**KEYWORDS:** Chalcogenide vacancies, Solid state NMR, DFT simulation, Nanoparticles.

**ABSTRACT:** Herein, we report the successful characterization of sulfur vacancies in ZnS nanoplatelets by in-depth high-field and DNP-enhanced solid-state NMR of  $^{33}\text{S}$  and  $^{67}\text{Zn}$  nuclei and DFT modeling. This two-dimensional 1 nm thick nanomaterial was obtained by reacting dicyclohexyl zinc complex,  $\text{ZnCy}_2$ , with  $(\text{TMS})_2\text{S}$  as the S source under mild conditions (45 °C) in dodecylamine. The joint experimental and theoretical study on these nanoplatelets evidenced that a large fraction of the Zn and S atoms are located near the surface covered by dodecylamine and that the deviation from stoichiometry (agreeing with energy gap and photoluminescence properties of non-stoichiometric material) is due to sulfur vacancies. Additionally, this work reports the first  $^{33}\text{S}$  DNP-NMR spectrum reported in the literature alongside several ultra-high-field  $^{33}\text{S}$  and  $^{67}\text{Zn}$  solid state NMR spectra.

## **INTRODUCTION**

Metal sulfide (MS) nanomaterials constitute an important class of functional materials<sup>1,2</sup> whose properties have great potential for applications in energy storage devices<sup>3,4</sup> including Li- or Zn-ion batteries,<sup>5,6</sup> electrochemical water splitting,<sup>7-9</sup> as well as photocatalysis.<sup>10-12</sup> In addition, their magnetic properties make them suitable for magneto-optic devices.<sup>13</sup> As such aforementioned applications are primarily related to the MS structural variability, deriving not only from the nature of the involved transition metal, but also from deviation of stoichiometry,<sup>14</sup> MSs have therefore attracted great attention, and numerous pathways have been designed for their synthesis.<sup>15-18</sup>

The basic question of interest is the interrelation between their properties and the nanoparticle (NP) size, morphology, and atomistic structure. For example, it has recently been shown that localized surface plasmon resonance (LSPR), arising from the oscillation of the electrons in the conduction band, appears not only in metallic materials, but also in MS with appreciable carrier density.<sup>19</sup> The hole density, which is related to the stoichiometry of the MS, affects not only the LSPR intensity but also the LSPR frequency.

Of all the MS, ZnS has been extensively studied because of its appealing electronic properties:<sup>20-</sup><sup>22</sup> It exhibits a wide band gap (3.7 eV) and a high exciton binding energy (40 meV), which enable the direct conversion of electric energy into visible light, without generating heat, or requiring chemical or mechanical triggers.<sup>20-22</sup> For these reasons, it is widely used in lasers, electroluminescent devices, flat panel displays, field emitters, infrared windows, and UV-light detectors.<sup>23</sup> It is environmentally friendly and non-cytotoxic,<sup>24</sup> thus suggesting possible applications also in biomedicine.<sup>25</sup> Additionally, ZnS exhibits excellent photocatalytic capacity owing to its strong oxidation and high negative potentials of excited electrons.<sup>26</sup> This has been demonstrated by Peng and co-workers, who have found optimum conditions to enhance the

stability and photocatalytic activity of ZnS materials, while at the same time they have noticed an inverse effect of the amount of S vacancies on the photocatalytic activity.<sup>27-30</sup>

Surprisingly, the reported studies dealing with the characterization of these S vacancies at the atomic scale remain scarce and most of the results are based on theoretical calculations. This is certainly due to the difficulty in obtaining experimental evidence of these S vacancies at atomic level.<sup>31</sup>

As a local characterization technique reaching atomic resolution, nuclear magnetic resonance (NMR) spectroscopy is a promising approach to probe the structures of vacancies. Nowadays, NMR is widely used to study the ligands at the surface of the inorganic NPs<sup>32</sup> or to characterize the inorganic core of NPs<sup>33</sup> when it contains isotopes with good receptivity, such as <sup>31</sup>P or <sup>27</sup>Al.<sup>34</sup> However, a major limitation of NMR spectroscopy is its lack of sensitivity, especially for isotopes with low natural abundance, low gyromagnetic ratio and with spin number  $I \geq 1$ , such as <sup>67</sup>Zn and <sup>33</sup>S, which often prevents the detection of most of the nuclei present in the inorganic NP cores.<sup>35</sup> This sensitivity issue is further exacerbated for the observation of defects, which represent a limited fraction of the NP atoms. To the best of our knowledge, no <sup>33</sup>S NMR spectrum of NPs has been reported so far, whereas <sup>67</sup>Zn NMR signals of NPs have only been detected for a few NPs, including ZnS,<sup>36</sup> ZnSe,<sup>37</sup> and ZnO.<sup>35</sup> Recently we demonstrated the possibility to acquire the NMR signals of <sup>67</sup>Zn nuclei located near the surface of commercial Al-doped ZnO NPs using dynamic nuclear polarization (DNP).<sup>38</sup> Therefore, the NMR characterization of ZnS remains a challenge, which if met, could provide access to new information for improving our understanding of the links between these S vacancies and the properties of the material.

Here, for the first time, the presence of S vacancies in ZnS nanoplatelets (NPLs) obtained by an organometallic approach is jointly studied by DFT modeling and NMR spectroscopy.

## RESULTS AND DISCUSSION

### Synthesis

The preparation of colloidal ZnS NPs has been often carried out by the hot injection or heat-up methods at elevated temperatures.<sup>39-45</sup> Traditionally, the sources of sulfur atoms have often been elemental sulfur,<sup>46, 47</sup> thioureas,<sup>48-51</sup> and thiols.<sup>52-54</sup> Additionally, commercially available bis-(trimethylsilyl) sulfide ((TMS)<sub>2</sub>S), has been reported as good sulfur atom precursor.<sup>55</sup>

Considering our previous work on the synthesis of ZnO NPs,<sup>56-58</sup> we reasoned that the synthesis of ZnS nanomaterials could be achieved using our ZnCy<sub>2</sub> complex as the precursor in presence of (TMS)<sub>2</sub>S as the S source (see Fig.1).

**Figure 1:** General reaction scheme of the synthesis of ZnS NPs (L – ligand, octylamine (OA), dodecylamine (DDA)) and TEM image of the obtained ZnS nanoplatelets under optimized conditions (*vide infra*).

Several experimental conditions were tested to achieve the controlled synthesis of the ZnS NPs (Table S1). Typically, ZnCy<sub>2</sub> was mixed with a given amount of the chosen ligand (*i.e.* octylamine, OA; or dodecylamine, DDA) at a given temperature (room temperature or 45 °C), in a THF solution or in the absence of solvent. Then (TMS)<sub>2</sub>S was introduced in the reaction vial under stirring and the reaction media was left to react from 16 up to 96 h. Under optimized reaction conditions (at 45 °C) without any added solvent lamellar nanosheets (nanoplatelets, NPLs) were reproducibly obtained. No trace of Si was detected by NMR measurement. The growth of our ultrathin NPLs can be attributed to the templating effect of formed micellar structures, which has previously been reported.<sup>59</sup> Indeed, the TEM image shown on Fig. 1 is similar to those reported by Zhang and co-workers. It is most possibly the same growth mechanism by soft templating that is responsible for this shape; the existence of a pre-organization with amines having already been suggested with organometallic precursors.<sup>60</sup> Compared to previously reported synthesis of ZnS lamellar nanosheets in an autoclave at 140 °C,<sup>61</sup> our approach allowed to obtain these nanoobject at 45 °C and under atmospheric pressure. In addition, the contrast of the TEM images is low, possibly because of the extremely small thickness of the sheets.<sup>62</sup>

TEM images also show the “moiré” patterns caused by the interference between the crystalline lattices of the stacked NPLs. The distance of ~2 nm between the adjacent NPLs implies the retention of capping ligands on the NPLs surfaces, which was further confirmed by NMR spectroscopy (see below). Note that TEM images of ZnS particles with homogeneous contrast

might also indicate small quantity of interfacial defect structures, such as stacking defects and twin structures.<sup>63</sup>

### Structural characterization and physical properties.

Figure 2 shows the powder X-ray diffraction pattern of the as-obtained ZnS NPLs, which corresponds to the hexagonal phase obtained usually at much higher temperature<sup>47</sup> (space group P63mc). In our case, the respective peaks of ZnS NPLs in the 25 – 80° 2 $\theta$  range are shifted towards larger 2 $\theta$  values, suggesting a shrinkage of the cell parameters evaluated to 3.5%. Such distortion of the network could be a consequence of the very small thickness of the NPLs, eventual undercoordination of Zn or both. In addition, as already observed, additional peaks characteristic of the ligand used in the synthesis are observed at lower 2 $\theta$  values (10 – 25°).<sup>48</sup>

**Figure 2:** Powder X-ray diffraction of ZnS nanoplatelets.

The as-obtained ZnS NPLs exhibit optical properties characteristic of small size NPs in agreement with TEM and powder diffraction pattern. The room temperature reflectance spectrum of the powder is shown in Figure 3. Compared with bulk ZnS for which regardless of the

polymorph, the band gap is equal to 3.68 eV, i.e. 337 nm at room temperature,<sup>64, 65</sup> the absorption peaks for the ZnS NPLs exhibits a large blue shift. An intense peak is observed at 250 nm (4.96 eV). Such a strong and narrow peak observed in the optical absorption spectrum of semiconductors is known to arise because of quantum confinement effect, which occurs in the case of NPs when the particle size becomes comparable with or smaller than the Bohr radius of exciton, i.e. bound electron-hole pairs.<sup>66</sup> In ZnS, assuming the effective mass of electron  $m_e^* = 0.40m_e$ , where  $m_e$  is the rest mass of the electron, and hole mass  $m_h = 0.61m_e$  with dielectric constant  $\epsilon = 5.2$ , the Bohr radius of exciton turns out to be 1.1 nm, which means that the quantum confinement effect becomes observable for NPL thickness of 1.1 nm. The photoabsorption onset corresponding to bulk semiconductor (energy gap  $\sim 3.54$  eV) expected at about 344 nm is observed in Figure 3 at 264 nm (energy gap  $\sim 4.7$  eV) which stems also from a strong confinement effect of the exciton. This observation agrees with previously reported results.<sup>67</sup>

**Figure 3:** Optical properties of ZnS nanoplatelets: reflectance spectrum and photoluminescence spectrum (insert).

The insert of Figure 3 reports the room temperature photoluminescence (PL) of the sample at excitation wavelength of 275 nm. Due to the high surface-to-volume ratio in these nanostructures, the PL is characterized by a high number of peaks indicating the presence of a variety of defect-related emission, such as surface defects, sulfur and zinc vacancies or interstitial atoms. We observe an overall higher intensity and marked dominance of the UV-blue region for the ZnS NPLs sample compared to commercially available bulk ZnS reference. Although no consensus exists in the literature on the precise identification of the spectral lines, it has been suggested that S or Zn vacancies are at the origin of an efficient PL emission in the UV-blue region.<sup>68, 69</sup> The higher observed intensity indicates that there are more emitting sites in the ZnS NPLs than in the bulk ZnS suggesting a larger stoichiometric deviation in the case of the NPLs.

Electrical resistance measurements performed on the ZnS NPLs powders, after washing processes to remove excess of ligands, show a very high electrical resistance value over 1 GΩ. Even at high temperatures - over 300 °C and up to 500 °C - the resistance of the ZnS NPLs remains above several hundred of megaohms. Generally, point defects, such as S vacancies in the structure, are associated as electron donors that can be transferred to the conduction band under thermal activation.<sup>70, 71</sup> Similarly, Zn vacancies may act as hole carriers in the structure. However, in our case it appears that the low dimensionality of the structure limits the conductivity level due to a strong trapping of the charge carrier (either electron or holes) associated with a very low mobility.

The optical results on the one hand, with a very high PL intensity indicate a large number of emissive sites. On the other hand, electrical conductivity suggests the presence of defects in the material, whose nature needs to be further analyzed. Therefore, NMR spectroscopic studies in

both the liquid and solid states, and DFT calculations were conducted to investigate the atomic-level structure of ZnS NPLs.

### **NMR spectroscopic study.**

The presence of DDA ligands on the ZnS NPLs were probed using  $^1\text{H} \rightarrow ^{13}\text{C}$  cross-polarization under magic-angle spinning (CP-MAS) NMR experiments (Figure S1). The changes in isotropic chemical shifts (Table S2) of the  $\text{CH}_2$  groups in the  $\alpha$  and  $\beta$  positions of the amine function of DDA ligand between DDA alone and ZnS·DDA NPLs evidence the coordination of the DDA at the ZnS surface. Moreover, several  $^{13}\text{C}$  signals of ZnS·DDA NPLs, especially the  $\text{CH}_2$  groups in the  $\beta$  and  $\gamma$  positions, are split into a major and a minor component, indicating the presence of two different types of coordinated DDA. The isotropic chemical shift of central methylene C atoms provides insights into the conformations of the alkyl chain. In the case of ZnS·DDA NPLs, the isotropic chemical shift of  $\text{CH}_2$  group is equal to  $\delta_{\text{iso}}^{\text{exp}} = 32.1$  ppm, which indicates an all-*trans* conformation. It can be concluded that ZnS·DDA NPLs has, as for DDA alone, an extended alkyl chain made of mainly methylene groups in *trans* conformation (as shown in Figure S2), in contrast to what is observed for ZnO NPs - synthesized following similar organometallic route - for which the DDA alkyl chain adopts a more bent structure with a higher population of *trans/gauche* or *gauche-gauche* conformations.<sup>35</sup>

To characterize the inorganic core of ZnS NPLs and especially to probe the presence of defects, the NMR spectra of  $^{67}\text{Zn}$  and  $^{33}\text{S}$  isotopes were recorded. Figure 4 shows the  $^{67}\text{Zn}$  signals at natural abundance of ZnS NPLs by improving their detection using high magnetic fields (18.8 and 35.2 T), irradiation of the satellite transition and quadrupolar Carr-Purcell Meiboom-Gill (QCPMG) detection.<sup>72, 73</sup> These spectra, for which  $^{67}\text{Zn}$  nuclei are directly excited, contain the

signals of both the surface and bulk sites. They exhibit discontinuities and cannot be simulated with a single  $^{67}\text{Zn}$  site, which indicates the presence of different Zn local environments. Furthermore, it was not possible to simulate the two spectra acquired at two different fields using Czjzek model,<sup>74</sup> which has been employed for ZnSe,<sup>37</sup> and ZnO NPs.<sup>35</sup> Hence, the Zn local environments in ZnS NPs are partially ordered. Conversely, the spectra acquired at 18.8 and 35.2 T can be approximately simulated using three  $^{67}\text{Zn}$  sites with isotropic chemical shifts,  $\delta_{\text{iso}}^{\text{exp}}$ , ranging from 297 to 313 ppm and quadrupolar coupling constants,  $C_Q$ , of 2.5, 7.5 and 10 MHz, respectively (Table S3).

**Figure 4:** (a) Experimental (black) and simulated (red) conventional  $^{67}\text{Zn}$  direct excitation spectrum of pristine ZnS·DDA NPs acquired at 18.8 T (top) and 35.2 T (bottom). The simulated

spectrum is the sum of three sites with  $C_Q = 2.5$  (orange), 7.5 (blue), and 10.0 (green) MHz. The panel (b) shows an expansion of the spectrum acquired at 35.2 T.

The measured isotropic chemical shifts are lower than that of  $ZnS_4$  sites (denoted  $Zn_{4c}$  hereafter) in microcrystalline wurtzite  $ZnS$  (365 ppm).<sup>75</sup> Furthermore, the  $C_Q$  values are significantly higher in  $ZnS$  NPLs than in microcrystalline  $ZnS$  ( $C_Q < 0.5$  MHz), where cubic symmetry results in vanishing quadrupolar interaction. This discrepancy indicates environment distortion breaking the cubic symmetry around  $^{67}Zn$  nuclei,<sup>36</sup> such as the presence of defects or surfaces.

Furthermore, the spectrum at 35.2 T exhibits a broad peak near 200 ppm. This signal is more visible in the QCPMG spikelet spectrum shown in Figure S3. This weak signal might arise from  $^{67}Zn$  nuclei near surfaces with  $C_Q \approx 10$  MHz but also near S vacancies (see DFT calculations below). No signal is detected below 180 ppm. Note that the QCPMG experiment is not quantitative since the different  $^{67}Zn$  sites can exhibit different decays of their signal intensity during the QCPMG acquisition.

High magnetic field was also employed to acquire 1D  $^{33}S$  direct excitation NMR spectra of  $ZnS$  NPLs at 18.8 and 35.2 T (Figure 5). These spectra were simulated simultaneously as a single central transition (CT) broadened by second-order quadrupolar interaction with best-fit parameters  $\delta_{iso}^{exp} = -621$  ppm,  $C_Q = 5.2$  MHz and an electric field gradient (efg) asymmetry parameter,  $\eta_Q = 0.40$ . The presence of a single CT for  $^{33}S$  nuclei, instead of three distinct CTs for  $^{67}Zn$  nuclei, stems from the lower sensitivity of  $^{33}S$  NMR parameters to the local environment, compared to those of  $^{67}Zn$  isotope (see DFT calculations below). This lower sensitivity results from the smaller atomic number of S element. The isotropic chemical shift is approximately 60 ppm lower to that of  $S_{Zn4}$  sites with  $\delta_{iso}^{exp} = -564$  ppm in microcrystalline wurtzite  $ZnS$ .<sup>76-78</sup> Like

for  $^{67}\text{Zn}$  nuclei, the  $^{33}\text{S}$  nuclei are subject to much larger quadrupolar interaction in ZnS NPLs than in microcrystalline wurtzite ZnS, which exhibits a vanishing quadrupolar interaction ( $C_Q = 0.3$  MHz). The larger quadrupolar interaction in ZnS NPLs stems from the presence of surface or defects, which increases the efg.

**Figure 5:** Experimental (black) and simulated (red) conventional  $^{33}\text{S}$  direct excitation NMR spectra of ZnS·DDA NPLs acquired at 18.8 T (top) and 35.2 T (bottom). The spectra are the FT of the sum of QCMPG echoes.

In order to observe the Zn and S sites located near the surface of ZnS·DDA NPLs, we also transferred the  $^1\text{H}$  magnetization to  $^{67}\text{Zn}$  and  $^{33}\text{S}$  nuclei using dipolar-mediated refocused INEPT scheme (*D*-RINEPT),<sup>38, 79</sup> and enhanced the signal using QCMPG detection along with dynamic nuclear polarization (DNP).<sup>34, 80, 81</sup> For the DNP-NMR experiments performed at 9.4 T and 105 K, the unpaired electrons were introduced in the sample by impregnating ZnS·DDA NPLs with a solution of 13 mM TEKPol nitroxide biradicals in 1,1,2,2-tetrachloroethane (TCE).

**Figure 6:** Experimental (black) and simulated (red) DNP-enhanced  $^1\text{H} \rightarrow ^{67}\text{Zn}$  *D*-RINEPT spectra of ZnS·DDA NPIs impregnated with 13 mM TEKPol solution in TCE acquired at 9.4 T and 105 K with  $\nu_{\text{R}} = 13.89$  kHz. The spectrum was the FT of the sum of QCMPEG echoes.

The DNP-enhanced  $^1\text{H} \rightarrow ^{67}\text{Zn}$  *D*-RINEPT spectrum of ZnS·DDA NPIs shown in Figure 6 is dominated by a manifold of narrow spinning sidebands with a centerband at 140 ppm. The centerband was identified by recording this NMR spectrum at four distinct MAS frequencies, 13.89, 12.5, 10.0, and 8.0 kHz, as shown in Figure S4. This spinning sideband manifold was simulated using a central transition line shape broadened by second-order quadrupolar interaction. As seen in Figure 6, the simulated NMR spectrum for a single site does not fully agree with the experimental one. This discrepancy might stem from different efficiency of *D*-RINEPT transfer for the different crystallite orientations, bulk magnetic susceptibility effects due

to the paramagnetic frozen radical solution<sup>82</sup> as well as the presence of different local environments near ZnS surface. The isotropic chemical shift is comparable to those measured in the conventional direct excitation spectrum of Figure 4, whereas the  $C_Q$  value is close to 7.5 MHz value measured for one signal of the same spectrum. Conversely, the sites with  $C_Q = 2.5$  MHz are not detected in the DNP-enhanced spectrum, which indicates that these sites are more distant from the ZnS surface. It should be noted that the signal with  $C_Q = 10$  MHz is too broad at 9.4 T to be detected.

The sensitivity gain provided by DNP was employed to detect the NMR signals of  $^{33}\text{S}$  nuclei located near the surface. The corresponding DNP-enhanced  $^1\text{H} \rightarrow ^{33}\text{S}$  *D*-RINEPT variable offset cumulative spectrum is shown in Figure 7. It represents the first example of  $^{33}\text{S}$  DNP-NMR spectrum reported in the literature. This  $^{33}\text{S}$  NMR spectrum can be simulated as a central transition broadened by second-order quadrupolar interaction with best-fit parameters  $\delta_{\text{iso}}^{\text{exp}} = -603$  ppm,  $C_Q = 5.0$  MHz and  $\eta_Q = 0.55$  (see Figure 7). The NMR parameters are also similar to those measured in the conventional  $^{33}\text{S}$  direct excitation NMR spectrum of Figure 5.

**Figure 7:** Experimental (black) and simulated (red) DNP-enhanced  $^1\text{H}\rightarrow^{33}\text{S}$  *D*-RINEPT variable offset cumulative spectrum of ZnS·DDA NPIs impregnated with 13 mM TEKPol solution in TCE acquired at 9.4 T and 105 K with  $\nu_{\text{R}} = 13.89$  kHz. The spectrum is the sum of four sub-spectra obtained by the FT of the sum of QCMPEG echoes.

### DFT Computational Studies.

To simulate the NMR properties of ZnS films, we used fully optimized slabs of different thickness: 6, 8, and 14 atomic layers, corresponding to 0.78, 1.1 and 2.1 nm thickness, respectively (the corresponding structures are displayed in Figures S5, 8a, and S6, respectively). Notice that with the notation  $\text{Zn}_{n_{\text{c}}}$  we refer to the number  $n$  of S atoms covalently bound to Zn. The results, however, are only moderately dependent on the number of layers in the slab. For each atom in the slab we calculated using DFT the NMR parameters,  $\delta_{\text{iso}}$ ,  $C_{\text{Q}}$  and  $\eta_{\text{Q}}$ , of  $^{67}\text{Zn}$  and

$^{33}\text{S}$  nuclei. A summary of the most important results extracted from the different models used in this study can be found in Table 1.

**Figure 8:** Side view of the 1.1 nm slab used to model ZnS NPLs with ZnS(10-10) surface and wurtzite structure with adsorbed  $\text{NH}_2\text{Me}$  molecules on one side a) devoid of vacancy and b) with one S vacancy created in the inner layers. The  $\delta_{\text{iso}}^{\text{calc}}$  (ppm) are given for selected atoms. Zn and S atoms are displayed as grey large and yellow small spheres, respectively. For the full set of  $\delta_{\text{iso}}^{\text{calc}}$ ,  $C_Q$  and  $\eta_Q$  values, see Tables S5 and S9.

**Table 1:** Overview of  $^{33}\text{S}$  and  $^{67}\text{Zn}$  NMR and DFT data obtained in this work.

NMR			
Sample	Nuclei	$\delta_{\text{iso}}^{\text{exp}}$ /ppm	$C_{\text{Q}}^{\text{exp}}$ /MHz
ZnS NPLs	$^{67}\text{Zn}$	310/313/296	2.5/7.5/10
	$^{67}\text{Zn}$ (DNP)	320	6.7
	$^{33}\text{S}$ (HF-1)	-621	5.2
	$^{33}\text{S}$ (DNP)	-603	5.0
ZnS wurzite Bulk <sup>96,100</sup>	$^{67}\text{Zn}$	365	< 0.5
	$^{33}\text{S}$	-564	0.3 <sup>a</sup>
DFT <sup>b</sup>			
Model	Atom sites	$\delta_{\text{iso}}^{\text{calc}}$ /ppm	$C_{\text{Q}}^{\text{calc}}$ /MHz
Free surface	Zn <sub>3c</sub>	314 to 345	~45.5
	S <sub>3c</sub>	-538 to -528	~7.0
Free sub-surface	Zn <sub>4c</sub>	325 to 342	10.5 to 11.7
	S <sub>4c</sub>	-547 to -533	~2.7
Amine coordinated surface	Zn <sub>3c</sub>	303 to 338	11.5 to 18.1
	S <sub>3c</sub>	-602 to -571	~6.7
Amine coordinated sub-surface	Zn <sub>4c</sub>	325 to 338	~7.3
	S <sub>4c</sub>	-606 to -595	~1.6
Surface site close to S-vacancies	Zn <sub>3c</sub>	200 to 385	13.2 to 46.7
	Zn <sub>4c</sub>	330 to 345	2.8 to 13.5
	S <sub>3c</sub>	-536 to -416	4.4 to 8.2

Core site close to S-vacancies	Zn <sub>2c</sub>	-43 to 35	13.8 to 34.0
	Zn <sub>3c</sub>	124 to 215	1.7 to 15.2
	Zn <sub>4c</sub>	320 to 390	0.9 to 4.5
	S <sub>4c</sub>	-592 to -394	1.2 to 7.5
“bulk” sites	Zn <sub>4c</sub>	353 to 363	0.2 to 0.6
	S <sub>4c</sub>	-580 to -585	0.3 to 0.6

<sup>a</sup> value calculated from reference 79. <sup>b</sup> The  $C_{\text{Q}}^{\text{calc}}$  range is based on the amplitude values ignoring the sign.

The  $^{67}\text{Zn}$  nuclei in the most inner layers of Zn of the largest simulated slab (with a thickness of 2.1 nm, as shown in Figure S6) exhibit an isotropic chemical shift of *ca.* 360 ppm and a small  $C_{\text{Q}}$  values (0.17 MHz for Zn 8 in Table S6). These parameters are consistent with the experimental values obtained for microcrystalline ZnS exhibiting isotropic shifts of 365 ppm and  $C_{\text{Q}}$  values <

0.5 MHz (Table 1).  $Zn_{3c}$  atoms of the clean surface (see Figure S6 bottom layer, Zn 14 in Table S6) has an isotropic chemical shift of 331 ppm, about 30 ppm lower than in the “bulk” but with a large  $C_Q$  value of 45 MHz. Similar isotropic chemical shifts are calculated for  $Zn_{4c}$  nuclei in the first atomic layer below the surface (Zn 2 in Table S6). The  $C_Q$  value of  $Zn_{4c}$  nuclei gradually increases from the center of slab to the first layer below the surface (11.22 MHz for Zn 13 in Table S6).

When a very thin layer of 0.78 nm (Figure S5 and Table S4) is considered the main features are maintained: the  $Zn_{3c}$  atoms of the clean surface have a chemical shift at 328 ppm (Zn 1 in Table S4), while  $Zn_{4c}$  in the inner layers are close to 350 ppm (Zn 3 and 4 in Table S4), consistent with their higher coordination number. Similar chemical shift of 354 ppm, is computed for  $Zn_{4c}$  atom in a 1.1 nm films, (see Figure 8a and Zn 4 to 6 in Table S5. Interestingly, the average of  $C_Q$  values for  $^{67}Zn$  nuclei in the core of slab with a thickness of 1.1 nm (Zn 3 to 6 in Table S5) is equal to 2.3 MHz, which is comparable to the smallest  $C_Q$  value (2.5 MHz) used to simulate the  $^{67}Zn$  NMR spectra. Conversely, this average  $C_Q$  value is significantly lower (1.0 MHz) for a thickness of 2.1 nm (Zn 3 to 12 in Table S6), whereas the minimal  $C_Q$  value of 3.05 MHz for a thickness of 0.78 nm (see Table S4) exceeds that measured experimentally. Therefore, the results obtained using the 1.1 nm thin layer that are consistent with both the TEM measurements and the strong quantum confinement effect observed in the reflectance spectrum, gives us confidence that the DFT model is appropriate in the NMR assignments.

Interestingly, the presence of amines on the ZnS NPIs does not induce a significant shift in the  $^{67}Zn$  NMR signal whether it is  $NH_2Me$  or  $NH_2Et$  (Figure S7, Table S7) with binding energy of 1.10 or 1.16 eV, respectively. However, it strongly reduces the  $C_Q$  value of  $Zn_{3c}$  and  $Zn_{4c}$  surface sites, which vary from ca. 45 MHz (Zn 14 in Table S6) to ca. 12 MHz (Zn 1 in Table S6).

The  $^{67}\text{Zn}$  signal with  $\delta_{\text{iso}}^{\text{exp}} \approx 320$  ppm,  $C_Q = 6.7$  MHz and  $\eta_Q = 0.2$  detected in DNP-enhanced NMR spectrum shown in Figure 6 stems primarily from  $\text{Zn}_{4c}$  atoms located in sub-surface layers of an amine covered ZnS NPLs. These subsurface  $^{67}\text{Zn}$  nuclei must also predominantly contribute to the signal with  $C_Q = 7.5$  MHz in the direct excitation spectrum, whereas the signal with  $C_Q = 10$  MHz must stems from surface sites bound to amine or sub-surface sites of free surface. The signals of  $^{67}\text{Zn}$  nuclei on free surface are too broad to be detected.

To go further in the simulation of the ZnS NPLs obtained by this organometallic route, we included the presence of S vacancies, which seem to be responsible for the PL emission in the UV-blue region (Figure 3). To this end, S atoms have been removed in various positions, from surface, sub-surface and inner layers of the slab (Figure 8b and Figures S8 to S11). The concentration of S vacancies was notably checked by considering supercells of different sizes,  $1 \times 1$  and  $2 \times 2$ , containing a single vacancy, which corresponds to a high (Figure S8, Table S9) and medium (Figure S9, Table S10) concentrations. The discussion refers to 14 layer slabs but results obtained with the 8 layer slabs were similar. A high concentration of S vacancies leads to the formation of  $\text{Zn}_{3c}$  and  $\text{Zn}_{2c}$  local environments, with shielded  $\delta_{\text{iso}}^{\text{calc}}$  values. In particular,  $\text{Zn}_{3c}$  nuclei (bulk S vacancies) have isotropic chemical shifts of approximately 170 ppm (Zn 6 and 7 in Table S10) and  $C_Q$  values between 4.8 and 10 MHz. Nevertheless, this shift can vary from 124 to 215 ppm, depending on the position of the vacancy (198-213 ppm in the 1.1 nm film, Figure 8b and Table S8). These  $\text{Zn}_{3c}$  sites could contribute to the weak signal at 200 ppm in the conventional  $^{67}\text{Zn}$  NMR spectra (Figure 4), even if it can also stems from surface  $^{67}\text{Zn}$  nuclei subject to large quadrupolar interaction. Two-coordinated  $\text{Zn}_{2c}$  nuclei resonate at  $\delta_{\text{iso}}^{\text{calc}}$  shifts ranging from  $-43$  to 35 ppm (17 ppm in the case shown in Figure S8). A full set of NMR data for the S vacancies at high concentration is reported in Table S9. Interestingly, the  $\text{Zn}_{2c}$  sites do

not form if the vacancies are sufficiently diluted (Figure S9, Table S10). The weak intensity around 180-200 ppm in the  $^{67}\text{Zn}$  NMR spectrum (Figure 4) acquired at 35.2 T suggests that the ZnS NPLs contain only a small amount of S vacancies since this spectrum is dominated by signals with  $\delta_{\text{iso}}^{\text{exp}} \approx 310$  ppm. However, as most of the  $C_Q$  values simulated for  $^{67}\text{Zn}_{3c}$  are high (between 1.7 and 15.2 MHz), these species are more difficult to observe than those subject to smaller quadrupolar interaction and as a consequence, their amount can be underestimated. Furthermore, the small thickness of NPLs does not help to evidence vacancies since  $^{67}\text{Zn}$  nuclei near vacancies are subject to larger quadrupolar interaction near surfaces than in the core region (see Tables S8 to S12). Moreover, the intensity of  $^{67}\text{Zn}_{3c}$  signal in QCPMG spectrum may be decreased by the faster decay of their signals during the acquisition compared to other  $^{67}\text{Zn}$  sites. Note also that some  $\text{Zn}_{4c}$  sites located close to the S vacancies (Zn 4 and 10 in Table S9, Zn 25, 26 and 31 in Table S10, Zn 8 in Table S11) have  $\delta_{\text{iso}}^{\text{calc}}$  ranging between 321 to 343 ppm and  $C_Q$  values ranging between 0.6 and 4.2 MHz. For instance, the average  $C_Q$  values of core  $^{67}\text{Zn}$  nuclei in Table S12 is equal to 3 MHz, which is close to 2.5 MHz value measured in the direct excitation spectrum. Finally, the central  $\text{Zn}_{4c}$  sites of ZnS NPLs without defects (Figure 8a, Zn 3 to 6 in Table S5) are predicted to have  $\delta_{\text{iso}}^{\text{calc}}$  above 354 ppm that do not seem compatible with the experimental NMR observations ( $\delta_{\text{iso}}^{\text{exp}} \approx 310$  ppm). These results strongly suggested that the ZnS NPLs most probably include Zn close to S vacancies.

Further proof to strengthen the latter observation was obtained by the simulation of the  $^{33}\text{S}$  NMR signals. The  $\text{S}_{4c}$  atoms of the inner layers have  $\delta_{\text{iso}}^{\text{calc}}$  of  $-593$  ppm and  $C_Q = 0.7$  MHz (Figure 8a, S 4 in Table S5). When thicker layers were considered, the inner  $\text{S}_{4c}$  atoms had chemical shifts closer to those of the bulk microcrystalline wurtzite ( $-564$  ppm in Table 1). For example, the  $\text{S}_{4c}$  atoms in the central layers of Figure S6 possess a  $\delta_{\text{iso}}^{\text{calc}} = -582$  ppm (S 6 and 7 in Table S6). The

$S_{3c}$  atoms of the free surface (Table 1) have  $\delta_{iso}^{calc}$  values ranging from  $-538$  to  $-528$  ppm and  $C_Q = 7$  MHz. The adsorption of  $NH_2Me$  molecules has a considerable effect on the isotropic chemical shift of the surface  $S_{3c}$  atoms as  $\delta_{iso}^{calc}$  becomes  $-599$  ppm (Figure 8a, S 1 in Table S5), whereas the  $C_Q$  value is only slightly affected. Remarkably, the isotropic chemical shift values calculated around  $-600$  ppm are more shielded than the values measured for microcrystalline wurtzite. On the other hand, the  $C_Q$  value of about 7 MHz calculated for the surface sites is consistent with the experimental parameters to simulate the conventional  $^{33}S$  NMR signal ( $\delta_{iso}^{exp} = -621$  ppm,  $C_Q = 5.2$  MHz) in Figure 5 and the DNP-enhanced NMR  $^{33}S$  NMR signal in Figure 7 ( $\delta_{iso}^{exp} = -603$  ppm and  $C_Q = 5.0$  MHz). This strongly suggests that a large fraction of the S atoms is located close to the surfaces where amine ligands are present.

Calculations of  $^{33}S$  NMR parameters for ZnS NPLs containing S vacancies were also performed (see Figures S8 to S11). For high concentrations of vacancy or vacancy aggregations, we found  $S_{4c}$  nuclei near S vacancies with  $\delta_{iso}^{calc}$  of  $-421$  and  $-465$  ppm ( $C_Q = -7.5$  and  $-5.4$  MHz, respectively), as seen in Figure S8 and Table S8. For diluted S vacancies (see Figure S9), the  $S_{4c}$  nuclei near S vacancies exhibit chemical shifts around  $-534$  and  $-561$  ppm, and  $C_Q$  values ranging from  $-5$  to  $-7$  MHz. For a 1.1 nm-thick ZnS slab with adsorbed  $NH_2Me$  molecules (see Figure 8b and Table S8),  $\delta_{iso}^{calc}$  is of  $-411$  and  $-512$  ppm ( $C_Q = -4.8$  and  $-3.8$  MHz, respectively). We can also note that for ZnS NPLs without defects (S 3 to 6 in Table S5), core  $S_{4c}$  nuclei are predicted to have  $\delta_{iso}^{calc}$  between  $-573$  and  $-593$  ppm with small  $C_Q$  values (less than 1.1 MHz) that do not seem to be compatible with the NMR observations, especially for the  $C_Q$  values. Indeed, the presence of defects increase the  $C_Q$  values (between 2.6 and 5.4 MHz) of  $S_{4c}$  nuclei close to the vacancies (S 9 in Table S9, S 23 to 28, 34 and 36 in Table S10, S 9 in Table

S11). Unfortunately, the resolution and the sensitivity of the  $^{33}\text{S}$  spectra at natural abundance even at 35.2 T is not good enough to be able to clearly evidence the  $\text{S}_{4\text{c}}$  nuclei close to S vacancies with deshielded resonances (from - 561 up to - 386 ppm) and high  $C_Q$  absolute values of > 4 MHz. However, the absence of a  $^{33}\text{S}$  signal with weak  $C_Q$  is consistent with the presence of vacancies inside the core of ZnS NPLs.

To summarize, the proposed model consists of a 1 nm thickness ZnS film with coordinated amine ligands, and a low but significant concentration of S vacancies. The majority of Zn sites have chemical shifts ( $296 \text{ ppm} \leq \delta_{\text{iso}}^{\text{exp}} \leq 313 \text{ ppm}$ ) and  $C_Q$  values ( $2.5 \text{ MHz} \leq C_Q$ ) significantly different from bulk  $\text{Zn}_{4\text{c}}$  sites ( $\delta_{\text{iso}}^{\text{exp}} = 365 \text{ ppm}$  and  $C_Q < 0.5 \text{ MHz}$ ) but in agreement with  $\text{Zn}_{4\text{c}}$  sites close to amine bound surface of ZnS and to S-vacancies. The  $C_Q$  value was even higher (6.7 MHz) for the Zn sites closest to the surface evidenced by DNP-enhanced  $^1\text{H} \rightarrow ^{67}\text{Zn}$  *D*-RINEPT experiment. The presence of S vacancies also lowered the  $\delta_{\text{iso}}^{\text{calc}}$  of  $\text{Zn}_{4\text{c}}$  sites close to them (mostly between 320 to 345 ppm) and increased the  $C_Q$  values (between 0.9 and 13.5 MHz) compared to bulk  $\text{Zn}_{4\text{c}}$  sites.  $\text{Zn}_{3\text{c}}$  nuclei in contact to S vacancies were also potentially observed under a weak  $^{67}\text{Zn}$  NMR signal around 180-200 ppm. Due to a lack of resolution and sensitivity even at 35.2 T, the  $^{33}\text{S}$  NMR spectra are less informative. Most of the S sites detected by  $^{33}\text{S}$  NMR have chemical shift and  $C_Q$  ( $\delta_{\text{iso}}^{\text{exp}} = - 621 \text{ ppm}$ ,  $C_Q = 5.2 \text{ MHz}$ ) in agreement with  $\text{S}_{3\text{c}}$  and  $\text{S}_{4\text{c}}$  atoms at or close to amine bound surface of ZnS ( $\delta_{\text{iso}}^{\text{calc}}$  around - 600 ppm,  $C_Q$  up to 6.7 MHz), and significantly different from bulk  $\text{S}_{4\text{c}}$  sites ( $\delta_{\text{iso}}^{\text{exp}} = - 564 \text{ ppm}$  and  $C_Q \sim 0.3 \text{ MHz}$ ). The presence of S vacancies leads also to an increase of  $C_Q$  values (up to 8.7 MHz) for  $\text{S}_{4\text{c}}$  sites close to them but should additionally lead to an increase of  $\delta_{\text{iso}}^{\text{calc}}$  (up to - 386 ppm). Overall, our model of ZnS NPLs of about 1 nm with coordinated amine ligands and S vacancies reproduces the

majority of the NMR data and is consistent with the results of the optical and conductive properties. In particular, the presence of S vacancies is supported by experimental  $^{33}\text{S}$   $C_Q$  constant value and  $^{67}\text{Zn}$  isotropic chemical shifts, higher and lower, respectively, than those calculated for ZnS nanoplatelets devoid of S vacancies (see Table S5), but also by the observation of  $^{67}\text{Zn}$  signal near 200 ppm and efficient photoluminescence emission in the UV-blue region (Figure 3).

## CONCLUSIONS

In this work,  $^{67}\text{Zn}$  and  $^{33}\text{S}$  solid-state NMR experiments at ultra-high-fields and DNP experimental data coupled with DFT calculations allowed for the first time to propose a structural model in full agreement with the observed optical and conductive properties of ZnS nanoplatelets. This nanomaterial obtained by an organometallic approach under mild conditions consists of ZnS nanoplatelets with a thickness of 1 nm covered by dodecylamine. These nanoplatelets contained defects based on sulfur vacancies and their presence was evidenced in photoluminescence and electrical resistance measurements. Furthermore, this study represents a step towards the use of NMR spectroscopy coupled with DFT calculations for a better understanding of the structure-properties relationship of metal sulfide nanocrystals, a very large family of materials with broad potential uses.
