**HAL** is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers. L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

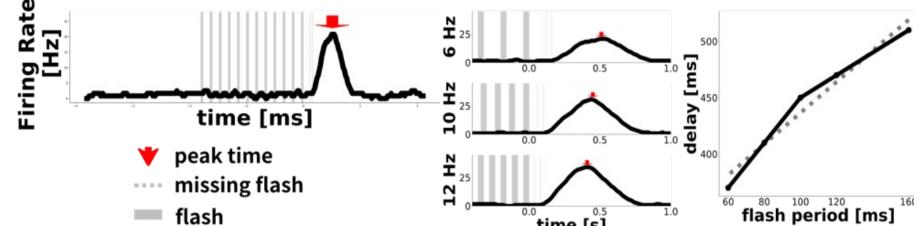

#### Abstract

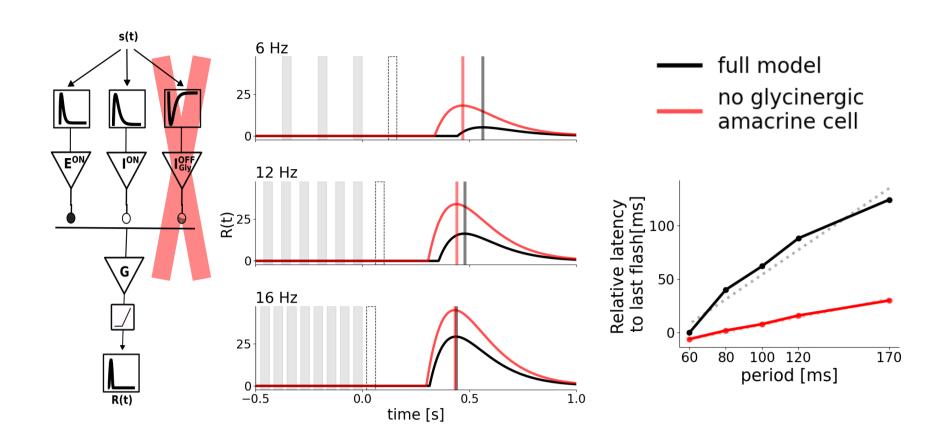

Model simulations show latency shift

#### OSR depends on the number of flashes in the stimulus

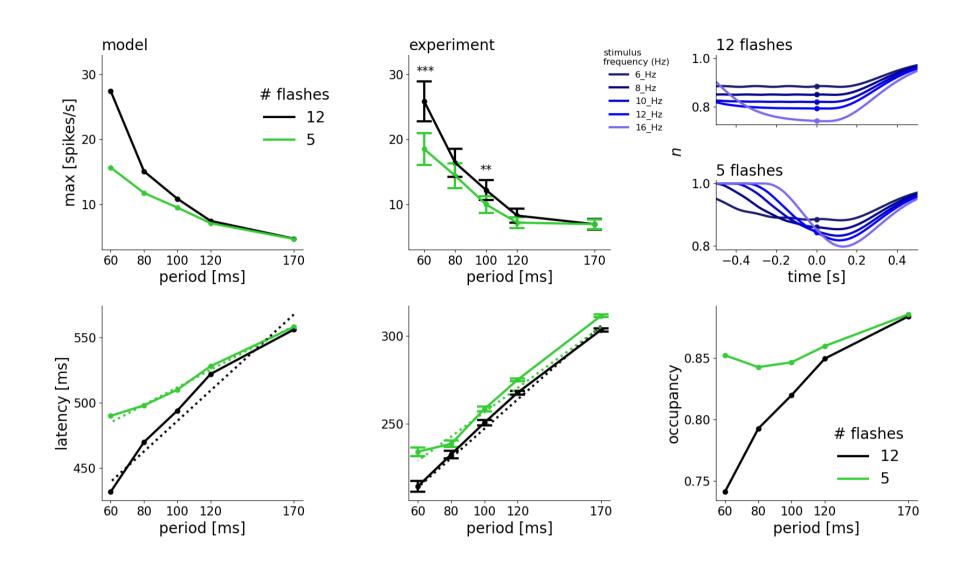

The retina emits an **Omitted Stimulus Response (OSR) [2]** when an expected flash in a sequence is missing. The latency of this response scales with the period of the stimulus 1-to-1, thus signalling the timepoint when the missing stimulus was expected. This is an example for predictive coding in the retina, with a temporal expectation of future stimuli

Computational model replicates experimental finding

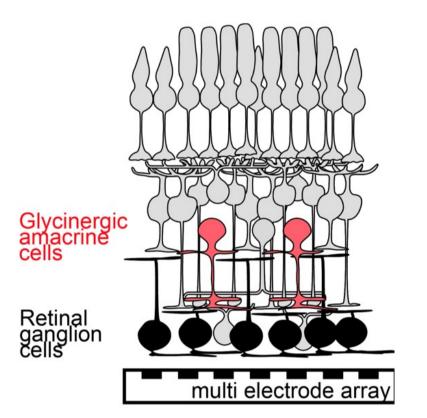

OSR to 12 and to 5 Flashes

time [s] — cell response

What is the underlying mechanism of the latency shift in the OSR?

# Glycinergic amacrine cells are necessary for latency shift

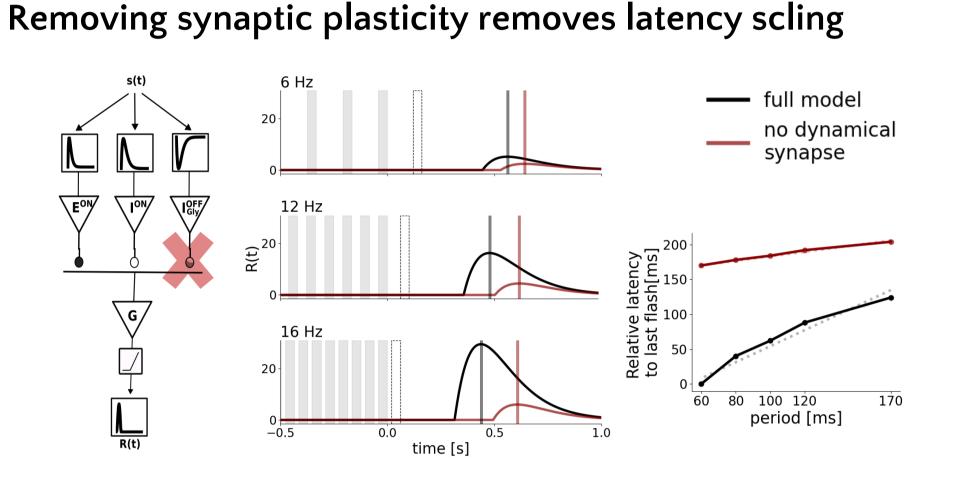

# Experimental Setup

- Electrophysiological recordings to stimulation with dark flashes of different frequencies
- blockade of pharmacological glycinergic transmission.

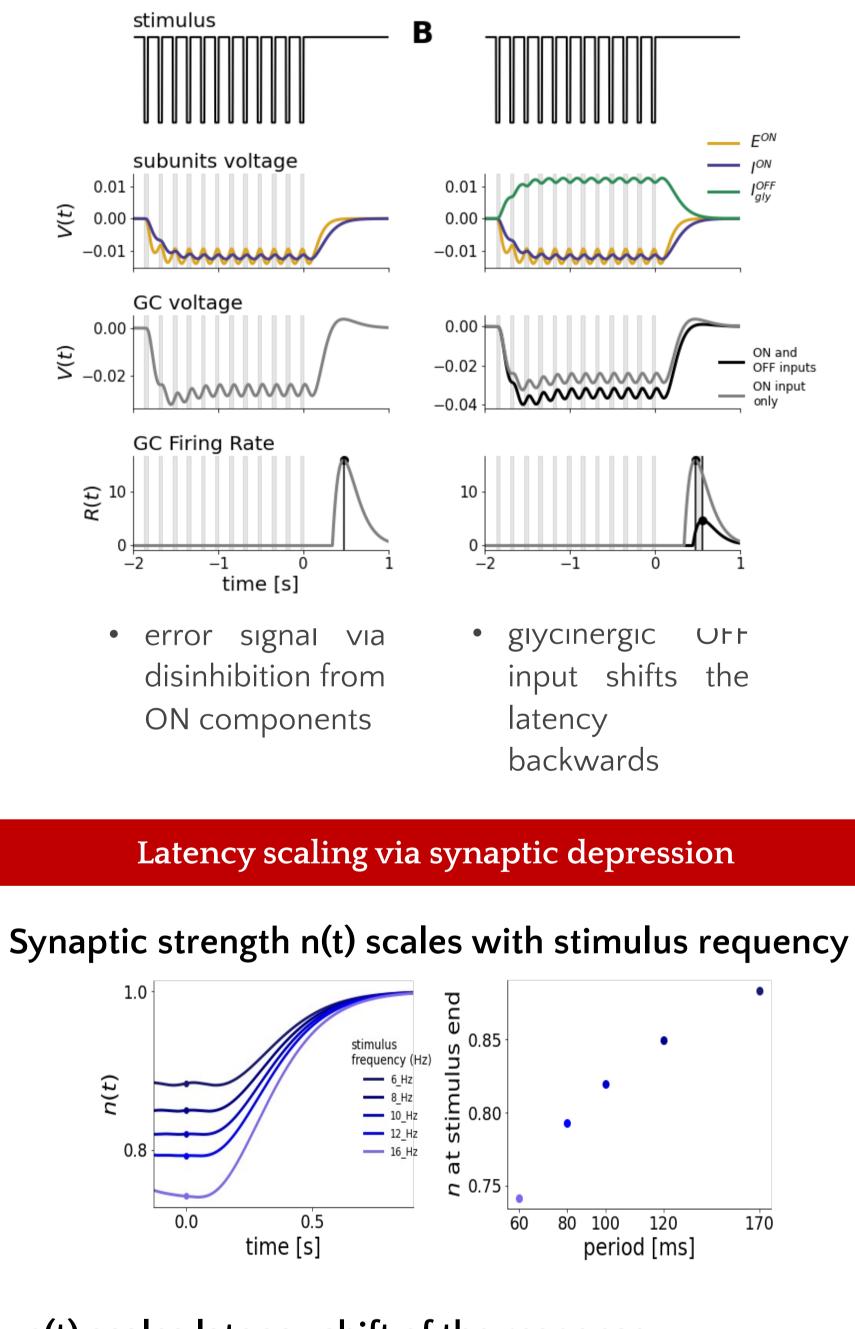

100ms

STA of cells with OSR

## Peak generation via disinhibiton

# Internal variables of the model

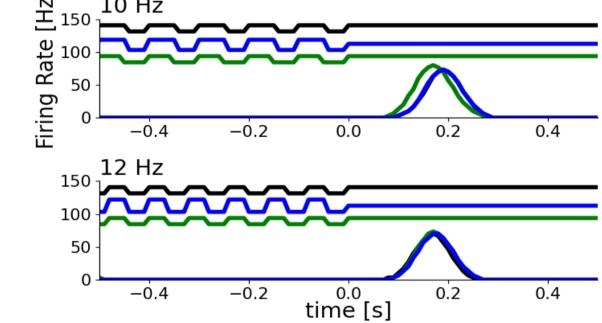

# Latency shift flattens for shorter stimuli

• In the model, this is due to lacking steady state of synaptic strength n(t)

### Does average luminace effect the OSR?

#### OSR to stimulus variations without average luminance decrease control flash Interval variation interval -Ó.2 0.2 -0.40.0 0.4 [H] 150 10 Hz

• The latency shift remains unchanged when the intervals between

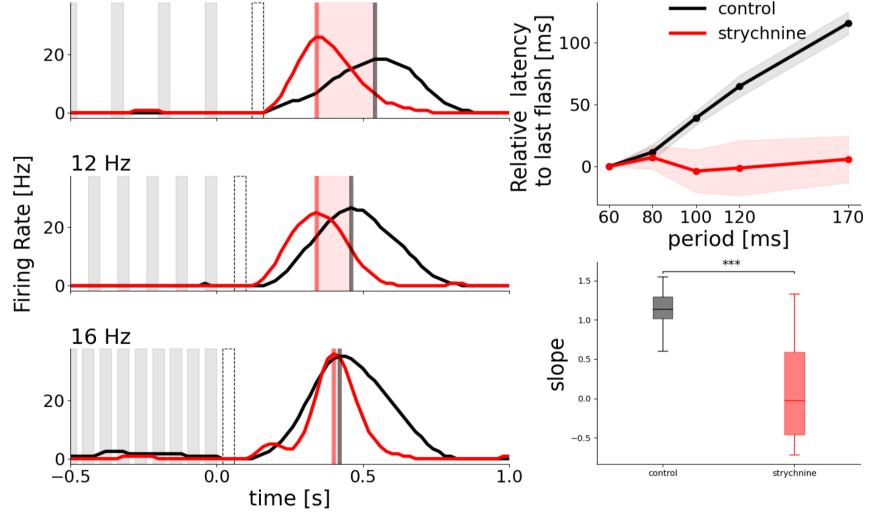

# Results

- ON cells exhibit an OSR to dark flashes
- cells • Glycinergic Amacrine are to form temporal necessary expectations.

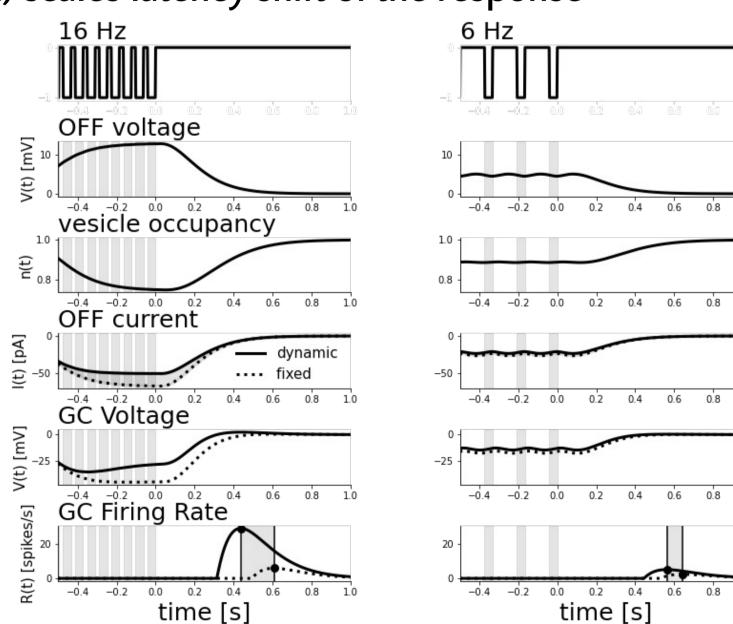

ION/

E<sup>O</sup>№

# n(t) scales latency shift of the response

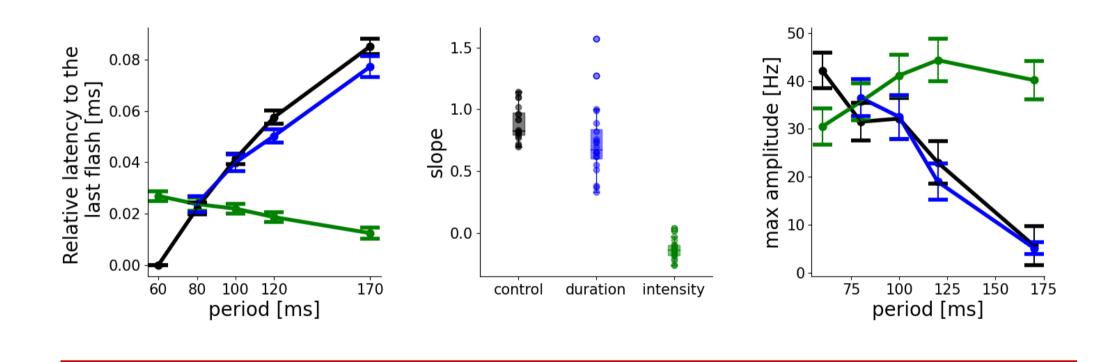

### flashes are brighter

Flash variation

חחו

• Latency shift is lost when the flashes change duration with frequency.

### Conclusion

The retina encodes complex and rapidly moving visual scenes via its hierarchical, multi-layered structure where most neurons respond by a graded variation of their membrane potential without spiking (except ganglion cells). Here, we show that the retina

forms error signals via excitation and slower inhibition (A)

(B) while **short-term plasticity refines temporal predictions** of future stimuli.

Besides temporal predictions on a spatially uniform stimulus, the retina has been shown to anticipate motion and to respond to changes in trajectories. Can we extrapolate the mechanism proposed here to a more general setting, where amacrine cells enable the anticipation of a moving object [4] while short-term plasticity enables a temporal refinement of speed estimation?

# Computational model

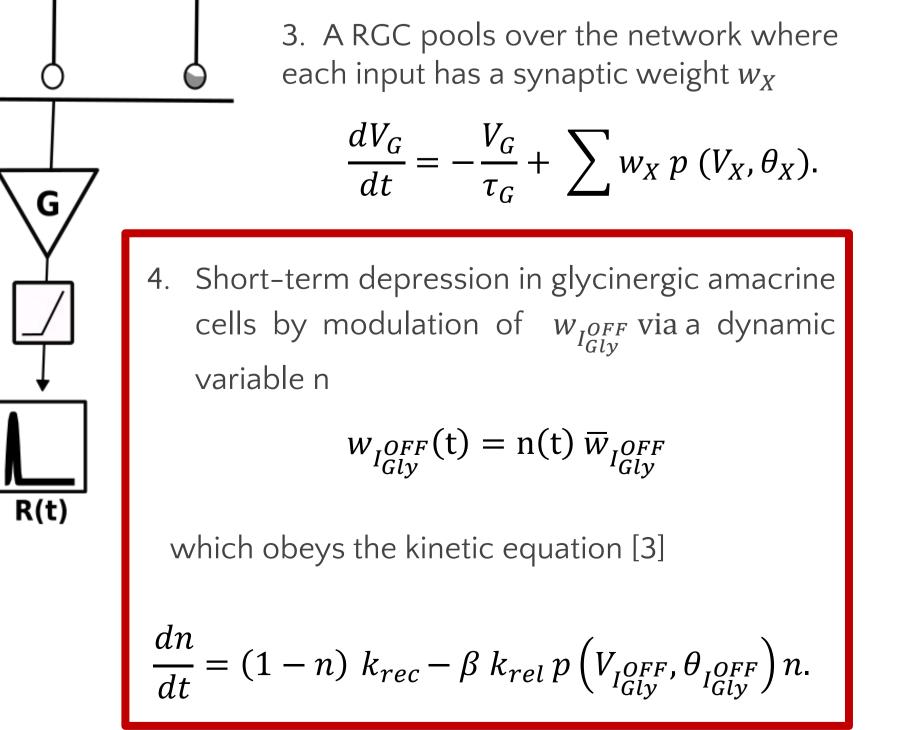

1. Convolution of the stimulus s(t)s(t) and a temporal kernel  $\alpha_X$  $F_X(t) = [\alpha_X * s](t),$ 

excitatory where () inhibitory

 $X = E^{ON}, I^{ON}, I^{OFF}_{Gly}.$ 🕞 dynamic

2. Signal integration via a dynamical system where  $V_X$  is the voltage of cell *X* with characteristic time  $\tau_X$ 

 $\frac{dV_X}{dt} = -\frac{V_X}{\tau_X} + F_X(t).$ 

- Depression reduces inhibition and thus latency shift
- Higher depression for fast frequency yields shorter a latency
- Little depression for slow frequency yields longer latency
