 11(e), showing distinct cycles.

754 Because of the prior normalization of differences, the patterns evident in Figure 11
 755 appear more important than they manifested in observation departure space analysis (in K) of
 756 Figure 10. These patterns present distinct spatial and temporal aspects that may easily be
 757 misinterpreted in terms of climate evolution terms, should they appear from an analysis of the
 758 observed geostationary radiance data after removal of other effects.

759 In summary, this example stresses the importance of correctly accounting for the satellite
 760 viewing angles when considering geostationary radiance data from water vapor channels, for
 761 climate applications. If this is not done, then erroneous signals will propagate into downstream
 762 applications, and get aliased into the findings, possibly affecting conclusions that may be drawn
 763 about regional patterns of changes.

765 **Figure 10.** Time-series of (a,b) mean (μ) and (c,d) standard deviation (σ) of departures for
 766 SEVIRI water vapor channels, using two different methods for the simulations: (a,c) assuming
 767 nominal satellite position at 0 degrees longitude; (b,d) assuming the actual satellite position, as
 768 reported in the data.

769

770 **Figure 11.** Results of PCA analysis of normalized differences between radiative transfer
 771 simulations (assuming actual satellite position minus assuming nominal satellite position), for
 772 two water vapor channels indicated in columns (1) and (2), as follows: row (a) shows the
 773 percentage of explained variance by PCA EOF, rows (b) to (d) show the spatial projections of
 774 the first 3 EOFs, and row (e) shows these EOFs' time-varying amplitudes. Note that because of
 775 normalization the patterns of amplitudes are to be interpreted qualitatively in spatial terms or
 776 temporally (e.g., frequency and phase). To further avoid mis-interpretation into actual departures
 777 (in K) the normalized amplitudes of EOFs are shown without numerical axes.

778 5.3 Relevance of uncertainty and observation horizontal local variability in a data record,
779 example with SSM/T-2

780 The SSM/T-2 microwave sounder data record was reprocessed by Hans et al. (2017),
781 including estimates of uncertainty for the antenna temperatures. A later release of these
782 reprocessed data included a cloud and rain mask (EUMETSAT, 2021), as these phenomena are
783 known to hamper the ability to use the 183 GHz data for water vapor retrieval. The analysis
784 presented in this section focuses on these channels.

785 The Quality Evaluation Report associated with the SSM/T-2 data record (EUMETSAT,
786 2021) shows that data present a few episodes of larger noise, most notably for the F-14 satellite
787 after 2001. This total uncertainty information is shown in Figure 12. Using this information,
788 episodes of increased noise may be removed by excluding all observations where the average
789 total uncertainty exceeds twice the pre-launch noise equivalent delta temperature (NEDT)
790 specifications of the given channel. The time periods that are removed by this procedure are
791 shown in the same figure.

792 Hereafter we show that the uncertainty information helps to pinpoint other effects in the
793 data. To this end, we consider the observation horizontal local variability (Δ), computed as the
794 standard deviation of the observations over a 3x3 horizontal array of neighboring pixels. We
795 further restrict our analysis to latitudes between 40°S and 40°N. This is to ensure the data large-
796 scale variability is driven by water vapor content and not by surface-induced emissivity, which
797 may be more poorly simulated in some situations, e.g. over sea-ice. We then bin all the results
798 according to the observation horizontal local variability (Δ), in bins of 0.1 K. For each bin, we
799 compute the data distribution (number of results found), as well as the mean and standard
800 deviation of departures. The results are shown in Figure 13. The peaks in the data distributions
801 indicate that the instruments have comparable noise characteristics. These peaks are situated in
802 the region of 0.6 to 0.8 K, which is in line with the instrument NEDT specifications. The gradual
803 increase in standard deviations as a function of observation horizontal local variability is also to
804 be expected.

805 The mean departures in Figure 13(a)-(c) are not all aligned with each other, but present
806 some (steady) offsets, depending on the satellites. This is most probably caused by the fact that
807 Antenna Pattern Corrections (APCs) were unknown and thus were not be applied during the
808 reprocessing. An alternative explanation for these offsets could be varying amounts of humidity
809 biases (over time) in the ERA5 reanalysis. Such small inter-satellite differences are not believed
810 to be a problem for applications of the SSM/T-2 data into reanalysis, which generally applies
811 bias corrections to such data when assimilating them. However, this does require further
812 attention, to enable, for example, direct use of the data to retrieve humidity information, unless
813 applying a priori approaches such as harmonization (e.g., Giering et al., 2019).

814 Finally, Figure 13 shows that the increase in observation horizontal local variability is
815 associated with a slow but steady decrease of the bias towards negative values in the departures.
816 This effect is most pronounced for the lowest-peaking channel in Figure 13(c), and consistent
817 with the findings of Calbet et al. (2018).

818 In summary, our simulation results indicate that the information about uncertainty and
819 observation horizontal local variability should be of interest for users of the SSM/T-2 data
820 interested, for example, in clear-sky humidity retrievals.

821

822

823 **Figure 12.** Total uncertainty (monthly mean) associated with the SSM/T-2 antenna temperatures,
 824 as a function of time, for the three 183.31 GHz channels, ordered from highest-peaking (a) to
 825 lowest-peaking (c), for all satellites (F-11, F-12, F-14, F-15, see colored labels). Dots indicate
 826 time periods excluded in subsequent data analysis because the uncertainty estimate exceeds twice
 827 the pre-launch NEDT specification.

828

829 **Figure 13.** For the three SSM/T-2 183.31 GHz channels, (a) to (c), mean (μ , solid lines) and
 830 standard deviation (σ , dashed lines) of departures (in K, left-hand-side vertical axis), as a
 831 function of the observation horizontal local variability (Δ , horizontal axis, in bins of 0.1 K), with
 832 dotted lines showing the data distribution (f , normalized in percent, right-hand-side vertical axis).

833 6 Discussion

834 There are several factors that could explain the departures between instrument data
 835 records and simulations from reanalyses reported and analyzed in this paper.

836 First, there is the issue of data independence. One needs to assess, for each comparison, if
 837 the observational data record was assimilated in the reanalysis that is used for the simulations.
 838 The data of several data records used in this paper were independent (SI-1, SSM/T-2, MRIR).
 839 Other data were partly or indirectly used in the reanalysis. As for example is the case for the
 840 MVIRI radiances, which were indirectly assimilated as another variable or derived product (such
 841 as atmospheric motion vector, or to construct the sea-ice or sea-surface temperature that was
 842 used as forcing in reanalysis). The HIRS data, on the other hand, were fully assimilated.

843 However, our analysis only considers the low-frequency variability of departures. This
844 variability is known to remain distinct between reanalysis and the assimilated data, thanks to the
845 mechanism of the variational bias correction, even if the possibility of aliasing the signals cannot
846 be ruled out completely.

847 Second, there are changes in reanalysis quality over time. These may be due to general
848 improvement of the observing system (e.g., Dee et al., 2011), or related to instances of degraded
849 performance owing to suboptimal data use or more challenging natural variability, insufficiently
850 observed, or suboptimal data use. When such changes occur, they will affect all comparisons, to
851 all sensors, making it easier to identify whether or not the problem stems from the reanalysis or
852 the satellite data record.

853 Third, even if different reanalyses (such as ERA5 and ERA-Interim) are from different
854 generations, they often used very similar observations input (especially in the early years). This
855 limits the degree of independence between comparisons to several reanalyses. For this reason,
856 global reanalyses from a wider diversity of producers should be selected in future work.

857 Fourth, there are instrument-induced effects that are not all understood or simulated. A
858 few of these effects are listed by Fennig et al. (2017), for example, for the Nimbus-7 SMMR data
859 record. These effects include unknown variations in the satellite zenith angle, errors in the
860 satellite attitude control, potential errors in the underlying level 1B processing and, more
861 generally, insufficient correction of instrument-induced effects (such as calibration, spill-over,
862 and polarization mixing). These are all effects that are best addressed at the source, and for
863 which the simulations can help quantifying the overall cumulated effects. Even in cases where
864 instrument errors cannot be corrected at the source, such as the case of the MRIR data record,
865 improvements in bias correction predictors will help in including early satellite data into either
866 data assimilation systems, or at least in its use as a check on aspects of a reanalysis for periods
867 with limited or no satellite data.

868 Fifth, the quality of radiance simulations to reproduce the variability in the observations
869 is not equal for all channels/instruments. This originates in the spatio-temporal scale and
870 magnitude of natural phenomena responsible for the variability, differing by instrument and
871 channel, as compared to instrument and simulation resolutions and uncertainties. One may cite as
872 an example MVIRI, an instrument whose IFOV (see Table 1) is much smaller than the horizontal
873 resolution of global reanalyses. The simulation of the MVIRI infrared window channel generally
874 performs better over ocean than land, but on the other hand, the simulation of the MVIRI water
875 vapor channel features larger spreads in departures than those of the window channels, owing to
876 the upper-air water vapor coarse-resolution and corresponding variability representation in the
877 reanalyses. Another example is when a satellite data record contains signals that originate from
878 changes not contained in the simulations, such as volcanic aerosols (AVHRR) or possible
879 changes in trace gases whose concentrations have evolved due to industrial emissions (SI-1). All
880 these cases can be summed up by the issue of representativeness uncertainty between
881 observations and reanalysis.

882 Overall, the general approach followed here can be summarized by three principles: (a)
883 “all else being equal, an improved reprocessing should lead to an improved fit of the observed
884 data to simulations”, and so should also (b) an improved simulation setup, and (c) an improved
885 reanalysis. While this work is not a proof of these principles, we note that we have not found
886 examples to the contrary in our investigations. However, one must remember that, under special

887 circumstances, the situation of two observations and simulations agreeing for the wrong reason
888 cannot be ruled out (e.g., Joiner et al., 2004). To reduce the chances of such mishap, we
889 emphasize that the comparisons as shown here should, as much as possible, draw on a large
890 number of data samples.

891 Another important element to consider, when analyzing departures between observations
892 and simulations, are the quality controls (Supplement Text S1). They may appear as trivial to
893 some readers, but far less obvious to others. While it should normally suffice to read the
894 documentation that accompanies every data record, and then to apply the quality flags suggested
895 by the documentation after reading the data, our experience suggests that more should be done in
896 the future to ease the application of quality flags. The aim should be to preserve the flexibility for
897 expert users but also to guide less-expert users and leave less room to interpretation.

898 Finally, an issue encountered during the course of this work was that each climate data
899 record tends to adopt a data representation that is contemporary to the time of the mission,
900 reflecting in general the data transmission constraints imposed by radio transmission bandwidth
901 and digitization. This is no different to practices followed to disseminate in-situ observation data.
902 However, if one priority is to improve inter-operability of datasets for comparisons and other
903 applications, the multitude of data models to represent observations is a barrier to integration.
904 Indeed, it requires, in each case, to adapt computer code. To circumvent this issue, initiatives
905 have been proposed, to promote a single data model (Nativi et al., 2008). Such initiatives will
906 greatly simplify the data integration and data comparisons, for example with other observations
907 or with models, possibly via simulations as shown here.

908 **7 Conclusions**

909 This paper applies radiance simulators to the Fundamental (Climate) Data Records
910 (F(C)DRs of several satellite instruments, using as input global climate reanalyses. While the
911 methodology of radiance simulators is not new, we demonstrate that their application enables
912 three classes of applications.

913 In the first class of applications, assumptions about a data record organization (order of
914 channels), its quality, or data corrections, may be verified. For this, we mostly draw from
915 examples where the data have been characterized long ago, such as the MVIRI and HIRS data
916 records, and much progress has been made since then. We use examples where the
917 methodological advance of reprocessing is on a level that benefits from a high-quality a priori
918 comparison to validate the impact, such as identifying image anomalies in geostationary images
919 or improving the coherence between data records and reanalyses with modern cloud masks.

920 Regarding the volcanic eruption of Mount Pinatubo, we find a cooling on the order of 1
921 K for brightness temperatures from AVHRR and HIRS window channels (short-wave and long-
922 wave alike), with concomitant increase in reflectance for the AVHRR near-infrared channel of a
923 few percent. We also revisit how fast the atmospheric effects of the eruption propagated away
924 from the Tropics. In line with previous findings, we confirm differences in the timing of peak
925 radiative effects of several months between the Mediterranean and the Southern Oceans as
926 compared to the Tropics, where the volcanic eruption had taken place.

927 In the second class of applications, coherence between global datasets of different natures
928 can be assessed. The high spectral resolution data collected by the SI-1 instrument allows
929 confirmation of improvements in the quality of the latest Japanese global reanalysis, JRA-3Q, for

930 stratospheric ozone. Spectral spikes in departures, observed for all reanalyses, also suggest that
931 several trace gases' (in particular halocarbons) concentrations assumed in the radiative transfer
932 may differ from actual concentrations in 1979. Furthermore, we present first estimates of SI-1
933 random uncertainty, assuming independence of random uncertainty between the sources of error.
934 Given such caveats, our findings suggest the combined instrument noise and radiative transfer
935 random uncertainties increase in the far-infrared region. In this respect, observations from the
936 future FORUM instrument will be useful to enhance general experience and understanding of the
937 performance of radiative transfer models in the far-infrared. At higher wavenumbers (600—1200
938 cm^{-1}), we find combined SI-1 instrument noise equivalent delta temperature (NEDT) and
939 representativeness uncertainties at 280 K to be generally in the range 0.8—1.0 K.

940 Another example shown, with MRIR, illustrates how differences, which could be
941 interpreted as incoherencies between reanalyses and observations, can be differently reduced
942 numerically, depending on the set of bias predictors chosen. While this can minimize systematic
943 differences, another importance of this approach is to gain understanding about the potential
944 sources of errors in the satellite data. This ties the present study to a third class of applications:
945 informing users on key characteristics of a data record.

946 In this third class of applications, we show cases of simulations of, and comparisons with,
947 data records from SMMR, SSM/T-2, and Meteosat second-generation. For SMMR, the findings
948 are that the existing data records suffer for the horizontally-polarized 21 GHz channel from large
949 oscillating biases, and that all channels exhibit a different behavior after a Special Observing
950 Period in 1986. Given the value of the SMMR data in bridging with the SSM/I data record, this
951 calls to consider a potential new reprocessing of the SMMR data record from the original data.

952 For SSM/T-2, we find that uncertainty information and horizontal local variability in the
953 observations make a large difference to improve the agreement between reanalysis and clear-sky
954 simulations. This suggests that these parameters would need to be taken into account in
955 applications, such as clear-sky humidity retrievals.

956 For Meteosat Second Generation, we find that the variability of the satellite position
957 around its nominal position has most likely left a signature in the data record. For climate
958 applications, such changes in position are needed to take into account or else they may get
959 aliased into regional patterns of changes in the downstream products.

960 For all cases of the third class of applications, the results do not constitute final
961 conclusions, but, instead, provide information for users and applications to take into account.

962 In all the examples shown in the study, the effort consists in bringing all the sources of
963 information into the same observation space (times, locations, instrument channel, and viewing
964 geometry), after having applied quality controls following the data records' user documentation.
965 Notwithstanding the particular issue posed by the diversity of observation data models, this
966 approach, if generalized and made more systematic, would aid tracking of progress in climate
967 reanalyses and satellite climate data records alike. This would help to accelerate the delivery of
968 high-quality climate data records to serve climate services. The prospects for such an activity are
969 not identified specifically in the GCOS Implementation Plan (World Meteorological
970 Organization (WMO) et al., 2022). However, this plan identifies an action to co-locate in-situ
971 and satellite measurements. The present paper demonstrates that there may be great benefits in
972 considering also state-of-the-art reanalyses in such co-locations.

973 The data records discussed in this paper are mostly limited to the representation of
974 atmospheric phenomena and corresponding satellite observations. In parallel, today's Earth
975 system models are developed to encompass more components, including anthropogenic effects.
976 One may thus expect the same methods as presented here to be applicable to support the
977 development of data records related to other observables that impact our environment, such as
978 human activity and biodiversity. These two fields are of utmost importance, provided that
979 physical methods are developed to relate these fields to satellite measurements via simulators.
980 For both fields, there have already been key developments (e.g., Gao et al., 2015; Schweiger &
981 Laliberté, 2022, respectively). The methods set forth in the present paper may serve to continue
982 progress in these areas and to support advances in long data records and corresponding models
983 that describe human activity and biodiversity.

984 Thirty years after the 1992 Earth Summit, it is worth remembering that its participants
985 had identified three topics to be tackled within regular meetings of Conventions Of the Parties
986 (COP), i.e., climate change, biodiversity collapse, and desertification. Today, these three topics
987 appear to be on a collision course, notwithstanding increasing demands for resources from a
988 growing world population. This calls for more urgent action to understand the inter-relations
989 between all these application areas, through better exploitation of environmental measurements,
990 models, and reanalyses, which integrate the most diverse sources of data for our environment.

991 **Acknowledgments**

992 This work benefited from strong inter-agency collaboration, noting support from the European
993 Union Copernicus Climate Change Service (C3S) and the institutions to which the authors are
994 affiliated. The EUMETSAT NWP-SAF is thanked for adding support to several instruments,
995 with special thanks to Emma Turner and James Hocking. The EUMETSAT CM-SAF is
996 acknowledged for providing data records used in this work, and special thanks are addressed to
997 Karl-Göran Karlsson, Abhay Devasthale, Martin Raspaud, Diana Stein, Nathalie Selbach,
998 Stephan Finkensieper, Karsten Fennig, Marc Schröder, and Rainer Hollmann. The authors wish
999 to thank NOAA for the SSM/T-2 Sensor Data Record. The authors also wish to thank librarians
1000 at EUMETSAT, NASA, and NOAA for help locating early satellite instruments' technical
1001 documentation.

1002 **Open Research**
