17 ***ABSTRACT***

18 The main drivers of Europe's climate during the Holocene result from the coupling and interplay
19 of external and internal radiative processes with the shifting patterns of many dynamic
20 components (e.g. glaciers, ocean currents, wind fields, vegetation cover). Those driving forces
21 were expressed across a range of geographical scales, from local to global, in a diverse set of
22 records forming a patchwork of evidence as to the fundamental pacing effect of climate on past
23 ecosystems. Various sedimentary deposits resulting from those complex forcing contexts bear
24 climatic signatures that it is not always easy to disentangle especially with respect to local
25 factors.

26 The present paper focuses on a coastal archaeological site on the Medoc peninsula (the Lède du
27 Gulp site in south-western France) that records Holocene palaeoenvironmental changes, decoded
28 here century after century and integrated with ongoing events on a pan-North-Atlantic scale.
29 Based on updated geoarchaeological approaches, thanks to new applications of proxies,
30 especially X-ray fluorescence (XRF) core scanning methods for this article, continuous
31 sedimentary records have been analysed in order to reconstruct a regional framework for past
32 ecosystem events, including events potentially related to human activity. Our work identifies
33 signals on various scales in the record under study, with both long- and short-term trends and
34 local and global imprints, but all closely bound up with proximal North Atlantic Ocean
35 dynamics. It highlights how western European environments (and so populations) were
36 dependent upon the linearity of climate evolution at the key Northgrippian/Meghalayan
37 transition.

40 Holocene; Neolithic; Climate dynamics; North Atlantic Ocean; Sea-surface conditions

41

42

43 1. Introduction

44 The question of the climatic determinism of the evolution of human societies is still much debated in
45 the scientific community. However, throughout the Holocene (last ~11.7 ka cal BP, e.g. [Walker et al.,](#)
46 [2019](#) and references therein), much evidence points to a close connection between human behaviour
47 (e.g. habitats, techniques, cultures, practices) and climatic conditions (e.g. [de Menocal, 2001;](#)
48 [Ruddiman and Thomson, 2001;](#) [Mayewski et al., 2004;](#) [Ruddiman et al., 2016](#)). The increase in the
49 number of human settlements largely coincides with the onset of the mid-Holocene (6–7 ka BP)
50 when the melting of boreal glaciers, global temperatures and sea level all stabilized (from [Jansen and](#)
51 [Björklund, 1985](#) to [Eynaud et al., 2018](#) and references therein). Those events are related to well-
52 known climatic subdivisions, with the termination of the warm (hypersothermal) Atlantic period (e.g.
53 [Jansen and Björklund, 1985](#)), recently included within the Northgrippian stage (e.g. [Walker et al.,](#)
54 [2019](#)), and corresponding to the cultural Mesolithic-Neolithic transition in Western Europe. The
55 Anthropocene, *sensu lato* (i.e. including the early Anthropocene hypothesis, see [Ruddiman et al.,](#)
56 [2011;](#) [Waters et al., 2018;](#) [Zalasiewicz et al., 2018](#)), introduces a new phase, with landscape and
57 habitat stability becoming highly random (still poorly evaluated) as a result of global climate
58 perturbations induced by mankind (e.g. [Ruddiman and Thomson, 2001;](#) [Crutzen, 2002;](#) [Steffen et al.,](#)
59 [2011;](#) [Waters et al., 2016;](#) [Zalasiewicz et al., 2018;](#) see also [Lambert et al., 2018](#) for an illustration
60 involving estuaries in north-western France).

61 It becomes essential, then, to test to what extent the dynamics of human populations are constrained
62 by climatic hazards, with their direct and indirect environmental corollaries. This question requires a
63 long-term (multi-millennial) perspective, which alone can provide access to time scales revealing
64 environmental thresholds and shifts that potentially affected (and even constrained) populations. In
65 this way, retrospective views are essential and make it possible to line up archaeological knowledge,
66 often of a diachronic character, alongside the Earth's natural reference system. This is one key
67 objective of palaeoclimatology, together with the extending of data beyond the brief time span of

68 instrumental records (and beyond biases arising from modern-day anthropogenic effects). Another
69 crucial objective is to draw up an inventory of past climatic situations, analogous to or contrasting
70 with the current period, to provide a clearer understanding of natural climate sensitivity and its
71 natural envelopes of variability from local to global scales (e.g. [Rehfeld et al., 2018](#); [Penaud et al.,](#)
72 [2020](#)).

73 On millennial scales, the dominant natural climatic modes still have to be detected: their
74 characterization being critical to improving the predictive capacities of climate models ([Liu et al.,](#)
75 [2014](#); [Hernandez et al., 2020](#)). This endeavour has recently led to major works on the compilation
76 and inter-comparison of climate series targeting the recent Holocene period in particular, i.e. the last
77 two millennia ([Kaufman et al., 2020](#); [PAGES 2k Network, 2013](#); [McGregor et al., 2015](#)). Solar and
78 volcanic activity (historical period) have been demonstrated to be key drivers, as has anthropogenic
79 activity for the most recent periods (e.g. [Ruddiman et al., 2011, 2016](#)). The Holocene has long been
80 viewed as a stable period compared to the last glacial (e.g. [Rehfeld et al., 2018](#)) and only a few
81 notable cold episodes due to drift-ice advection events mainly from the Labrador Sea and Arctic
82 Ocean have been identified as significant (known as Bond events, [Bond et al., 1997, 2001](#), or “Rapid
83 Climate Change” events (RCCs) of [Mayewski et al., 2004](#), including the 8.2 ka cal BP event; see also
84 [Fernane et al., 2015](#); [Penaud et al., 2020](#) for a synthesis for France). Studies conducted throughout
85 northern Europe reveal periods of severe storms during the Holocene (e.g. [Goslin et al., 2018a and b,](#)
86 [2019](#)), and such events, which are especially well highlighted in Brittany (e.g. [Van Vliet Lanoë et al.,](#)
87 [2014](#)), have mostly been linked with cold periods, even locally in south-west France where our study
88 is focused ([Clarke et al., 2002](#); [Bertran et al., 2020](#); [Bertran and Fouéré, 2020](#)). Storm frequency has
89 also been related to one of the most significant modes of climate variability in the northern
90 hemisphere, the North Atlantic Oscillation (NAO), and to AMOC (Atlantic Meridional Overturning
91 Circulation) dynamics (e.g. [Sorrel et al., 2012](#); [Goslin et al., 2018a and b, 2019](#); [Hernandez et al.,](#)

92 2020). However, the processes that govern these infra-orbital climatic instabilities are still subject to
93 discussion.

94 The present work similarly aims to detect and account for Holocene palaeoenvironmental changes,
95 with special consideration of scaling effects in those processes, ranging from local to synoptic views.

96 The paper takes advantage of a dual approach combining climate history and human history. This is
97 done by way of two overlapping lines of study, with the twofold exploitation of: (1) a coastal
98 sedimentary accumulation feature recording the presence of human activity from Mesolithic and
99 Neolithic times (e.g. Verdin et al., 2019a), in addition to high-resolution facies variability, that is
100 directly comparable with (2) reference archives from which a tentative reconstruction of Holocene
101 climatic modes can be made (especially work derived from the ANR HAMOC, see
102 acknowledgments).

103 The main events consistent with records for the proximal Bay of Biscay will be highlighted here
104 together with the extent to which they are in phase with indices of climatic oscillations detected on a
105 broader spatial scale.

106

107

108 **2. The exceptional Lède du Gulp record**

109 The Lède du Gulp (LDG) site is an archaeological site buried under modern dunes along the western
110 shore of the north Medoc peninsula, on the administrative boundary of the towns of Soulac-sur-Mer
111 and Grayan-et-l'Hôpital (Figure 1). This site is currently subject to chronic erosion, typical of
112 Aquitaine coastal zones associated with a river mouth (Gironde estuary). The area has been studied
113 by archaeologists since the mid-20th century and high-resolution excavations were conducted
114 between 1972 and 1999, especially on the topmost layers dated from the Iron Age (Hallstatt
115 civilization) where evidence of a local industry (and even habitats) dedicated to salt production was

116 reported (e.g. [Frugier, 1972, 1975](#); [Roussot-Larroque and Villes, 1988](#)). The archaeological site
117 probably covered as much as half a hectare (i.e. 5000 m²) judging by the local rate of erosion (close
118 to 10 m/year, e.g. [Aubié and Tastet, 2000](#)) and the discoveries of human artefacts in the vicinity,
119 reported both in the intertidal zone and in nearby depressions within the modern supratidal dunes. In
120 2014 drastic erosion of the shore and the dune front left a circular residual butress (relief inversion,
121 [Figure 1c](#)) some 15 m in diameter and about 4 m high, made up of an accumulation of peaty and
122 sandy mud (see [Faye et al., 2019](#); [Verdin et al., 2019a](#)). Rescue excavations were undertaken in
123 October 2014 revealing an extraordinary archaeological content ([Verdin et al., 2016, 2019a and b](#))
124 and allowing the recovery from the butress of continuous vertical sedimentary sequences up to 3 m
125 in length. A large set of analyses was applied to the recovered sequences (see [Faye et al., 2019](#) for the
126 whole array of acquired data and detailed description of the studied records) and revealed an
127 uninterrupted high-resolution record for the last 10 ka. The present work follows on from [Faye et al.,](#)
128 [2019](#) and [Verdin et al., 2019a](#), which presented in detail the geology and sedimentology of the LDG
129 site, and the stratigraphic and archaeological contexts, respectively. Additional radiocarbon datings
130 ([Table 1](#)) enable us to focus here on climate-related proxies (especially those of palynological
131 analyses and high-resolution X-ray fluorescence - XRF scanning for major element quantification) in
132 a robust chronostratigraphic framework (9–3 ka interval). The sedimentological context of the
133 residual butress from which the sequences were retrieved is linked to a circular depression within
134 blue-grey clayey-sands (completely eroded in 2014), infilled with argillaceous (and some
135 arenaceous) peaty deposits to a depth of approximately 4 m, since 10.5 ka BP at least; this age being
136 the oldest obtained by drilling (labelled SC1 in [Table 1](#)) in the deeper part of the peaty clays before
137 their transition with the blue-grey sandy deposits surrounding and delimiting the peaty depression. It
138 is assumed the depression was formed in an inner estuarine marshland in a context of karstic erosion,
139 possibly forced by thermokarstic processes (see [Faye et al., 2019](#) for a discussion of this hypothesis)
140 considering the age obtained for the basal section of the record.

141 This new high-resolution Holocene record makes it possible to document long- and short-term
142 palaeoenvironmental variations both locally and globally. In line with ongoing efforts by the
143 palaeoclimatology community to compile past climatological records from diverse settings (e.g.
144 [Kauffman et al., 2020](#), see also for instance existing sequences within the framework of the European
145 pollen database, <http://www.europeanpollendatabase.net/fpd-epd/bibli.do>, or work compiled for the
146 last 2 ka: <https://pastglobalchanges.org/science/wg/2k-network/scientific-goals>), it may provide key
147 signals in a context of growing human influence throughout the last millennia, helping us to identify
148 natural and anthropogenic shifts that have driven changes in European landscapes.

149

150 **2.1. Methods**

151 The detailed sampling protocol in the field together with the details of laboratory analyses of the
152 sediment sequences LDG-G3 (-1.154745; 45.466222) and LDG-G4 (-1.154759; 45.466085) are
153 described in [Faye et al. \(2019\)](#). Briefly, after the recovery of sections several metres in length
154 (continuous slab-composite sequences based on Nx25 cm long aluminium slides, with N=11 for
155 LDG-G3 and N=9 for LDG-G4, respectively) from the bottom to the top of the buttress, non-
156 destructive (scanning, using classic and X-ray imaging, coupled with spectroradiometry and XRF
157 measurements) and destructive analyses were conducted at the EPOC laboratory (see [Faye et al.,
158 2019](#)). The latter comprised a complete sub-sampling of sediment sections at 1 cm intervals for
159 sieving (at 150 μm) of the samples in order to determine their lithology and biostratigraphy (with
160 grain-size analyses of raw samples, visual description of the sandy > 150 μm fraction, radiocarbon
161 datings – [Table 1](#), and palynological processing and analyses for the < 150 μm fraction).

162 The results presented and discussed here were compiled by age after the construction of independent
163 age scales for the LDG-G3 and LDG-G4 sequences (hereafter referred to as G3 and G4) based on 4
164 and 5 datings for each, respectively. Those chronological markers presented no reversals along the
165 sequences ([Figure 2](#)) and the global stratigraphy of the site covered at least the last 10.5 ka cal BP.

166 This was confirmed by separate datings obtained on organic archaeological remains (see [Verdin et](#)
167 [al., 2019a](#) and [Faye et al., 2019](#)). Age models were obtained by a polynomial regression (order 3). To
168 validate this approach, age-depth models were also produced with the “Undatable” age-depth
169 modelling routine ([Lougheed and Obrochta, 2019](#)) providing very similar age-model equations (not
170 used in the following, but their 1σ and 2σ envelopes are plotted in [Figure 2](#) to illustrate the
171 coherence of the methods).

172 Statistical analyses were conducted on XRF ratios (variables being the element/SUM ratio, the most
173 common way to normalize raw XRF cps data, and equivalent to relative percentages) to validate the
174 interpretation of the elemental changes detected. Those analyses were performed with PAST software
175 (PAleontological Statistics, Hammer et al., 2001). Our multivariate analysis based on an ordination
176 method, principal component analysis (PCA), was supplemented by ternary plots also provided by
177 PAST tools to better understand the significance of the highest scores on the main components.

178 Holocene sea-surface hydrographic conditions from the proximal southern Bay of Biscay PP10-07
179 core, used here for a comparison with the LDG signals, were reproduced from earlier works by [Mary](#)
180 [et al. \(2017\)](#) and [Eynaud et al. \(2018\)](#). Reconstructed hydrographic data were derived from
181 planktonic foraminifera assemblages after the MAT1007 transfer functions developed at EPOC (see
182 [Eynaud et al., 2018](#) for a review of this approach). For this article, past sea-surface salinities (SSS)
183 were added to sea-surface temperature (SST) information thanks to an update of the modern
184 hydrographical database (mainly after the World Ocean Atlas 2013;
185 <https://www.nodc.noaa.gov/OC5/woa13/woa13data.html>, see methods in [de Vernal et al., 2020](#)). This
186 update enabled us to robustly reconstruct SSS on the basis of planktonic foraminifera (Root mean
187 square error of prediction of 0.7 psu).

188

189 **2.2. Main results and interpretation perspectives of the recorded signals**

190 XRF data from the G3 and G4 sequences have been compared systematically (when data co-exist) as
191 the parallel between them provides very important information as to whether the records are coherent
192 and complete. Actually, because of the large number of human artifacts found within the buttress
193 during excavation, including wattle-work structures of a metre or so in size (Verdin et al., 2019a,
194 López-Romero et al., 2021), doubts have arisen about whether the stratigraphy is continuous. The G3
195 and G4 sequences retrieved were some 15 metres apart (Figure 1), at the southern and northern ends
196 of the buttress, respectively. Figures 3 and 4 show that, whatever the elemental ratio or concentration
197 considered (as seen with the ratios for Fe/SUM in Figure 3b, S/SUM in Figure 3h, and Ti/SUM in
198 Figure 4f), few discrepancies are to be found between the records whether in depth (see Faye et al.
199 2019) or age (despite independently built age-models). This confirms that the LDG site stratigraphy
200 obtained is not only robust but also that it was not impacted by past human activities, at least on its
201 outer edges.

202
203 By means of the diverse proxies, the studied records provide a detailed account of local
204 environmental changes (linked or not to human influences, see Faye et al., 2019 for further details on
205 the sedimentology of the sequences analysed) over the time window from 9 to 3 millennia (ka) before
206 the present (cal BP, i.e. ~7 to 1 ka cal BCE/CE). As underlined in Figures 3 and 4, the most
207 noticeable features encountered in those records are related to stepwise changes in most of the
208 proxies. These changes reflect well-known environmental events within the Holocene and can be
209 sequenced consistently with the climatic history of this period, with from the base to the top of the
210 sequence:

211 – A first period of 3 millennia (from 9.4 to 7.1 ka cal BP) that records rapid but moderate amplitude
212 changes in the proxies studied and so in the environmental contexts of the deposits. In the study area,
213 that period was one of dense forest cover (Figure 3d) with predominantly deciduous *Quercus* (Figure
214 3j) and a moderate contribution of *Pinus* trees (Figure 3f). This part of the early Holocene (the

215 Greenlandian, [Gibbard, 2018](#), also corresponding to the preboreal and boreal chronozones, [Figure 4](#)
216 still records significant climate changes mainly due to melt-water pulses associated with the retreat
217 and melting of boreal ice-sheets (e.g. [Elmore et al., 2015](#); [van der Bilt et al., 2015](#)). We have chosen
218 to illustrate the regional expression of this decay in the declining volcanic activity in the Massif
219 Central ([Figure 4h](#)) which may have caused lithospheric relaxation.

220 – A transitional period, between 7.1 and 6.1 ka cal BP, where all the proxies record radical shifts
221 with marked excursions ([Figure 3](#)). None of the records depict similar values either before or after
222 that period, and the changes are especially drastic for pollen assemblages ([Figure 3d-e-f and 3j-k](#)) and
223 the K/SUM, S/SUM, Ca/SUM, Br/SUM ratios ([Figure 3g-h-i and 3c](#)). Two peaks in *Pinus* pollen
224 bracket this short interval ([Figure 3f](#)). They are found along with a major decline in forest cover but
225 they may also indicate strong winds (the preferential mode of dispersion of *Pinus* pollen grains)
226 across the study area. This interval is also characterized by the largest values observed in the Fe/SUM
227 record ([Figure 3b](#)) and by an excursion in the Br/Si signal in G3 ([Figure 4e](#)). Those observed changes
228 are contemporaneous with mid-Holocene sea-level stabilization and precede the dip in insolation
229 after 6 ka (e.g. [Lorenz et al., 2006](#)) and then the period known as the Neoglacial cooling in the
230 northern hemisphere ([Figure 4](#)).

231 – Finally, the 6.1 to 3.4 ka cal BP period exhibits relatively flat records with rare excursions of the
232 proxies from their background values, except between 5.4 and 4.8 ka cal BP, where moderate to high
233 amplitude peaks are detected in granulometry ([Figure 3a](#)) and in the Fe/SUM, K/SUM ([Figure 3b-g](#))
234 and Br/Si signals of G3 especially ([Figure 4e](#)). The decline in forest cover is confirmed and attested
235 by the corresponding expansion in grassland ([Figure 3d-e-f-j-k](#)). The period encompasses the
236 Northgrippian-Meghalayan transition ([Gibbard, 2018](#); [Walker et al., 2019](#); [Curran et al., 2019](#)) and is
237 marked locally by the onset of dune build-up along the Aquitanian coast, although dune migration
238 and invasion peaked later ([Tastet and Pontee, 1998](#); [Clavé, 2001](#); [Clarke et al., 2002](#); [Stéphan et al.,](#)

239 [2019; Bertran et al., 2020; Bertran and Fouéré, 2020](#)), during historical times (not covered by our
240 records).

241

242 Apart from this distinct time division within the records compiled for the Holocene, the most
243 significant result is that local changes detected in the XRF-derived data fit quite well, both in their
244 pacing and amplitudes, with those relating to a hemispheric or even global climatic signature.

245 These common detected trends argue for large scale processes imprinted within the records, despite
246 numerous local geomorphological evolutions in the vicinity of the LDG site, that one can imagine to
247 be factors of bias in its sedimentology, but which, visibly here, do not overprint or obliterate regional
248 (i.e. the North Atlantic province) signals and global scale forcings.

249 [Figure 4](#) especially underlines the fit between LDG records and Holocene chronostratigraphic and
250 climatological reference frameworks. These frameworks have been extensively supplemented over
251 the last 20 years (see the number of existing records in the compilation in [Kauffman et al., 2020](#))
252 pointing out the strength of regionalism in the detected signals, and showing that climate is not the
253 result of a single ruling component. Furthermore, uncertainties in those reconstructions are not
254 failures in comprehending the system but rather proof of its extraordinary complexity. Local signals
255 are a mixture of environmental interplay and the unravelling of the associated factors at play is
256 critical to an understanding of changes in past ecosystems.

257

258 **3. From a local to a global perspective**

259 The LDG archaeological site thus extends our knowledge by providing an opportunity to test the
260 synchronicity of well-known Holocene climatic and environmental events on France's south-west
261 coast at a site that captured influences of natural ecosystem changes and growing anthropic pressure.

262 The reconstructed history may thus yield new information about the co-evolution of local natural
263 habitats and human trajectories within the framework of major climatic trends.

264

265 **3.1. Significance of the information recovered from the LDG archaeological site: What are**
266 **we recording?**

267 Sedimentary records integrate different physical and biogeochemical processes occurring on various
268 scales of time and space. Detecting climate events in such records is a complex matter and calls for
269 the local window of study to be opened up to broader contexts, to avoid misinterpretation or
270 misdetection in the environmental history. Here the perspective is thus drawn on the scale of the
271 Atlantic basin, which is known to concentrate various kinds of systemic response because of its key
272 role in the natural evolution of climate. Several records were selected to support our approach (Figure
273 4): they are distributed from pole to pole and selected so that events occurring during the Holocene
274 can be viewed against a regional or global background.

275 Local signatures and proxies reflect long-term climatic variations throughout the period under study.
276 This is especially true when comparing temperature signals, both on large geographical scales and for
277 more proximal systems (here SST of the southern Bay of Biscay). Our analyses show that the
278 K/SUM ratio seems to follow summer SST trends as reconstructed for the eastern tropical Atlantic
279 Ocean (Figure 4c and j). Similar coherence is observed for the Ti/SUM ratio, which fits neatly within
280 the envelope of global mean temperature anomalies (as compiled by Marsicek et al., 2018, Figure 4f
281 versus 4m). The Mn/SUM and Br/Si ratios similarly track the long-term evolution of summer SSTs
282 as reconstructed for the Bay of Biscay with, especially, a very flat signal after 6 ka cal BP (Figure 4d
283 versus 4k and Figure 4e versus 4l). Between 9 and 3 ka cal BP, the AP/NAP (arboreal – including
284 *Pinus*/non arboreal pollen) ratio shows the same declining values towards the present as those of the
285 global concentration of atmospheric methane (Figure 4g versus 4n). This observation may relate to a
286 close connection between vegetation dynamics and the global methane budget (i.e. from Sánchez-

287 [Goñi et al., 2008](#) to [Beck et al., 2018](#)). However, the question of the latitudinal position of methane
288 sources and related vegetation type contributions is still open, especially for the Holocene, and is
289 furthermore puzzling with regard to the “early anthropogenic hypothesis” (e.g. [Ruddiman and](#)
290 [Thompson, 2001](#)). There are signs of forest clearance at the LDG site as early as 7 ka ([Figure 3d-e-f-](#)
291 [j-k](#)). Unfortunately the LDG records do not yield data for the last 3 ka. Therefore our study does not
292 encompass the mid-to-late Holocene rise seen in methane concentrations and attributed to the land-
293 use changes and forest clearance concomitant with agricultural development ([Tzedakis, 2010](#);
294 [Ruddiman et al., 2016](#)).

295 The LDG sequences reveal several short-lived events superimposed on this early to mid-Holocene
296 trend. Some of these events are directly reflected in the compiled reference records, while others
297 appear to be exclusively local. The early Holocene especially records larger amplitude fluctuations
298 with three short but prominent peaks (maximum of 150 years’ duration) which are clearly visible in
299 the Zn/SUM ratio ([Figure 4b](#)) at 8.7, 8.3 and 8.1 ka cal BP. Those peaks reflect sudden SST changes
300 in the proximal Bay of Biscay ([Figure 4k](#) and [4l](#)) with significant warmings in annual SST (up to
301 8 °C, [Figure 4l](#)) at 8.7 ka cal BP. The last two peaks bracket the well-known cold “8.2 ka event” of
302 the NGRIP stratotype ([Figure 4i](#), [Vinther et al., 2006](#); [Rasmussen et al., 2006](#)) related to the complete
303 disappearance of the Laurentian ice cap with the drainage of Lake Agassiz (e.g. [Clark et al., 2001](#))
304 that ended the Greenlandian ([Walker et al., 2019](#)). This spiky and noisy signal, well expressed in the
305 Zn/SUM ratio ([Figure 4b](#)), continues with recurrent events every 2 to 3 centuries up to 6 ka and then
306 flattens. This flattening seems to mark nearly all the records and is also seen in the proximal Bay of
307 Biscay, with mean annual SSTs reaching stable modern values (close to 14 °C, [Figure 4l](#)). This
308 stability is also confirmed for regional summer SST anomalies ([Figure 4k](#)) at the distal Cape Verde
309 tropical site ([de Menocal et al., 2000](#), [Figure 4a](#)), with anomalies remaining close to zero, suggesting
310 steady climatic conditions over the North-Eastern Atlantic. Two late events can, however, be pointed
311 out (especially seen in the Fe/SUM and K/SUM ratios): they occur at 5.4 and 4.8 ka respectively

312 (Figure 3b and g and 4c), in a warm context as inferred from the related temperature records, and are
313 well circumscribed within the LDG site (corresponding also to brief lows in CH₄ concentration)
314 where they delimit a sand deposition event as measured in G3 (Figure 3a).

315

316 The changes highlighted at the local LDG site thus illustrate the change in sediment facies (see also
317 Faye et al., 2019 for the interpretation of grain-size data in the LDG records), occurring consistently
318 with environmental change. But what is the genetic link between the proxies used and climate? Since
319 the generalization of XRF core scanning tools, many attempts have been made to identify the
320 significance of elements in diverse sedimentary contexts (see especially the compilations in Croudace
321 and Rothwell, 2015; Croudace et al., 2019; for the organic matrix at the LDG site, see also Longman
322 et al., 2019). The most significant ratios in the LDG record (as deduced from the PCA analysis of G3
323 and also seen in G4) include the Fe/SUM, Ca/SUM, K/SUM, Si/SUM and S/SUM ratios. All of these
324 display high scores (negative and positive) for the two first components, accounting for 96% of the
325 variance (Figure 5). Ternary plots were drawn in addition to identify the sedimentological
326 significance of key ratios (Figure 5b). However, as previously illustrated with Figures 3 and 4, other
327 ratios of low weight in the PCA (Zn/SUM, Mn/SUM, Ti/SUM and Br/Si) should not be ignored as
328 they also clearly reflect environmental changes. Classically, in siliciclastic sediments from the North
329 Atlantic region, Ti, K, Si and Fe abundances are related to terrigenous inputs while Ca, Sr, S and Br
330 are related rather to biogenic production (e.g. Richter et al., 2006; Rothwell and Croudace, 2015;
331 Mojtahid et al., 2019; Longman et al., 2017, 2019). Additionally, S is often used as a proxy for
332 oxygen depletion/anoxia (Rothwell and Croudace, 2015).

333 In a similar coastal context (mouth of the Rega Valley, Baltic Sea), Harff et al. (2011) interpret
334 Holocene lithological facies by PCA analysis also performed on XRF data, attributing high
335 concentrations of K and Ti to high terrestrial discharge, whereas low K and Ti are associated with
336 increasing pelagic deposition together with a potential imprint of aeolian dust inputs. This scheme is

337 of course basin-dependent and the drainage valley of the Gironde and its surrounding geological
338 formations are quite different, preventing us from making a similar direct interpretation for our study
339 site. It can be further complicated by the large amount of organic matter (peaty facies) in our record.
340 However, considering a very recent Holocene study conducted in similar peaty sediments, and
341 despite a highly specific environment, namely the Mohos volcanic crater (Eastern Carpathians,
342 Romania; Longman et al., 2017), K and Ti concentrations (supplemented by Si concentrations) were
343 again evoked as key elements for monitoring deposition fluctuations in dust sources (ranging from
344 proximal loessic provenances to distal Saharan ones). In a Danish coastal lake (Filso), closed by sand
345 dunes during the Holocene, Goslin et al. (2017, 2018a and b, 2019) identify Mn, Fe and S as opposed
346 to Si and K. They attribute this contrast to a sandy origin associated with a river source characterized
347 by high Mn, Fe and S contents, whereas beach and dune sands are identified by high Si and K values.
348 Again, this interpretation is specific to their study area, but it is comparable to observations made on
349 the basis of LDG-G3 data, except for Ti, which is very scarce in our record. This is also consistent
350 with the geochemical analyses documented at the scale of the Aquitaine basin in Sitzia et al. (2017)
351 for fossil aeolian deposits: with K and Si found in aeolian sands and Ti in their analysis bearing a
352 signature related to loess and the fine fraction of cover-sands. In the LDG-G3 record, K and Si
353 content are positively correlated on PC1 and PC2, forming one common pole. Mn and S exhibit
354 contrasting polarities, and are negatively correlated on PC1 and PC2 (Figure 5a). Fe is the most
355 abundant element with a high negative score on PC2 (whereas its score is moderately positive on
356 PC1, Figure 5a) and contrasts with Ca (with a high negative score on PC1). The (Si+K)/Fe ratio can
357 therefore be here used as a tracer of sand blows over the LDG site.

358 Fe is a redox-sensitive element; to ascertain its degree of mobility in our record, correlations can be
359 tested between what are considered to be immobile (Ti) and mobile (K) elements. Actually,
360 according to Rothwell and Croudace (2015), high correlation between Ti and Fe and between Ti and
361 K indicates “that the downcore distribution of those elements is mostly unaffected by post-

362 depositional mobilisation via groundwater leaching and/or organic activity”. In G3, we obtained a
363 high correlation between Fe and Ti (R^2 : 0.9162) and between Ti and K (R^2 : 0.9347).

364 At the LDG site, other significant trends in elements, as identified in [Figure 4](#), include: (1) Mn/SUM
365 and Br/Si match the low amplitude evolution of SST in the Bay of Biscay whereas K/Sum matches
366 changes from the tropical site ODP658; (2) Ti/SUM, although low, matches global mean temperature
367 anomalies. Those elements therefore point to a direct/indirect link with the North Hemisphere
368 climatic regimes that we examine further in the next section.

369

370 **3.2. Forcing at play and teleconnections on the pan-Atlantic scale during the Holocene**

371 In order to synthesize information yielded by the LDG records and integrate it into a genetic
372 perspective of environmental pressures at play, we compiled a final figure ([Figure 6](#)) comparing the
373 respective loadings on PC1 and 2 (and their related key elemental ratios and proxies in the LDG)
374 with reconstructions of various forcings over the period of interest. Those forcings are classified so as
375 to describe trends which reflect:

376 – a long term evolution, as seen with PC1 ([Figure 6e](#)), here compared with the emblematic SST
377 record from the Scotian margin (north-western subpolar Atlantic) after [Sachs \(2007, Figure 6k\)](#), used
378 in several compilations for Holocene climatic changes ([Marcott et al., 2013](#); [Marsiceck et al., 2018](#));
379 – sub-millennial variability imprinted in PC2 ([Figure 6f](#)) and here compared with the Atlantic
380 storminess record reconstructed from Danish records by [Goslin et al. \(2018a and b, Figure 6c\)](#), Arctic
381 glacier activity detected in the sensitive region of Svalbard after van der [Bilt et al. \(2015, Figure 6a\)](#),
382 and the proximal sea-surface conditions in the Bay of Biscay (Cap-breton canyon terrace record,
383 some 200 km from the LDG site, [Eynaud et al., 2018, Figure 6i](#)).

384 A striking correspondence between climate modulations over the Holocene is thus detectable for the
385 various sites in the compilation over both the short and the long term (despite the use of different
386 dating methods). This reinforces previously raised observations (also illustrated in [Figures 3 and 4](#))

387 and demonstrates that the LDG site has recorded the combination of local and distal climatic shifts,
388 emphasizing the high degree of coupling and teleconnections driving environmental changes during
389 the Holocene around the North Atlantic Ocean.

390 Many modern-day modes of climatic variability (namely for our zone, the NAO, Atlantic
391 Multidecadal Variability/Oscillation: AMV/AMO, Northern Annular Modes: NAM also named the
392 Arctic Oscillation: AO) have already been evoked to explain Holocene variability. All infer a strong
393 coupling between the atmosphere and Atlantic Ocean dynamics (e.g. [Curan et al., 2019](#); [Hernández et
394 al., 2020](#)) especially along the track of westerlies. Here, we illustrate this coupling by sea-surface
395 salinity (SSS) reconstructions for the southern Bay of Biscay ([Figure 6i](#)), those SSS values
396 remarkably reflecting the storminess index of [Goslin et al. \(2018a and b, Figure 6c\)](#), with high SSS
397 values corresponding to high storminess. The genetic link explaining this correspondence, intrinsic to
398 ocean/atmosphere couplings, lies also in teleconnections that are not easy to disentangle, and
399 potentially convergent and interrelated processes: wind tracks and stresses over the ocean, dynamics
400 of the North Atlantic gyres driving saline incursions in the Bay of Biscay (from the south and the
401 north as well potentially), precipitation changes over Europe, Mediterranean outflow (MOW)
402 modulations (e.g., [Lozier and Stewart, 2008](#)), all affecting the balance of modern-like modes (see the
403 recent article of [Montoya Duque et al., 2021](#), trying to find a genetic link between midwinter
404 European climate and storm tracks).

405 The mid-Holocene transition marks a critical shift in the records, as is well expressed in PC1
406 especially, objectively related to the well-known cooling trend following the climatic optimum after
407 the stabilization of boreal glacier melting and of the sea-level rise to its modern level, but not only
408 that. In many western European records, climatic deteriorations then intensified. This corresponds
409 roughly to the onset of primary dune aggradation in the bas-Médoc which culminated between 5 and
410 2 ka BP with prominent migration phases during historical times ([Tastet and Pontee, 1998](#); [Bertran et
411 al., 2020](#); [Bertran and Fouéré, 2021](#)). The progressive influence of dune invasions and migrations

412 along the Aquitanian coast may be expressed throughout the LDG records. It is suggested that active
413 phases of dune building occurred during negative NAO-phases and in relation to the availability of
414 sedimentary material (Clavé, 2001; Clarke et al., 2002; Van Vliet Lanoë et al., 2014; Bertran and
415 Fouéré, 2021). It is worth noting that the mid-Holocene also corresponds to accelerated regression
416 (clearance?) of European forests (as recently underlined on a regional Atlantic scale by Penaud et al.,
417 2020 and also seen locally, Figure 3d-e-f-j-k, Figure 6d) and thus that dune aggradations may also be
418 related to biorhexistasy effects.

419 This mid-Holocene shift has been observed in many records on the basis of many different proxies
420 (both marine and terrestrial); mechanistically it was often related to geographical shifts in the NAO
421 centres or related modes (e.g. Mauri et al., 2014), but no consensus really exists to identify a rather
422 positive or negative NAO-like configuration after or before. Probably, the stabilization of ice-sheet
423 melting rates at that time, as a corollary to steady sea-levels and few changes in the altimetry of
424 residual boreal ice-sheets, may have promoted the onset of modern climatic modes coupling
425 atmospheric and oceanic dynamics in the North Atlantic province. However, the literature contains
426 too few reconstructions of NAO, AMO or AMOC variability for the mid-Holocene transition to
427 generalize a pattern regarding those modes.

428 The following sub-millennial changes are furthermore difficult to relate to natural climatic shifts
429 alone, as anthropogenic influences increased with the settlement of Neolithic populations
430 (synchronously thus with the mid-Holocene shift). The LDG record provides new evidence when
431 looking at the related PC2 proxies (bottom part of Figure 6: b, f, g, h). Actually, the striking
432 coevolution of those local proxies with Svalbard glacier advance indexes (van der Bilt et al., 2015,
433 Figure 6a) between 6 and 3 ka cal BP, argues for common drivers in both temperate and boreal
434 latitudes. Furthermore those drivers had to be capable of generating a rapid transfer of perturbations,
435 as the most abrupt ones detected occurred in less than a century. Four events are especially noticeable
436 regarding their synchronicity: at 5.4, 4.8, 4.2 (a well-known Holocene climatic event, e.g. Jalali et al.,

437 2019), and even at 3.3 ka, the termination of the G3 record being due to the recovery of a highly
438 peaty facies preventing us from collecting an undisturbed sample from the topmost layers (see Faye
439 et al., 2019). The centennial scale glacier advances reported by van der Bilt et al. (2015, Figure 6a)
440 thus find direct counterparts (or vice-versa) in the sand-blowing regression (as seen in the (Si+K)/Fe
441 ratio in Figure 6b) and thus conversely peat developments along the Aquitaine coasts. This suggests
442 that for times when wetter conditions are recorded in Aquitaine, something which also seems to have
443 coincided with the dynamics of storm events in Denmark (Figure 6c), small Svalbard glaciers were
444 expanding. This clearly attests to the crucial role of warm humid advections in the climate balance of
445 western Europe whatever the latitude considered. The mechanisms behind this convergence are thus
446 not exclusively linked to an NAO-like pattern, which on the contrary decouples and contrasts mid-
447 latitudes and polar-latitudes of Europe in terms of humidity conditions. Instead, we observe here a
448 synchronicity which suggests and highlights a factor controlling temperature and humidity
449 simultaneously along the eastern North Atlantic (possibly occurring under a relaxed north-
450 hemispheric gradient). A “climatic valve”, capable of nurturing small glaciers in Svalbard, storminess
451 in Denmark and humidity in SW France, argues for multi-year-lasting dynamics and therefore an
452 oceanic driver. The best candidate is modulation of the intensity of North Atlantic Drift (NAD)
453 inflows towards the pole in the Nordic seas, i.e. in AMOC dynamics. The most recent literature
454 suggests that AMOC was a key driver of Europe’s Holocene climate, notably implying a strong
455 reactivity with ice compartments (from marine-terminating glaciers, e.g. Curran et al., 2019, or sea-
456 ice cover as well, e.g. Klein et al., 2014; Găinușă-Bogdan et al., 2020). The causes of AMOC internal
457 variability have still not been fully identified as they imply diverse interactions and feedbacks (purely
458 physical – thermo-haline – or wind-related or both, but also probably linked to sporadic events such
459 as volcanic forcing and to biospheric changes impacting the Earth’s radiative budget), in a context of
460 primary external insolation forcing. Despite those complex loops, one of the most probable, and often
461 cited, processes is the recirculation of warm, (sub)tropically-sourced, Atlantic waters, along the

462 boundaries of the subtropical and subpolar gyres (Eynaud et al., 2018; Curran et al., 2019). The
463 eastward extension of the North Atlantic subpolar gyre, recently documented for the Holocene by
464 Colin et al. (2019) in the Rockall Trough, may have modulated this recirculation. It is worth noting
465 that the comparison of the millennial scale fluctuations identified in the composite record of cold-
466 water coral ϵNd by Colin et al. (2019) matches the (Si+K)/Fe ratio in G3 with especially high ϵNd
467 values recorded for low (Si+K)/Fe values. Interestingly those low values are also recorded for high
468 salinity values in the Bay of Biscay, something that we can relate to the modern observations of
469 Lozier and Stewart (2008) who attribute salinity anomalies in the eastern North Atlantic temperate
470 basins to a eastward expanded SPG blocking the northward MOW circulation up to the Nordic seas,
471 synchronously to a subpolar front moving eastward, a positive NAO index and strong westerlies.
472 Our study thus shows that even isolated records can capture climatic signals in a very sensitive
473 manner and are all very good candidates and proxies for directly or indirectly inferring the global
474 dynamics of climate. Past sequences usefully supplement modern observations and modelling
475 exercises as their indirect and integrated character may be an asset for picturing concepts on a
476 synoptic and comprehensive scale.

477

478 **3.3. Human population dynamics**

479 The transitions highlighted and events identified in the LDG sequences also correspond to major
480 shifts in European population dynamics and cultural developments during the Holocene as
481 summarized hereafter. The Neolithic period, marked by the expansion of farming and a radical shift
482 in belief systems, even if diachronous across Europe (due to a north-westward progression of
483 acculturation for central and northern Europe and a westward maritime-related progression for
484 Mediterranean Europe), coincided with the mid-Holocene, which is particularly well expressed here
485 as previously discussed (Figures 4 and 6). Beyond this major transition, the events at 5.4, 4.8 and 4.2
486 ka occurred at times of drastic changes, related especially to a succession of megadroughts in Eurasia

487 and Africa (e.g. [Brooks, 2006](#); [Weiss, 2016](#); [Griffiths et al., 2020](#) and references therein). Those
488 events encompassed the Late Neolithic/Chalcolithic periods and the transition to the Bronze Age,
489 which are recognized as periods of increasing social complexity ([Kristiansen and Larsson, 2005](#);
490 [Brooks, 2006](#); [Milevski, 2013](#)).

491 The 4.2 ka event has been chosen as the date of the transition between the Northgrippian and the
492 Meghalayan ([Walker et al., 2019](#)). It is related to severe drought in the tropics and subtropics, that
493 may have also affected European populations (e.g. [Drysdale et al., 2006](#)) as suggested by discoveries
494 of groundwater collection systems and wells, contemporaneous with this episode and abandoned
495 subsequently (see e.g. the “Motillas” Bronze Age horizon in central Spain, [Mejías Moreno et al.,](#)
496 [2014](#)). At the LDG site and in its vicinity (e.g. the nearby site of Amélie beach), this period saw a
497 significant increase in the number of Late Neolithic and Bronze Age remains, as past and present
498 archaeological research has demonstrated (e.g. [Roussot Laroque, 2007](#); [López-Romero et al., 2021](#)).
499 Climate may have impacted local populations in several ways, but published evidence for the LDG
500 site ([Roussot Laroque, 1999](#); [Roussot Laroque, 2007](#); [Roussot Laroque, 2010](#)) has documented
501 occupation changes (gaps included) rather in relation to weather extremes such as drought and
502 storminess. Several well-preserved wattle structures, probably related to the salt industry, have been
503 found after 6 ka cal BP within the site (see pictures in [Verdin et al., 2019a](#) and [López-Romero et al.,](#)
504 [2021](#)) indicating repeated exploitations of the area by Neolithic humans. During the Bronze Age, for
505 which a very dense collection of anthropic artefacts has been collected, gaps in settlement were also
506 reported to be synchronous with interruptions in farming pressure ([Roussot Laroque, 2007](#)).

507 This evidence suggests that during the part of the Holocene under study here, randomness due to
508 sudden changes was superimposed on the long-term climatic trend initiated with deglaciation, and
509 may have drastically impacted both the environment and human populations.

510

511 **4. Conclusion**

512 This study focused on a high-resolution archaeological record encompassing the early to late
513 Holocene transition. On the basis of a palaeoenvironmental approach relying mostly on XRF and
514 palynological (pollen) data, we found evidence for specific breaks in the sedimentological record that
515 all find direct counterparts in the well-known pan-Atlantic climate shifts. The record under study
516 reveals a long-term trend, classically echoing the evolution of Holocene insolation forcing, with
517 superimposed short-term events bearing a more local signal related mainly to proximal North
518 Atlantic Ocean dynamics. It highlights how western European environments (and therefore
519 populations) were dependent upon the linearity of climate evolution. It suggests also that high-time-
520 resolved records made up of both archaeological and environmental remains, even if local and at first
521 sight “disturbed” by the presence of anthropic artefacts, are in fact, where they prove to be
522 continuous, highly valuable sequences worth detailed study to better identify risk and resilience
523 factors capable of affecting human societies.

524

525 **5. Author contributions**

526 All authors contributed to the published work. FE wrote the paper and conceptualized the study as
527 part of the joint direction (funding acquisition and administration; investigation and methodological
528 frameworks; analyses) of the LITAQ (conducted with FV) and HAMOC (conducted with CrC)
529 projects. YM, EL-R, AP and CC were involved in both projects and contributed to the data produced
530 and the related scientific discussions. CB was in charge of the analysis of pollen grain assemblages
531 in G3.

532

533 **6. Data availability**

534 The data published in this article are available on request from FE.

535

536 **7. Declaration of competing interest**

537 The authors declare that they have no known competing financial interests or personal relationships
538 that could have appeared to influence the work reported in this paper.

539

540 **8. Acknowledgements**

541 Financial support for this research was obtained thanks to the LITAQ project (“*Du Pléistocène à*
542 *l’Anthropocène : connaître les mécanismes passés d’évolution des populations -végétales, animales,*
543 *humaines- et des milieux pour prédire les réponses futures. L’exemple du LITtoral Aquitain*”,
544 supported by the French National Research Agency/ANR in the Programme Investissement d’Avenir
545 framework - ANR-10-IDEX-03-02 within the Inter-clusters of Excellence COTE – ANR-10-LABX-
546 45 and LaScArBx – ANR-10-LABX-52), and by the ANR HAMOC Project (“*Holocene North-*
547 *Atlantic Gyres and Mediterranean Overturning Dynamic through Climate Changes*” - Grant ANR-
548 13-BS06-0003). Fundings were also obtained for the analyses thanks to the INSU- EC2CO DRILL
549 project FAST-LITAQ (“*Formations Argilo-Sableuses & Tourbes LITtorales AQUitaines : de leur*
550 *intérêt dans l’évolution des falaises dunaires du Médoc*”) and to the INSU-TELLUS-ARTEMIS
551 2017 project “*Dynamique des peuplements humains et Climats : du Paléolithique à nos jours, mieux*
552 *contraindre les périodes de ruptures culturelles*”. The authors would like to thank all the other
553 participants in these projects for their fruitful collaboration and discussion. We thank Isabelle Billy
554 for XRF core-scanning measurements and Ludovic Deveaux for the pollen preparation.

877

878 **Figure captions**

879 **Figure 1:** Maps showing the location of the Lède du Gurg (LDG) archaeological site (A): in
880 western Europe; (B): zooming in on the Bay of Biscay margin with other regional marine
881 sequences of interest; (C) Google map view of the residual buttruss in the intertidal zone
882 between March and October 2014 before the excavation operations.

883 **Figure 2:** Age-depth relationship (polynomial regression) for the two sampled sequences G3
884 (grey) and G4 (blue). The marks locate the dated samples in depth and time. Dates are calibrated
885 and corrected with CALIB7.0.2. software. The 1σ and 2σ envelopes (dotted lines) obtained with
886 Undatable software (Lougheed and Obrochta, 2019) are also shown to validate the polynomial
887 construction of age models for G3 and G4, respectively.

888 **Figure 3:** Compilation of sedimentological results obtained for G3 (black curves a, b, c, g, h, i)
889 and G4 (blue curves in b, h) sequences, compared with key pollen data in G3 (d, e, f, j, k).

890 **Figure 4:** Comparison of key results from the G3 and G4 sequences (b, c, d, e, f, g) with some
891 recent Holocene reference records with: (a) bipolar insolation values (June at 60° S and July at
892 65° N) in boreal summers after Berger and Loutre, 1991; (h) Massif central eruptions (total
893 number: attested and supposed) after Miallier et al. 2012; (i) NGRIP $\delta^{18}\text{O}$ record after Vinther et
894 al., 2006 and Rasmussen et al., 2006; (j) mean summer SST anomaly in the central eastern
895 Atlantic after de Menocal et al., 2000; (k) mean summer SST anomaly in the southern Bay of
896 Biscay after Eynaud et al. 2018; (l) mean annual SST in the southern Bay of Biscay after Eynaud
897 et al. 2018; (m) global mean temperature reconstruction minus North Atlantic records from
898 Marcott et al. 2013 from the compilation by Marsicek et al. 2018; and (n) CH_4 atmospheric
899 concentration after Beck et al. 2018. Vertical stripes identify sudden short-lived changes in the
900 signals with pink stripes corresponding to warm SST oscillations and light purple stripes to cold

901 SST. Green boxes at the top identify rapid climate change (RCC) intervals after Mayewski et al.,
902 2004 (temporal limits reproduced from their Figures 1 to 4). Archaeological and climatological
903 divisions commonly used in the North Atlantic region and Europe have been added (after the
904 compilation published in Eynaud et al., 2019 and López-Romero et al., 2021).

905

906 **Figure 5:** Statistical analysis of the XRF results from the G3 sequence, with (a): scores and their
907 significance on PC1 and PC2; (b) ternary plots of key element abundances and (c) their along
908 core distribution (in age) compared to PC1 and PC2 loadings.

909 **Figure 6:** Comparison of the respective loadings on PC1 (e) and 2 (f) – and their related key
910 elemental ratio and proxies in LDG (b, d, g, h, j) – with Holocene reconstructions: (a) Arctic
911 glacier activity detected in the sensitive region of Svalbard after normalized titanium loss on
912 ignition (Ti/LOI) measurements in a core from Hajeren Lake (van der Bilt et al. 2015); (c)
913 Atlantic storminess record reconstructed from Danish archives by Goslin et al. (2018a and b); (j)
914 reconstructed sea-surface salinities (SSS) in the Bay of Biscay (PP10-07 core: this work, Mary et
915 al., 2017; Eynaud et al., 2018); (k) SST record from the Scotian margin (after Sachs et al., 2007
916 and Marsicek et al. 2018) and (l) Dinocyst NAD linked species (*% O. centrocarpum*) in core
917 CBT-CS11 (after Penaud et al., 2020). Vertical stripes: as in Figure 4, the pink stripe
918 corresponds to warm Bay of Biscay SST oscillations and light purple stripes to cold SST. Grey
919 stripes have been added to identify Neoglacial glacier advances in Svalbard after van der Bilt et
920 al. (2015). Archaeological and climatological divisions commonly used in the North Atlantic
921 region and Europe have been added (after the compilation published in Eynaud et al., 2019 and
922 López-Romero et al., 2021).

923

924

925 **Table caption**

926 **Table 1:** Age control points (radiocarbon datings) for the Holocene section of the Lède du Gulp
927 (LDG) site.
