Abstract

Traditional Worst-Case Execution Time analysis derives an upper-bound to the execution time of a program for any possible combination of its software and hardware parameters. In comparison, Parametric Worst-Case Execution Time analysis derives a WCET formula that depends on the parameters. The formula can then be instantiated for some given parameter values, to produce a WCET that is specific to those values, and thus tighter.

In this work, we present a technique that, by static analysis of binary code, automatically produces a formula that represents the WCET of a procedure as a function of its arguments. The formula captures how the control-flow, and thus the WCET, depends on the arguments that appear in branch conditions (loop conditions and if-then-else conditions).

We detail two applications of this technique. In our first and main application, we show that WCET formulas can be instantiated during the parametric analysis itself, to make it modular. The code of a procedure is analysed only once, and the WCET of a call to that procedure is obtained by instantiating the corresponding formula with the parameter values passed at the call site.

Second, we show that WCET formulas can be instantiated at runtime, to implement adaptive real-time systems. We discuss how this can be leveraged to: 1) implement real-time systems that follow the recently proposed semi-clairvoyant mixed-criticality scheduling approach; 2) implement adaptive control-command laws.

Keywords – Worst-Case Execution Time analysis, real-time systems, abstract interpretation

1 Introduction

In real-time safety critical systems, it is of paramount importance to guarantee that computation is performed within certain time bounds. Avionics, aerospace, or autonomous car systems, are all examples of real-time safety critical systems. To guarantee that real-time constraints are satisfied, the developer needs first to compute bounds on the execution time of each task of the system, and then to guarantee that all tasks are scheduled in such a way that they will always meet their deadlines.

The execution time of a task often exhibits a large variability related to software parameters (e.g. program inputs) or hardware parameters (e.g. cache state). Static Worst-Case Execution Time (WCET) analysis aims at providing a *safe* upper-bound to the execution time of a task

*This work is partially funded by the French National Research Agency, Sywext project (ANR-19-CE25-0002).

for any possible combination of the software and hardware parameters. Ideally, the estimated WCET must also be *tight* (close to the actual WCET) to keep resource over-provisioning to a minimum.

Traditional WCET analysis produces a constant numeric upper-bound to the WCET, that bounds the execution of the task for any possible combination of the hardware and software parameters. Instead, *parametric WCET analysis* produces a *formula* that represents the WCET as a function of the parameters. The formula can later be *instantiated* with actual parameter values to provide an upper-bound to the execution time for those parameter values. The instantiated WCET is usually tighter than in the traditional approach, as it considers a lesser number of possible execution scenarios.

Formula instantiation can be performed either off-line (before system execution) or on-line (during system execution). We propose to use formula instantiation during the WCET analysis itself to make it modular. For each procedure, the analysis produces a formula that represents the WCET as a function of the procedure arguments. The WCET for a procedure call is then computed by instantiating the formula with the parameter values at the call site. This significantly reduces the complexity of the analysis, thus enabling to analyse more complex programs.

On-line formula instantiation can be used to implement an *adaptive* real-time system. A real-time task typically releases periodically new jobs to execute. The task formula can be instantiated at job release to determine the job WCET considering the current parameter values. The system behaviour can then be adapted depending on the instantiated WCET. This can be leveraged to implement systems that follow the model considered in semi-clairvoyant scheduling for mixed-criticality systems [1, 14, 10], or to implement adaptive control-command laws.

1.1 Motivating example

We motivate our work with the example of Figure 1, previously presented in [25]. This procedure is part of an implementation of the G.723 speech encoding standard, taken verbatim from TACLeBench [23].

The G.723 codec is based on Adaptive Differential Pulse Code Modulation (ADPCM). During the signal encoding, each sample `sl` of the input signal is compared against a value `se` predicted based on previous samples. The difference `d=sl-se` is quantized to a logarithmic factor represented by argument `dqln`. The procedure reconstructs the difference signal based on that value (it also takes the `sign` of the value and the adaptive quantization step `y` as arguments). If the difference `dqln` is low[1] compared to the quantization step `y` (line 6), the reconstructed difference is set to 0 (line 7[2]). Otherwise (`else` branch), the procedure computes the antilog of `dql`, assuming a fixed-point signed representation of the real value `dqln`.

Our analysis applied to the corresponding assembly code detects that the branching instruction corresponding to source line 6 depends on two procedure arguments (arg_2 a.k.a. `dqln`, and arg_3 a.k.a. `y`), and infers the branch conditions $4 \times arg_2 + arg_3 \leq -1$ for the `then` case and $4 \times arg_2 + arg_3 \geq 0$ for the `else` case. Then, it produces a WCET formula that depends on those branch conditions.

Let us emphasize that the WCET variations are neither due to aberrant values, nor predictable before runtime, as they depend on the shape of the input signal.

This example has been chosen for illustrative purposes thanks to its simplicity. It shows that we can characterize the impact of argument values on the WCET of a procedure. The variation of WCET for such small function is a few tens of processor cycles, hence it is not useful to instantiate its WCET formula on-line: the evaluation function takes almost as much time as the potential

[1] Addition on logarithmic values (`dqln` and `y`) amounts to multiplication.

[2] `dql` is signed, in two's complement, which explains the test at line 7.

```
1  int reconstruct(int sign, int dqln, int y)
2  {
3    short dql, dex, dqt, dq;
4
5    dql = dqln + ( y >> 2 );
6    if ( dql < 0 )
7      return ( ( sign ) ? -0x8000 : 0 );
8    else {
9      dex = ( dql >> 7 ) & 15;
10     dqt = 128 + ( dql & 127 );
11     dq = ( dqt << 7 ) >> ( 14 - dex );
12     return ( ( sign ) ? ( dq - 0x8000 ) : dq );
13   }
14 }
```

Figure 1: Speech encoding, reconstructing the difference signal

maximum variability (see line *g723_enc_reconstruct* in Table 4 in Section 8.1.5). However, other more complex functions show a much larger variability and computing the formula on-line makes sense for those functions (see Section 8.1 for a complete set of experiments).

We underline the fact that, although procedure `reconstruct` is only a part of the complete encoder program, it is representative of many signal processing algorithms, which are pervasive in real-time systems, and whose computations and WCET vary depending on the input signal.

1.2 Contributions

In this paper we first present a parametric WCET analysis, which analyses the binary code of a procedure to produce a formula that represents the WCET of the procedure as a function of its arguments. Then, we detail how formula instantiation can be used during the WCET analysis itself to make it modular. We also illustrate how on-line formula instantiation can be leveraged to implement adaptive real-time systems.

Our approach is based on two of our previous works, on symbolic WCET computation [9], and on abstract interpretation of binary code [8]. In a nutshell, symbolic WCET computation starts from the Control-Flow Graph of the program (CFG), translates it into a Control-Flow Tree (CFT), transforms the CFT into a WCET formula, and finally simplifies the formula to reduce its size.

Although our analysis relies on foundations presented in the two papers mentioned above, many novel contributions and extensions were necessary to make it work in a coherent and automatic way. These extensions are detailed in this paper. First, we devise an analysis that infers *input conditionals*, that is to say predicates on procedure arguments that serve as branch conditions, either in conditional statements or in loops. This analysis extends the relational abstract interpretation of binary code proposed in [8] and is presented in Section 5. Also, we introduce a new type of node in the CFT to represent conditional branches subject to input conditionals. This is presented in Section 6.1. Second, in Section 6.2 we extend the symbolic computation to support formulae where the input conditionals appear as parameters. Furthermore, in Section 6.3 we propose extensive simplification procedures to reduce the size of the formulae. We also provide a compiler that generates C code, which is optimized to have low WCET, to evaluate the formula on-line (Section 6.4).

We detail an extension of the parametric analysis in Section 7, which makes the analysis

modular. This extension concerns both the abstract interpretation and the symbolic WCET computation steps.

Our evaluation consists of two parts. In Section 8.2 we illustrate how on-line formula instantiation can be leveraged to implement adaptive real-time systems. Based on experiments on TACLeBench, we demonstrate in Section 8.1 that our approach is **adaptive**, **embeddable**, and also **automated**:

- *Adaptivity*: the instantiated WCET can vary significantly when we take into account the value of the procedure arguments. Our approach detects *dynamically* infeasible paths, that is to say paths that are infeasible because of the current procedure argument values.
- *Embeddability*: the size of the WCET formula and the instantiation time are kept to a minimum, so as to enable on-line execution.
- *Automation*: our approach takes the binary code of a procedure as input and produces a WCET formula dependent on the procedure arguments as output, without requiring assistance from the programmer.

This paper is an extended version of [25]. The extensions include:

- The modular WCET analysis extension and its evaluation;
- The application of our method to the implementation of adaptive real-time systems;
- A more in-depth presentation of the background ([9], [8]), so as to make the paper more self-contained;
- A more detailed presentation of the inference of input conditionals.

2 Related works

The most widely used WCET analysis technique is the Implicit Path Enumeration Technique (IPET) [29]. It takes a representation of the compiled program in the form of a graph (the Control-Flow Graph – CFG), and explores it to build an Integer Linear Programming (ILP) problem. The graph structure and the hardware features (pipeline, cache, etc.) are encoded by linear constraints, and the solution of the problem is a numerical upper bound to the execution time of the program. An extensive survey on WCET and IPET is presented in [39].

Symbolic techniques have been considered in WCET analysis for different purposes. [11, 12, 17] uses symbolic techniques to speed up the analysis. In [30], symbolic analysis is used to trade off analysis time against tightness. Wilhelm et al. [40] model the effect of pipelines on the WCET using symbolic states. Reineke et al. [33] demonstrate how to represent various architectural effects, e.g. processor frequency, memory latencies or memory sizes, using parametric WCET analysis. However, even though these approaches are symbolic, their *results* are not parametric.

The problem of computing WCET formulae that depend on various parameters has been studied before. Approaches that rely on source code analysis have been proposed. In [38], the authors proposed a technique that produces a parametric formula that mixes constant integer values for WCET, that accounts for the effect of the instruction cache, and unknown integers for loops bounds. The formula of the inner loop is produced before the formula of an outer loop such that the inner loop formula can be included in the outer loop formula. Coffman et al. [18] extended this formula model such that it can compute the maximum between several parametric paths at runtime. The technique has then been used in [31, 32] to perform DVFS. One limitation

of source code analysis is the need to account for compiler optimizations that may change the structure of the Control-Flow Graph, making the resulting WCET pessimistic.

Regarding binary-level analyses, in [5] Altmeyer et al. rely on parametric ILP [24] to adapt IPET analysis to the parametric case, but the symbolic ILP solver makes the approach computationally inefficient. In [15], Bygde et al. propose a different non-IPET approach: the minimal propagation algorithm, which is more efficient but also less tight. Althaus et al. [3, 4] try to improve on both efficiency and tightness with a parametric path analysis. On top of that, their approach is the first that can produce a formula with several non-nested and symbolic loops.

Tree-based parametric WCET analyses have also been considered as a parametric alternative to IPET. Colin et al. [20] introduced a tree-based model of programs dedicated to symbolic WCET analysis. This model uses two expressions per tree node: a WCET symbolic expression and a frequency expression, which represent the number of executions of the tree. However, they did not consider the problem of producing such a model from a program. Ballabriga et al. [9] also proposed a tree-based symbolic WCET computation approach but detailed how to produce the tree model from a CFG. Their approach can represent a wider range of hardware and software timing effects than previous tree-based WCET analyses: it supports parametric loop bounds and parametric execution blocks (blocks of code whose WCET is a parameter). However, the programmer needs to manually specify which elements of the program are parameters. We could use parametric execution blocks to represent parametric conditional statements: replace each conditional statement by a parametric execution block, where the parameter represents the WCET of the different alternatives of the conditional statement. This would, however, cause space explosion for nested conditional statements.

Our work is indirectly related to infeasible paths analysis, for which several approaches have been proposed in the WCET analysis community: using abstract interpretation [28, 36, 16], symbolic execution [26, 27], or SMT solvers [13, 34, 35]. A survey about infeasible paths analysis can be found in [22]. These works focus on detecting (and often exploiting) *statically* infeasible paths, i.e. a program path that can never be executed because of some exclusive branch conditions and assignments. In comparison, our approach detects *dynamically* infeasible paths, that is to say paths that are infeasible because of the current procedure argument values.

We conclude this section with a summary of how our work compares with existing works. First, existing works mostly consider parametric loop bounds only, none consider conditional statements with parametric conditions. Our experiments show that programs containing loop bounds that depend on procedure arguments are rarer than programs containing conditional statements that depend on procedure arguments. Second, existing works support a single parameter, or additions between a single parameter and a constant, which is insufficient to represent many input conditionals, such as for instance that of the motivating example of Figure 1. In comparison, we support conjunctions on linear inequalities on parameters. Finally, no existing work is simultaneously adaptive, automated and embeddable.

3 Overview

We illustrate the workflow of our approach on the program of Figure 2. Starting from the binary code of function f, the analysis consists of the following steps.

CFG extraction the binary code is translated into a Control-Flow Graph, where nodes are basic blocks[3] and edges represent the program control-flow. We obtain a CFG with basic blocks

[3] A *basic block* is a sequence of instructions such that if the first instruction of this sequence is executed, then the remaining instructions of that sequence are executed as well.

```
1  f:                      @  int f(int n) {
2    @ ...                 @    /* A */
3    str r0, [fp, #-32]    @    /* A */
4    @ ...                 @    /* A */
5    ldr r3, [fp, #-32]    @    /* A */
6    cmp r3, #10           @    if (n <= 10) /* A */
7    bgt .L2               @    { /* still A */
8    @ ...                 @      /* C */
9    b  .L3                @    } /* C */
10 .L2:                    @    else {
11   @ ...                 @      /* B */
12 .L3:                    @    }
13   @ ...                 @    /* D */
14   ldr r3, [fp, #-32]    @    /* D */
15   cmp r3, #-1           @    if (n <= -1)  /* D */
16   bgt .L4               @    { /* still D */
17   @ ...                 @      /* F */
18   b .L5                 @    } /* F */
19 .L4:                    @    else {
20   @ ...                 @      /* E */
21 .L5:                    @    }
22   @ ...                 @    /* G */
23   bx lr                 @    return; /* still G */
24 .global  main           @  }
25 main:                   @  int main() {
26   @...                  @    /* ... */
27   ldr r0, [fp, #-8]     @    /* Setting parameters */
28   bl f                  @    f(i); /* function call */
29   @ ...                 @  }
```

Figure 2: Running example

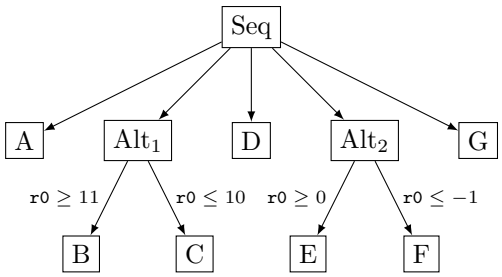

Figure 3: Control-Flow Tree for function f of Figure 2

A to G. We rely on OTAWA [7] for this step.

Hardware analysis the hardware analysis infers the WCET of each basic block. Let us assume that the resulting WCET obtained for A, E, F is 10, for C, G is 5, and that the WCET of B and D are symbolic (denoted $\omega(B)$, $\omega(D)$). We also rely on OTAWA for this step.

Inferring input conditionals the abstract interpreter identifies the value stored in `r0` as an argument (a.k.a. n) of procedure f at line 1 (as per function call conventions). At line 7, it infers $\texttt{r0} \geq 11$ as the *input conditional* for branching to label *L2* (a.k.a. block B) and $\texttt{r0} \leq 10$ if we do not branch. Similarly, the input conditionals $\texttt{r0} \geq 0$ and $\texttt{r0} \leq -1$ are inferred at line 16. We extend the abstract interpretation analysis of [8] to infer predicates on conditional branches and loops which depend on function arguments (see Section 5).

CFT with symbolic input conditionals The CFG is translated into the Control-Flow Tree (CFT) depicted in Figure 3. It consists of a sequence (the root node *Seq*) of basic blocks (A, D, G) and of alternatives (Alt_1, Alt_2) between two subtrees (B or C, resp. E or F). Output edges of alternative nodes are annotated with the input conditionals inferred by the abstract interpreter. We extend the CFT of [9] with a new type of alternative node to model conditional branches (see Section 6.1).

WCET formula The CFT is translated into a WCET formula. Essentially: the WCET of a *Seq* node is the sum of the WCETs of its subtrees (denoted $\oplus$); the WCET of an *Alt* node is the maximum among the WCETs of its subtrees (denoted $\uplus$); the WCET of an alternatives' subtree is multiplied by its input conditional (denoted $\circledast$, where the input conditional can be seen as its binary equivalent, i.e. 1 if the input conditional is true, 0 otherwise). Thus, we obtain:

$$10 \oplus (((\texttt{r0} \geq 11) \circledast \omega(B)) \uplus ((\texttt{r0} \leq 10) \circledast 5)) \oplus \omega(D) \oplus$$
$$(((\texttt{r0} \geq 0) \circledast 10) \uplus ((\texttt{r0} \leq -1) \circledast 10)) \oplus 5$$

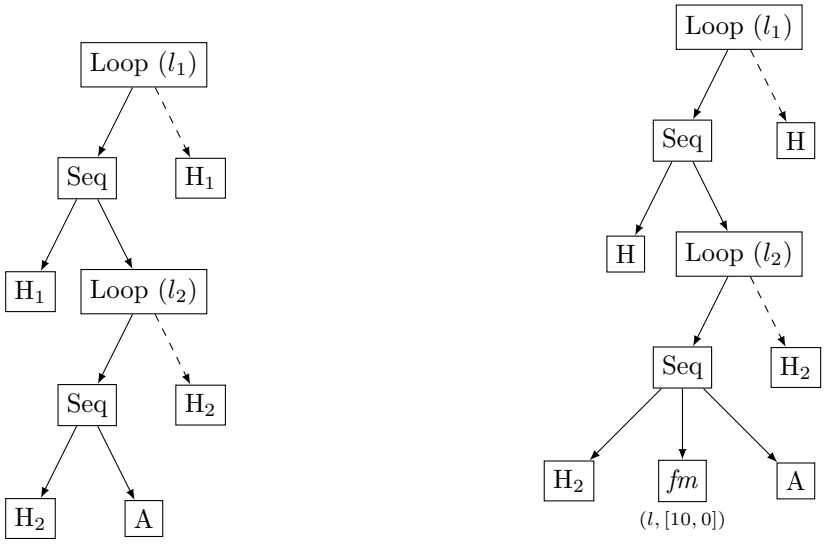
The new $\circledast$ operator is introduced in Section 6.2.

Formula simplification The formula contains symbolic values, therefore it cannot be reduced to a numeric value. Instead, we reduce its size using special simplification rules. We obtain:

$$25 \oplus (((\texttt{r0} \geq 11) \circledast \omega(B)) \uplus ((\texttt{r0} \leq 10) \circledast 5)) \oplus \omega(D)$$

First, we simplified $(((\texttt{r0} \geq 0) \circledast 10) \uplus ((\texttt{r0} \leq -1) \circledast 10))$ to 10, since $\texttt{r0} \geq 0$ and $\texttt{r0} \leq -1$ are complementary conditions multiplied by the same value (10). Then, we used commutativity to gather and reduce constant values ($10 + 5 + 10 = 25$).

It is important to underline that, for the sake of clarity, in this example we show a simplified version of the formula. Actually, in order to correctly model the impact of caches, each WCET is represented by a *list* (see Section 4.1). Therefore, the operators used in the symbolic formula are special operators defined on lists. This means that, unfortunately, we could not reuse classical simplification procedures for integer formulae; instead, we had to establish and prove the correctness of our own simplification rules. This work is described in Section 6.3.



(a) Before transformation

(b) After transformation

Figure 4: Instruction cache transformation

Formula instantiation The formula is instantiated when symbolic values become known. For instance, assuming $n = 0$ (i.e. `r0` $= 0$), $\omega(B) = \omega(D) = 8$, we obtain a WCET of 38. Note that a non-parametric analysis would produce a higher WCET in this case, namely 41. The instantiated WCET reflects the fact that execution paths that include B are infeasible when $n = 0$. In Section 6.4, we present a simple compiler that, starting from a (previously simplified) formula, produces C code whose WCET is low and can be easily bounded. It can be embedded in the program to enable adaptive scheduling.

4 Background

In this section we recall the theoretical background on which our work relies.

4.1 Symbolic WCET computation

We first recall the main concepts of symbolic WCET computation [9]. It starts from a CFG representation of the binary program under analysis. First, it translates the CFG into a *Control-Flow Tree* (CFT). A Control-Flow Tree is similar to a Control-Flow Graph, in the sense that it also represents the possible execution paths of a program, albeit with a tree structure. Being a tree structure, the CFT is prone to recursive WCET analysis. The WCET of a CFT is expressed as a formula that follows the tree structure and in which we can fairly easily introduce symbolic values.

4.1.1 Control-Flow Tree

A Control-Flow Tree can be one of:

- Leaf(b), which holds the basic block b of the program;

- Seq$(t_1, \ldots, t_n)$, which represents the sequential execution of trees $t_1, \ldots, t_n$;
- Alt$(t_1, \ldots, t_n)$, which represents the execution of one tree among $t_1, \ldots, t_n$;
- Loop(l, t_b, n, t_e), which represents the loop, identified uniquely by l, that repeats the execution of t_b at maximum n times and exits by executing the tree t_e.

Example 4.1. *Figure 4a shows a CFT with a loop nested into another loop, repeating several times the code in the basic block A. Nodes H_1 and H_2 are the loop tests, repeated at the beginning of each iteration of the loop and also when exiting the loop (the dashed edge indicates the exit node).*

4.1.2 Abstract WCET

When located inside a loop, successive iterations of a CFT node can yield different WCETs. The WCET of a CFT is represented as an *abstract WCET*, defined as a pair (l, w), where l is a loop identifier and w is a list of integers sorted in non-increasing order. The list can contain duplicates and its smallest element is implicitly repeated infinitely.

Example 4.2. $(l, [10, 10, 5, 3])$ *represents the WCET of a node inside loop l. The WCET of the node is at most twice 10, once 5, and 3 for all other iterations of loop l.*

Example 4.3. *Let us illustrate how we can represent the effect of the instruction cache. Consider the CFT of Figure 4a. Assume that a cache categorization technique [2] determines that A contains a* first-miss *cache access, i.e. the instruction is in the cache for all iterations except the first one. Assume also that the cache miss penalty is 10 cycles. This is modelled in Figure 4b by a leaf fm with WCET* $(l, [10, 0])$.

The following definitions on the program topology are required to define operations on abstract WCET:

- Loop l_1 is said to *contain* loop l_2, denoted $l_2 \sqsubseteq l_1$, if the header of l_2 is located inside the body of l_1;
- $\top$ is a fictive loop that refers to the program top-level scope;
- $\bot$ is a fictive empty loop;
- Let L denote the set of loops of the program. Then, $(L \cup \{\top, \bot\}, \sqsubseteq)$ is a lattice;
- $l_1 \sqcap l_2$ denotes the greatest lower bound of l_1 and l_2, that is to say the greatest element of $\{l : l \sqsubseteq l_1 \wedge l \sqsubseteq l_2\}$

We now remind operations on abstract WCETs. Let $a = (l, w)$ and $a' = (l', w')$ be abstract WCETs. Then:

- θ is the null abstract WCET, where $\theta = (\top, [0])$.
- $w[n]$ denotes the $(n+1)^{\text{th}}$ greatest element of w;
- $(l", w") = a \oplus a'$ is a pointwise sum, such that $w"[i] = w[i] + w'[i]$ and $l" = l \sqcap l'$;
- $a \uplus a' = (l \sqcap l', (w \cup w') \setminus \{k : k < min(w) \vee k < min(w')\})$ is an order-preserving list union, except that elements smaller than infinitely repeated ones are dropped;
- $(l, w)^{n, l'}$ represents an iteration over (l, w). There are two cases:

– if $l = l'$, then it sums the n greatest elements of w;
– if $l \neq l'$, then it sums the elements of w by packs of n.

More formally (see Example 4.5 for an illustration):

$$(l, w)^{n,l'} = \begin{cases} (\top, [\sum_{i=0}^{n-1} w[i]]) & \text{if } l = l' \\ (l, \bigcup_{i \in \mathbb{N}} [\sum_{j=0}^{n-1} w[i \times n + j]]) & \text{otherwise} \end{cases}$$

Example 4.4. *We illustrate operations on abstract WCET below:*

- *Let* $w = (l, [10, 10, 5, 3])$. *Then* $w[2] = 5$, *and* $w[5] = 3$ *since* 3 *is repeated infinitely;*
- $(l, [4, 3, 2]) \oplus (l', [3, 1]) = (l \sqcap l', [4 + 3, 3 + 1, 2 + 1]) = (l \sqcap l', [7, 4, 3])$*;*
- $(l, [4, 3, 2]) \uplus (l', [3, 2, 1]) = (l \sqcap l', [4, 3, 3, 2])$. *Value* 1 *is dropped because it is smaller than the minimum WCET of the left operand;*
- $(l, [5, 4])^{4,l} = (\top, [5 + 4 + 4 + 4]) = (\top, [17])$*;*
- *Assuming* $l \neq l'$, *we have* $(l, [5, 4])^{4,l'} = (l, [5 + 4 \times 3, 4 \times 4]) = (l, [17, 16])$.

4.1.3 Computing the WCET of a control-flow tree

Using the abstract WCET representation above, the abstract WCET $\omega(t)$ of a CFT t is computed inductively on the CFT structure as follows:

$$\begin{aligned} \omega(\text{Leaf}(b)) &= \omega(b) \\ \omega(\text{Seq}(t_1, \ldots, t_n)) &= \omega(t_1) \oplus \ldots \oplus \omega(t_n) \\ \omega(\text{Alt}(t_1, \ldots, t_n)) &= \omega(t_1) \uplus \ldots \uplus \omega(t_n) \\ \omega(\text{Loop}(l, t_b, n, t_e)) &= \omega(t_b)^{n,l} \oplus \omega(t_e) \end{aligned}$$

Example 4.5. *In Figure 4b, there are two nested loops:* l_1 *and* l_2. *The first-miss leaf fm has WCET* $(l, [10, 0])$. *When* $l = l_1$ *(resp.* $l = l_2$*) a cache miss occurs each time we enter* l_1 *(resp.* l_2*). In the first case, for a complete execution of the program, the miss penalty applies only once, whereas in the second case it applies for every iteration of* l_1*, since* l_2 *is* entered *at each iteration of* l_1. *Assuming* $\omega(A) = (\top, [15])$, $\omega(H_1) = (\top, [5])$, $\omega(H_2) = (\top, [5])$, *assuming 3 iterations for each loop* l_1, l_2, *and denoting* t *the CFT of Figure 4b, we have:*

$$\begin{aligned} \omega(t) &= (\top, [5]) \oplus ((\top, [5]) \oplus (l, [10, 0]) \oplus (\top[15]))^{3,l_2} \oplus (\top, [5]))^{3,l_1} \oplus (\top, [5]) \\ &= ((\top, [5]) \oplus (l, [30, 20])^{3,l_2} \oplus (\top, [5]))^{3,l_1} \oplus (\top, [5]) \end{aligned}$$

If $l = l_1$ *(single miss):*

$$\begin{aligned} \omega(t) &= ((\top, [5]) \oplus (l_1, [70, 60]) \oplus (\top, [5]))^{3,l_1} \oplus (\top, [5]) \\ &= (l_1, [80, 70])^{3,l_1} \oplus (\top, [5]) \\ &= (\top, [220]) \oplus (\top, [5]) \\ &= (\top, [225]) \end{aligned}$$

If $l = l_2$ *(three misses):*

$$\begin{aligned} \omega(t) &= ((\top, [5]) \oplus (\top, [70]) \oplus (\top, [5]))^{3,l_1} \oplus (\top, [5]) \\ &= (\top, [80])^{3,l_1} \oplus (\top, [5]) \\ &= (\top, [240]) \oplus (\top, [5]) \\ &= (\top, [245]) \end{aligned}$$

When some parameters of the CFT are unknown, $\omega(t)$ produces a formula containing symbolic values. For now, symbols can be of two kinds (this will be extended in the following sections):

- A *symbolic WCET*. For instance, $X \uplus (l, \{4\})$, where X is an unknown WCET;
- A *symbolic loop bound*. For instance, $(l, \{5, 3\})^{N,l'}$, where N is an unknown integer loop bound.

$\omega(t)$ produces a formula that is linear in the size of t. When the formula contains symbolic values, it cannot be reduced to a single operand. However, in order to decrease its size and evaluation time, the formula is reduced using simplification rules based on mathematical properties of the abstract WCET operations. For instance, $((l, \{5\}) \oplus X) \uplus ((l, \{4\}) \oplus X)$ reduces to $(l, \{5\}) \oplus X$.

As a final step, the reduced formula is translated into C code, that can be used off-line or on-line to instantiate the formula when symbol values become known.

4.2 Abstract interpretation of binary code

We will now recall the main concepts of the abstract interpretation procedure of [8]. *Abstract interpretation* [21] is a general static analysis method that infers program invariants. It propagates an *abstract state* of the program, which overapproximates the set of all possible *concrete states*, until a fixpoint is reached. It is *sound*, in the sense that the invariants it infers hold for any possible concrete program state.

While abstract interpretation usually targets source code, we rely on the abstract interpretation procedure for *binary* code proposed in. [8] because we want to inject the inferred invariants into our WCET analysis, which is applied to binary code. We summarize the main features of this interpretation procedure below.

4.2.1 Polyhedra

We begin with a quick reminder about the definition of a polyhedron. Let $\mathcal{V}$ be a set of variables and $\mathcal{C}$ be a set of linear constraints (equalities and/or inequalities) on the variables in $\mathcal{V}$. Then, $\langle c_1, \ldots, c_m \rangle$ is the polyhedron consisting in all the vectors in $\mathbb{Z}^n$ that satisfy the constraints $c_1, \ldots, c_m$, where $c_i \in \mathcal{C}$ for $1 \leq i \leq m$. Less formally, a polyhedron p can be viewed as the multi-dimensional geometrical shape that represents the set of possible values of the variables of $\mathcal{V}$ for which all the equalities and inequalities in $\mathcal{C}$ are satisfied. The variables of a polyhedron are also called its *dimensions* in the literature. We denote $p" = p \sqcap_\diamond p'$ the polyhedron consisting of the union of the constraints of p and p'; *vars*(p) the set of variables of p.

One important operation is the ability to do a *projection* of a polyhedron p on a subset $\mathcal{V}' = \{x_0, \ldots, x_n\}$ of its variables. The result is a polyhedron p' with less variables, such that every possible value $\{v_0, \ldots, v_n\}$ that satisfies the constraints of p also satisfies the constraints of p' and vice versa. To better understand the meaning of this operation it may be useful to think of geometric shapes in a 3D space: a projection on the variables (x, y) of a cube in (x, y, z) is simply the geometric projection of the cube on the plane (x, y). We will use projections in Section 5 to explain how we treat conditionals for building a parametric formula.

Example 4.6. *This example illustrates the projection operation:*

$$proj(\langle x_2 = x_0, x_3 = x_1 - 32, x_2 \leq 10 \rangle, \{x_0\}) = \langle x_0 \leq 10 \rangle$$

Table 1: Abstract states at several program points in Figure 2

line	Polyhedron	Registers	Memory
2	$p_2 = \langle\rangle$	$\mathcal{R}^\sharp_2 = \{\texttt{r0} : x_0, \texttt{fp} : x_1\}$	
4	$p_4 = \langle x_2 = x_0, x_3 = x_1 - 32\rangle$	$\mathcal{R}^\sharp_2$	$*^\sharp_4 = \{x_3 : x_2\}$
6	p_4	$\mathcal{R}^\sharp_6 = \{\texttt{r0} : x_4, \texttt{r3} : x_2, \texttt{fp} : x_1\}$	$*^\sharp_4$
8	$p_8 = p_4 \sqcap_\diamond \langle x_2 \leq 10\rangle$	$\mathcal{R}^\sharp_6$	$*^\sharp_4$
11	$p_{11} = p_4 \sqcap_\diamond \langle x_2 > 10\rangle$	$\mathcal{R}^\sharp_6$	$*^\sharp_4$

4.2.2 Abstract state

In abstract interpretation of binary code, an abstract state a is a tuple $(p, \mathcal{R}^\sharp, *^\sharp)$, which consists of a polyhedron p, a register mapping $\mathcal{R}^\sharp$ and an address mapping $*^\sharp$. We have $\mathcal{R}^\sharp(r) = v$ iff the variable v represents the value of the register r in p. Also, we have $*^\sharp(x_1) = x_2$ iff x_2 represents the value at the memory address represented by the variable x_1. We use the term *data location* to refer indistinctly to registers or memory addresses in the rest of the paper. We denote $m' = m[x : y]$ the mapping such that $m'(x) = y$ and $\forall x' \neq x : m'(x') = m(x')$.

Example 4.7. *In the following abstract state, register r_0 contains a positive value and address* 7872 *contains a value greater than that of r_0:*

$$(\langle x_1 \geq 0, x_2 = 7872, x_3 \geq x_1\rangle, \{r_0 : x_1\}, \{x_2 : x_3\})$$

4.2.3 Interpretation procedure

The procedure proceeds by forward abstract interpretation [21] applied to ARM A32 programs. A program P is represented as a sequence of labeled instructions $l_0 : I_0, l_1 : I_1, \ldots, l_n : END$, where I_k is the instruction at label l_k $(0 \leq k \leq n)$ and END terminates the program. The result $M = interpret(P)$ maps each label to the abstract state immediately *before* the execution of the corresponding instruction. An important specificity of this interpretation procedure is that the mapping between variables and data-locations can change as the interpretation progresses.

Example 4.8. *Table 1 details the abstract states at several points of the program of Figure 2. We assume that the value of n is not modified in the program. Until line 4, the register* `r0` *contains the value n, represented by variable x_0. Assume that* `r0` *is used to store the result of some arithmetic operation at line 4. As a result, at line 6 the value of* `r0` *does not correspond to argument n anymore, instead it is mapped to a new variable x_4 that corresponds to the value computed at line 4. Note that variable x_0 still represents the value of the argument n in the abstract state at line 6.*

5 Inferring input conditionals

In this section, we extend the abstract interpretation analysis from [8] to infer the input conditionals of a binary program. We consider 32-bit ARM programs, but the analysis can easily be extended to other architectures with similar procedure call conventions.

5.1 Identifying procedure arguments

By convention [6], 32-bit ARM programs pass the first four arguments of a procedure call through registers `r0`, `r1`, `r2` and `r3`. Additional arguments are passed through the stack. In our experiments, we found that few procedures use more than four arguments. Therefore, in the following we only consider arguments passed through these registers, which we call *input registers*.

We modify the abstract interpreter so that it identifies the polyhedra dimensions that are associated to input registers. As the dimension-to-data-location mapping evolves during the interpreter progression, a dimension represents a procedure argument if and only if it is mapped to one of the input registers in the abstract state at the starting location of the procedure.

Example 5.1. *In Figure 2, we identify the polyhedron dimensions to which* `r0` *is associated in the abstract state at line 1, that is to say* x_0*. Now assume that line 4 changes the value of* `r0` *to perform some computations. Thus,* `r0` *is mapped to another dimension:* x_4*. As a result, in the subsequent abstract states (e.g. the branch at line 7) the analysis correctly identifies that* x_0 *corresponds to a procedure argument and that* x_4 *is not one.*

5.2 From polyhedra to input conditionals

In this section, we explain how we extract input conditionals from the abstract states of the program.

5.2.1 Conditional statements

When the interpreter analyses a conditional branching instruction, it adds the corresponding condition to the abstract state of the branch target; this is called *filtering*. We modify the analysis so that, whenever a filtering occurs, we project the resulting polyhedron over the dimensions previously identified as procedure arguments. As a result, we obtain a polyhedron corresponding to the constraints that the input registers must satisfy in order to branch to the corresponding location. These constraints consist in a conjunction of inequalities on input registers, which we call *input conditionals*.

Example 5.2. *In figure 2, in the abstract state at line 8 of Table 1, the register* `r3` *is associated to the variable* x_2*, which is equal to* x_0 *(i.e. the procedure argument). Since line 8 is in the* then *block of the conditional statement, it contains the filtering condition* $x_2 \leq 10$*. To obtain the input conditional, we project the polyhedron over the variable* x_0*:*

$$proj(\langle x_2 = x_0, x_3 = x_1 - 32, x_2 \leq 10\rangle, \{x_0\}) = \langle x_0 \leq 10\rangle$$

In the general case, the input conditionals are passed unchanged to the CFT builder. There are however two particular cases:

- If the projected polyhedron has no constraints (universe polyhedron), this either means that the branch condition contains no constraints on procedure arguments, or that the constraints cannot be represented by a polyhedron (e.g. a disjunction of constraints). From a WCET point-of-view, we can safely over-approximate to an unconditional branch, i.e. the input conditional is set to *true*.
- If the projected polyhedron has unsatisfiable constraints (empty polyhedron), the branch target is dead code, then the input conditional is set to *false*.

```
1  f:                      @  int f(int x){
2    @ ...                 @    // r0 contains x
3    str  r0, [fp, #-16]   @    // (fp-16) contains x
4    mov  r3, #1           @    int res = 1;
5    str  r3, [fp, #-8]    @
6    mov  r3, #0           @    int i = 0;
7    str  r3, [fp, #-12]   @
8  .L2:                    @    do{ // mov gr, #0 when entering the loop
9    ldr  r3, [fp, #-8]    @
10   lsl  r3, r3, #1       @      res += res;
11   str  r3, [fp, #-8]    @
12   ldr  r3, [fp, #-12]   @
13   add  r3, r3, #1       @      i++;
14   str  r3, [fp, #-12]   @
15   ldr  r2, [fp, #-12]   @
16   ldr  r3, [fp, #-16]   @      // add gr, gr, #1
17   cmp  r2, r3           @    }
18   blt  .L2              @    while(i < x);
19   ldr  r3, [fp, #-8]    @
20   mov  r0, r3           @    // r0 contains res
21   @ ...                 @    return res;
22   bx  lr                @  }
```

Figure 5: Assembly and C code of a loop

5.2.2 Loop bounds

If the branch instruction is located in a loop header, we compute a loop bound instead of a conditional. This is done using a "ghost" register, that does not correspond to an actual data-location used by the program register but represents the induction variable of the loop. The register is set to 0 at the entry of the loop and is incremented at each loop iteration.

Let p denote the polyhedron of the abstract state at the loop header, obtained after the abstract interpretation has reached a fixpoint. Let *args* denote the set of procedure argument variables, and g denote the variable mapped to the ghost register. Function $lbound(p, args, g)$ computes the loop bound as follows. First, it computes $p' = proj(p, args \cup \{g\})$. From there, two cases can occur:

- p' contains exactly two inequalities where the ghost register variable appears: one of them indicates that the ghost register variable is positive (a loop bound is always positive) and the other one is the loop bound.
- Otherwise, we are not able to compute a loop bound and it must be provided by the user.

Example 5.3. *The code of a simple f consisting of a simple loop is detailed in Figure 5. When entering the loop, the ghost register* `gr` *is initialized to 0 inside the abstract state of the analysis similarly to a* `mov gr, #0`*, as shown in comment at line 8. Then, at the end of each iteration* `gr` *is incremented. At the end of the loop interpretation, the state of the loop contains the bound to the value of the ghost register. Thus, assuming that x_0 is the dimension that corresponds to the argument x, we have: $\mathcal{R}^\sharp(gr) \leq x_0$. We simply replace $\mathcal{R}^\sharp(gr)$ with lb such that we have $lb \leq x_0$.*

6 Symbolic WCET with input conditionals

In this section, we detail how we extend the symbolic WCET computation approach from [9] to support input conditionals.

6.1 Control-flow Tree with input conditionals

We extend the previous definition of alternative nodes so that an input conditional is associated to each alternative.

Definition 6.1. *Let $(t_1, \ldots, t_n)$ be a set of CFTs, $(e_1, \ldots, e_n)$ be a set of input conditionals and $1 \leq k \leq n$. The* deterministic alternative *node $Alt(e_1 \to t_1, \ldots, e_n \to t_n)$ represents an alternative between the execution of one tree among $(t_1, \ldots, t_n)$, such that the tree t_k can be executed only if e_k is true.*

Example 6.1. *Figure 3 depicts the CFT obtained for the program of Figure 2. For instance, we can see that the input conditional $\texttt{r0} \geq 11$, whose inference was detailed in Example 5.2, appears as an input conditional to execute B in the deterministic alternative node Alt_1.*

Concerning loop nodes, their definition remains unchanged, except that the loop bound n can now be a linear expression on procedure arguments.

Example 6.2. *The node $Loop(l, t_1, 4 \times \texttt{r0} + \texttt{r1}, t_2)$ represents a loop identified by l, that executes $4 \times \texttt{r0} + \texttt{r1}$ times the tree t_1 and exits by executing the tree t_2.*

6.2 WCET formulas with input conditionals

We define a new operator $\circledast$ that multiplies a WCET by an input conditional. It has higher priority $\oplus$ and $\uplus$ operators, but lesser priority than the other operators. It is used to compute the WCET of an Alt node:

$$\omega(\text{Alt}(e_1 \to t_1, \ldots, e_n \to t_n)) = e_1 \circledast \omega(t_1) \uplus \ldots \uplus e_n \circledast \omega(t_n)$$

Definition 6.2. *Let e be an input conditional and w be an abstract WCET.*

$$e \circledast w = \begin{cases} w & \text{if } e \text{ is true} \\ \theta & \text{otherwise} \end{cases}$$

Example 6.3. *The subtree Alt_1 of Figure 3 is translated into the formula $(\texttt{r0} \geq 11) \circledast \omega(B) \uplus (\texttt{r0} \leq 10) \circledast (\top, \{5\})$. This corresponds to $\omega(B)$ if $\texttt{r0} \geq 11$, or to $(\top, \{5\})$ otherwise.*

6.3 Simplifying WCET formulas

The size of the formula $\omega(t)$ is linear in the number of nodes of t. In this section, we detail simplification rules to reduce the size of WCET formulae. The simplification procedure applies simplification rules in an order that follows the classic integer arithmetic simplification strategy described in [19].

Commutativity

$$(e_k \wedge e_l) \circledast w_1 \mapsto (e_l \wedge e_k) \circledast w_1 \qquad \text{if } e_l \lhd e_k \tag{1}$$
$$e_k \circledast w_1 \oplus e_l \circledast w_2 \mapsto e_l \circledast w_2 \oplus e_k \circledast w_1 \qquad \text{if } e_l \lhd e_k \tag{2}$$
$$e_k \circledast w_1 \uplus e_l \circledast w_2 \mapsto e_l \circledast w_2 \uplus e_k \circledast w_2 \qquad \text{if } e_l \lhd e_k \tag{3}$$

Factorization

$$e_k \circledast w_1 \oplus e_l \circledast w_1 \mapsto w_1 \qquad \text{if } e_l \Leftrightarrow \neg e_k \tag{4}$$
$$e_k \circledast w_1 \uplus e_l \circledast w_1 \mapsto w_1 \qquad \text{if } e_l \Leftrightarrow \neg e_k \tag{5}$$
$$e_k \circledast w_1 \oplus e_l \circledast w_2 \mapsto e_k \circledast (w_1 \oplus w_2) \qquad \text{if } e_k \Leftrightarrow e_l \tag{6}$$
$$e_k \circledast w_1 \uplus e_l \circledast w_2 \mapsto e_k \circledast (w_1 \uplus w_2) \qquad \text{if } e_k \Leftrightarrow e_l \tag{7}$$
$$e_k \circledast w_1 \oplus (e_k \wedge e_l) \circledast w_2 \mapsto e_k \circledast (w_1 \oplus e_l \circledast w_2) \tag{8}$$
$$e_k \circledast w_1 \uplus (e_k \wedge e_l) \circledast w_2 \mapsto e_k \circledast (w_1 \uplus e_l \circledast w_2) \tag{9}$$

Multiplication

$$e_k \circledast \theta \mapsto \theta \tag{10}$$
$$e_k \circledast w_1 \mapsto \theta \qquad \text{if } e_k \Leftrightarrow \mathit{false} \tag{11}$$
$$e_k \circledast w_1 \mapsto w_1 \qquad \text{if } e_k \Leftrightarrow \mathit{true} \tag{12}$$
$$e_k \circledast (e_l \circledast w_1) \mapsto e_k \circledast w_1 \qquad \text{if } e_k \Leftrightarrow e_l \tag{13}$$

Loops

$$(e_k \circledast w_1)^{it,l} \mapsto e_k \circledast (w_1)^{it,l} \tag{14}$$

Figure 6: Rewriting rules with input conditionals

6.3.1 Simplification rules

The new simplification rules for WCET formulae that contain input conditionals are detailed in Figure 6. e_k and e_l are input conditionals, w_1 and w_2 are abstract WCETs, l is a loop identifier and *it* is a loop bound. These rules are added to the rules of [9]. For each rule of the form $l \mapsto r$ we must prove that $l = r$. We illustrate the general proof principle for rule (8) below. The equivalence proofs of l and r for all these rules can be found in A.

Property 6.1. $e_k \circledast w_1 \oplus (e_k \wedge e_l) \circledast w_2 = e_k \circledast (w_1 \oplus e_l \circledast w_2)$

Proof. Case by case on the possible values of e_k and e_l. We write 0 (resp. 1) as a shorthand for *false* (resp. *true*).

1. Case: $e_k = 0$

$$0 \circledast w_1 \oplus (0 \wedge e_l) \circledast w_2 = \theta \oplus 0 \circledast w_2 = \theta$$
$$0 \circledast (w_1 \oplus e_l \circledast w_2) = \theta$$

2. Case: $e_l = 0$

$$e_k \circledast w_1 \oplus (e_k \wedge 0) \circledast w_2 = e_k \circledast w_1 \oplus 0 \circledast w_2 = e_k \circledast w_1$$
$$e_k \circledast (w_1 \oplus 0 \circledast w_2) = e_k \circledast (w_1 \oplus \theta) = e_k \circledast w_1$$

3. Case: $e_k = e_l = 1$

$$1 \circledast w_1 \oplus (1 \wedge 1) \circledast w_2 = w_1 \oplus 1 \circledast w_2 = w_1 \oplus w_2$$
$$1 \circledast (w_1 \oplus 1 \circledast w_2) = 1 \circledast (w_1 \oplus w_2) = w_1 \oplus w_2$$

□

Factorization rules require to test the equivalence of input conditionals. The equivalence test is detailed in Section 6.3.2. For distributivity, we rely on an order relation $\lhd$ on input conditionals (see Section 6.3.3 below) so that they can only be applied in one direction, to ensure termination of the simplification. Multiplication rules are direct consequences of the definition of the operator $\circledast$.

6.3.2 Testing input conditionals equivalence

Checking the equivalence of an input conditional to either *true* or *false* is straightforward. No simplification rule can create a new predicate that is equivalent to *true* or *false*. Therefore, we can simply check (syntactically) that the input conditional is the predicate *true* or the predicate *false*.

In other cases, to test the equivalence of two input conditionals, we first put them in *normal form*. Then, equivalence amounts to a syntactic equality. An input conditional is in normal form iff:

1. The left-hand side of comparison operators is 0;
2. Comparison operators are either $\leq$ or $=$;
3. Terms are ordered by increasing parameter identifiers;
4. The last term is a constant.

Example 6.4. *The normal form of input conditional* $10 \geq 15 + \texttt{r1} + \texttt{r0}$ *is* $0 \leq -\texttt{r0} - \texttt{r1} - 5$.

6.3.3 Termination of the simplification procedure

The orientation of each rule is such that either of the following holds: 1) r has less operands than l; 2) r has less parentheses than l; 3) input conditionals in l are "smaller" than those in r according to relation $\lhd$ (defined below). Based on these properties, we can define a strict order relation $\prec$ such that we have $l \prec r$ for each rule. This ensures that the simplification procedure terminates. The ordering relation on input conditionals is defined as follows:

$$\begin{aligned} e_k \lhd e_l \Leftrightarrow & (\mathrm{lid}(e_k) < \mathrm{lid}(e_l)) \vee \\ & (\mathrm{lid}(e_k) = \mathrm{lid}(e_l) \wedge \mathrm{size}(e_k) < \mathrm{size}(e_l)) \vee \\ & ((\mathrm{conj}(e_k) = \mathit{false} \wedge \mathrm{conj}(e_l) = \mathit{false}) \wedge \\ & (\mathrm{lid}(e_k) = \mathrm{lid}(e_l)) \wedge (\mathrm{size}(e_k) = \mathrm{size}(e_l)) \wedge \\ & (\mathrm{linconst}(e_k) < \mathrm{linconst}(e_l))) \end{aligned} \tag{15}$$

Where *lid* returns the lowest parameter identifier (or -1 if there is no parameter), *size* returns the number of terms in an input conditional, *linconst* returns the constant (-1 for a conjunction), of the input conditional and *conj* is true iff the input conditional is a conjunction of input conditionals.

Example 6.5. *Consider the input conditionals* $0 \leq \texttt{r0} + \texttt{r1} + 10 \wedge 0 \leq \texttt{r2}$. *We have:*

$$\begin{aligned} \mathit{lid}(0 \leq \texttt{r0} + \texttt{r1} + 10 \wedge 0 \leq \texttt{r2}) &= 0 \\ \mathit{size}(0 \leq \texttt{r0} + \texttt{r1} + 10 \wedge 0 \leq \texttt{r2}) &= 6 \\ \mathit{linconst}(0 \leq \texttt{r0} + \texttt{r1} + 10) &= 10 \\ \mathit{conj}(0 \leq \texttt{r0} + \texttt{r1} + 10 \wedge 0 \leq \texttt{r2}) &= \mathit{true} \end{aligned}$$

6.4 Formula instantiation

We compile the simplified formula into a C procedure, whose arguments correspond to the arguments of the procedure under analysis. This procedure can be executed off-line, e.g. for sensitivity analysis, or on-line, e.g. to implement an adaptive real-time system.

In order to improve the performance for on-line use, we ensure that the C compiler optimizations can be applied efficiently thanks to the following rules: 1) the resulting program is standalone, i.e. no library dependencies; 2) WCET lists are represented by several integer variables, one for each list value; 3) only simple conditional statements are allowed: no loops, no pointers and no function calls. In this way, we can easily bound the execution time of the evaluation formula, and its WCET is very low.

Note that since the WCET of a procedure is the worst-case for any possible execution scenario, executing the instantiation code before executing the procedure *cannot* increase the WCET of the procedure.

7 Modular WCET analysis of pure functions

In this section, we present an extension of our approach, a modular analysis that analyzes each procedure independently. This extension is currently limited to pure functions, that is to say functions without side-effects.

Algorithm 1 Summary construction

1: **function** ConstructSummary(P)
2: $\quad \mathcal{A}^\sharp \leftarrow \{r_0 : x_0, r_1 : x_1, r_2 : x_2, r_3 : x_3\}$
3: $\quad \mathcal{A}_1^\sharp \leftarrow \mathcal{A}^\sharp$
4: $\quad s \leftarrow (\top, \mathcal{A}_1^\sharp, \emptyset)$
5: $\quad (p_P, \mathcal{R}_P^\sharp, *_P^\sharp) \leftarrow interpret(s, P)$
6: $\quad p_s \leftarrow proj(p_P, Img(\mathcal{A}^\sharp) \cup \{\mathcal{R}_P^\sharp(r_0)\})$
7: $\quad$ **return** $(p_s, \mathcal{A}^\sharp, \mathcal{R}_P^\sharp)$

7.1 Modular abstract interpretation

In our previous abstract interpretation analysis [8], procedure calls were inlined. Inlining has two negative impacts on the analysis complexity. First, when a procedure is called several times in the same program, it must be analysed several times. Second, the number of variables used to analyze a procedure has an exponential impact on the complexity of the analysis of the procedure. Inlining adds variables of the sub-procedure to those of the calling procedure, thus exponentially impacting the complexity. Modular abstract interpretation avoids these two drawbacks, thus significantly reducing the complexity of the analysis and improving its scalability.

In this section we detail a modular abstract interpretation analysis, which relies on the extensions previously presented in this paper. Each procedure is analyzed only once per program analysis, and in isolation from other procedures. The analysis consists of two parts: 1) inferring a *summary* for each procedure, representing how a call to the procedure impacts the state of the caller; 2) deriving *call predicates* for each procedure call, which represent constraints on the values of the procedure arguments at the call site. Call predicates are not required for the modular abstract interpretation of the program, they are only used during the symbolic WCET computation step.

In the following, a program is represented as a set of procedures $\mathcal{P}$, one of which is the main procedure, i.e. the entry point of the program. A procedure $p \in \mathcal{P}$ is defined as a sequence of labeled instructions $l_0 : I_0, \ldots, l_n : END$.

7.1.1 Procedure summary

In the 32-bit ARM convention [6], the value returned by a procedure is stored in register r_0. The summary of a procedure is defined as a tuple $(p, \mathcal{A}^\sharp, \mathcal{R}^\sharp)$, where (there is no memory mapping since we only consider procedures without side effects):

- p is a polyhedron that represents the abstract state of the analysis at the end of the procedure interpretation[4];
- $\mathcal{A}^\sharp$ is an argument mapping, that associates a variable of p to each procedure argument stored in a register before the execution of f;
- $\mathcal{R}^\sharp$ is a register mapping.

Algorithm 1 details the summary construction. Line 2 constructs a register mapping that maps a fresh variable to each procedure argument (stored in registers r_0 to r_3). State s at line 4 represents the initial state of the procedure. Line 5 interprets the procedure P starting from

[4]For procedures with several exit edges, the CFG reconstruction step adds a single node to which all exit edges point.

```
1  add_nozero:              @  int add_nozero(int a , int b){
2    add  r2, r0, r1        @    int res = a+b;
3    cmp  r2, #0            @
4    bne  .L2               @    if(res == 0){
5    add  r2, r2, #1        @      res++;
6  .L2:                     @    }
7    mov  r0, r2            @    return res;
8    bx   lr                @  }
9
```

7	$p_7 = \langle x_0 + x_1 \leq x_2 \leq x_0 + x_1 + 1 \rangle$	$\mathcal{R}^\sharp_7 = \mathcal{R}^\sharp_3$
8	$p_8 = p_7 \sqcap_\diamond \langle x_4 = x_2 \rangle$	$\mathcal{R}^\sharp_8 = \mathcal{R}^\sharp_7[r_0 : x_4]$

Figure 7: A simplified pure function that sums its inputs and never returns 0

the initial state s. The only value that is modified by a pure procedure is its return value. In addition, this value only depends on the procedure arguments. Therefore, at line 6 we project the state obtained at the end of the variables mapped to the arguments and to the return value. Line 7 returns the procedure summary.

Example 7.1. *The procedure* add_nozero *in Figure 7 is a pure function. Its return value depends on its two input arguments. To ease understanding, the assembly code is slightly simplified compared to what a compiler would actually produce. The procedure is summarized as:*

$$(proj(p_8, Img(\mathcal{A}^\sharp) \cup \{\mathcal{R}^\sharp_8(r_0)\}), \mathcal{A}^\sharp, \mathcal{R}^\sharp_8) = (\langle x_0 + x_1 \leq x_4, x_4 \leq x_0 + x_1 + 1 \rangle, \mathcal{A}^\sharp, \mathcal{R}^\sharp_8)$$

In other words, $arg_1 + arg_2 \leq return\_value \leq arg_1 + arg_2 + 1$.

7.1.2 Summary instantiation

Let $p[x_i/x_j]$ denote the polyhedron resulting from the substitution of variable x_j by x_i in p. The instantiation of a procedure summary is detailed in Algorithm 2. It takes as arguments the procedure summary $(p_s, \mathcal{A}^\sharp_s, \mathcal{R}^\sharp_s)$ and the abstract state at the procedure call $(p, \mathcal{R}^\sharp, *^\sharp)$. At line 2, it creates a fresh copy of the summary, where all the variables of the summary are substituted by fresh variables. From line 3 to line 5, it substitutes the variables mapped to procedure arguments in the summary by the actual argument variables at the call site. Line 6 intersects the (modified) polyhedron of the summary with the polyhedron at the call site. From line 7 to line 10, it updates the register mapping of the caller to account for the register modifications performed by the callee. Line 11 returns the abstract state obtained after the call.

Example 7.2. *The procedure* caller *of Figure 8 calls the procedure* add_nozero *at label 5. By instantiating the summary obtained in Example 7.1, we obtain the abstract state* $(p_{6'}, \mathcal{R}^\sharp_{6'}, *^\sharp_{6'})$ *at*

```
1  caller:                  @  int caller(int x, int y, int z){
2    add  r3, r0, r1        @    int f = x + y;
3    mov  r1, r2            @    // set z as second argument
4    mov  r0, r3            @    // set f as first argument
5    bl   add_nozero        @
6    mov  r3, r0            @
7    mov  r0, r3            @    return add_nozero(f, z);
8    bx   lr                @  }
9
```

$$
\begin{aligned}
p_{6'} &= p_{5'} \sqcap_\diamond (\langle x'_0 + x'_1 \leq x'_4 \leq x'_0 + x'_1 + 1 \rangle [x_{10}/x'_0, x_9/x'_1]) \\
\mathcal{R}^\sharp_{6'} &= \mathcal{R}^\sharp_8[r_0 : x'_4, r_1 : x_9] \\
*^\sharp_{6'} &= \{\}
\end{aligned}
$$

where x'_n denotes the fresh variable substituted for x_n in the summary.

7.1.3 Call predicates

We derive call predicates at each call site. Each call predicate relates one argument of the callee to the arguments of the caller. In other words, it provides information on how this argument passed to the callee depends on the arguments of the caller.

Definition 7.1 (Call predicate)**.** *Let f be a procedure with an instruction that calls a procedure g at label l_i. Let $M = interpret(f)$, $(p, \mathcal{R}^\sharp, *^\sharp) = M[l_i]$. Let A_f denote the set of variables mapped*

to the arguments of f. Let A_{g_i} be such that $A_{g_i}(j)$ denotes the variables of the $(j+1)^{th}$ argument passed to g at call site l_i[5]*. The* call predicate *$cpred_{g_i}(j)$ is defined as:*

$$cpred_{g_i}(j) = export(proj(p, Img(A_f) \cup \{A_{g_i}(j)\}))$$

where $export(p')$ exports p' as a set of constraints, after substituting $A_f(k)$ by the identifier `f_k`*, and $A_{g_i}(j)$ by the identifier* `g_i_j`*.*

Example 7.3. *Consider the procedure* caller *in Figure 8. For the call to* caller *at label 5, we have:*

$$\begin{aligned} cpred_{add\_nozero}(0) &= export(proj(p_{5'}, \{x_5, x_6, x_7, \} \cup \{x_{10}\}) \\ &= export(\langle x_{10} = x_5 + x_6 \rangle) \\ &= \{add\_nozero_0 = caller_0 + caller_1\} \end{aligned}$$

Similarly, we obtain $cpred_{add\_nozero}(1) = \{add\_nozero_1 = caller_2\}$

7.2 Modular WCET analysis

In this section, we detail the modular WCET analysis, which relies on the input conditionals and call predicates inferred by the abstract interpretation.

7.2.1 Procedure calls and control-flow trees

In our previous work on symbolic WCET computation [9], for each procedure call, the CFT of the callee is inlined in the CFT of the caller. Instead, for our modular WCET analysis we introduce a new kind of tree to represent a procedure call.

Definition 7.2 (Call control-flow tree)**.** *Let f be a procedure and $(m_1, \ldots, m_n)$ be a set of call predicates. The tree $Call(f, (m_1, \ldots, m_n))$ represents a call to the procedure f, where $m_k = cpred_f(k)$ for $1 \leq k \leq n$.*

The abstract WCET of a call is defined as:

$$\omega(\text{Call}(f, (m_1, \ldots, m_n))) = f(m_1, \ldots, m_n)$$

where f identifies the WCET formula of f.

Example 7.4. *For the example of Figure 8, the WCET of* caller *is:*

$$w_1 \oplus add\_nozero(add\_nozero_1 = f_1 + f_2, add\_nozero_2 = f_3) \oplus w_2$$

where w_1 and w_2 are the WCET of the instructions before and after the procedure call.

7.2.2 Simplification

We instantiate sub-formulas of procedure calls during formula simplification. To do so, we update input conditionals so that they depend on arguments of the caller rather than on arguments of the callee. More formally, we introduce the following simplification rule:

$$f(m_1, \ldots, m_n) \mapsto inst(f, p, Dom(p))$$

[5] In the following we omit subscript i when clear from context.

where[6]:

$$
\begin{aligned}
p &= \langle m_1, \ldots, m_n \rangle \\
inst((l, w), p, vs) &= (l, w) \\
inst(w \oplus w', p, vs) &= inst(w, p, vs) \oplus inst(w', p, vs) \\
inst(w \uplus w', p, vs) &= inst(w, p, vs) \uplus inst(w', p, vs) \\
inst(e \circledast w, p, vs) &= proj(p \sqcap_\diamond \langle e \rangle, vs) \circledast inst(w, p \sqcap_\diamond \langle e \rangle, vs) \\
inst(w^{n,l}, p, vs) &= \begin{cases} inst(w, p, vs)^{n,l} & \text{if } n \text{ is constant} \\ inst(w, p, vs)^{lbound(p \sqcap_\diamond \langle lb \leq n \rangle\}, vs, lb), l} & \text{otherwise} \end{cases}
\end{aligned}
$$

Example 7.5 (Sub-formula instantiation)**.** *Consider the two procedures* caller *and* add_nozero *of Figure 7 and Figure 8. Assume the WCET of* add_nozero *to be:* $w_3 \oplus ((add\_nozero_1 + add\_nozero_2 = 0) \circledast w_4) \oplus w_5$.

After simplification, we obtain the following WCET for procedure caller*:*

$$w_1 \oplus (w_3 \oplus ((caller_1 + caller_2 + caller_3 = 0) \circledast w_4) \oplus w_5) \oplus w_2$$

8 Evaluation

In this section we present the evaluation of our approach. First, we detail experiments on TACLeBench. Second, we illustrate how on-line formula instantiation can be leveraged to implement adaptive real-time systems.

8.1 Experiments

We first present our experimental setup, to enable the reproduction of our experiments. Then, we detail our benchmarks selection process. Finally, we provide metrics obtained by running our tool on the selected benchmarks.

8.1.1 Experimental setup

We implemented our approach[7] as an extension to OTAWA, an open-source WCET analysis tool [7]. We used the following hardware setup:

- Modeled processor: 1 ALU, 1 FPU, 1 MU. Integer addition costs 1 cycle, floating point addition 3 cycles, multiplication 6 cycles, division 15 cycles. It has a 4 stages pipeline (fetch, decode, execute, commit), a fetch queue of size 3, fetches 2 instructions per cycle, and executes up to 4 instructions in parallel;
- L1 instruction cache: 64KB, LRU replacement policy, 1-way. The miss penalty is 10 cycles;
- Compilation: each benchmark is compiled as a standalone binary file using GCC version 10.3.1 for ARM, with flags -O0 -g -nostdinc -nostdlib -mtune=cortex-a8 -mfpu=neon -mfloat-abi=hard. *cjpeg_wrbmp* uses a custom memcpy implementation in order to compile with gcc, which does not compile without standard library otherwise;
- Analyses execution times: they are measured on an Intel® Core™ i7-8550U CPU @ 1.80GHz × 8 with 16 GB of RAM.

[6] Recall that function *lbound* was defined in Section 5.2.2

[7] Available on request for reviewing purposes. A public-access link will be provided for the final version of the paper.

8.1.2 Benchmark selection

We run our experiments on the TACLeBench benchmarks suite [23]. We did not analyze all the procedures of the benchmarks:

- 11 programs are not supported by OTAWA (out of the 54 of TACLeBench): 2 because of recursions (*fac* and *recursion*), 9 because of the incomplete support for division instructions (*adpcm_dec, adpcm_enc, ammunition, cjpeg_transupp, epic, h264_dec, huff_enc, quicksort* and *susan*);
- 181 procedures have arguments, out of the 1032 procedures of the other programs;
- OTAWA does not handle well procedures with switch-cases, thus we do not use such procedures;
- The polyhedra analysis only supports the integer data-type. Thus it derives incorrect results for 4 procedures (*gsm_enc_norm, isqrt_usqrt, st_calc_Var_Stddev* and *st_sqrtf*);
- The polyhedra analysis is intractable for 31 procedures: it either executes for more than an hour, or runs out-of-memory. This happens for procedures with complex memory access patterns, which leads to an explosion of the number of dimensions in the polyhedron.

Among the remaining procedures, we present only the procedures for which the polyhedra analysis derived at least one input conditional. Each procedure name is prefixed with the program it is part of (e.g. *fft_modff* is from the *fft* program). Only *gsm_dec_Long_Term_Synthesis_Filtering* and *mpeg2_dist2* have more than 4 arguments; we simply ignore the other arguments.

Four procedures have just parametric loop bounds: *audiobeam_adjust_delays*, *audiobeam_calculate_energy*, *audiobeam_find_max_in_array* and *audiobeam_find_min_in_arr*. Five procedures have both parametric loops bounds and parametric conditional statements: *audiobeam_calc_distances*, *g723_enc_quan*, *ludcmp_test*, *minver_minver* and *minver_mmul*. The remaining procedures only have parametric conditional statements.

8.1.3 WCET adaptivity

Table 2 summarizes our results regarding WCET adaptivity. The *Procedure* column contains the name of the analyzed procedure. We first report the WCET computed with *IPET*. The *CFT* sub-columns indicate the *Lowest* and the *Highest* WCET computed by our technique, as well as the difference between these two columns in percentage (in the *Diff* column).

For 26 out of 31 procedures, the adaptivity, i.e. the difference between the highest and the lowest WCET, is more than 5%. Many examples exhibit from 30% to 70% adaptivity, usually due to parametric conditional statements. Regarding loops, our tool supports linear loop bounds, which is not the case for related works supporting parametric loops bounds: they support only a single parameter or the sum of one parameter and an integer. However, the presented procedures do not rely on bounds other than a single parameter.

The highest adaptivities (those over 90%) are exhibited when loop bounds can range down to 0, which can actually be considered unrealistic. Another case is procedure *minver_minver*, for which the lowest WCET corresponds to an unrealistic argument value: it occurs when the size of the matrix to inverse is lower than 2 or higher than 500, in which case the procedure returns immediately.

Only two procedures exhibit no variability even though their WCET formula contains parameters. The *fft_modff* formula contains two alternatives, one of which has the input conditional *true* because the actual condition in the program contains a disjunction. The WCET of the *true*

Table 2: WCET adaptivity (in cycles)

rijndael_enc_fseek	449	381	449	15.1

alternative is higher than that of the other alternative, which explains the absence of adaptivity. The *audiobeam_calculate_energy* formula contains a parametric loop bound whose maximum value is 0 in TACLeBench.

The *Highest* WCET is slightly higher than the WCET inferred by IPET (1.4% on average, 0% minimum, 12.7% maximum). This is because: 1) the transformation from CFG to CFT can introduce execution paths that do not exist in the CFG (see [9] for details); 2) the hardware analyses are slightly more pessimistic in our approach (e.g. loops with multiple exits impair the pipeline analysis, loop headers duplicated by the transformation to CFT impair the cache analysis).

8.1.4 Analysis time

The analysis times of IPET and our technique are presented in Table 3. The *IPET* column exhibit the analysis time with IPET. The *CFT* sub-columns indicate the analysis time for our technique: *Polyhedra* indicates the time spent in abstract interpretation, while *Symbolic WCET* indicates the time spent in WCET computation. The sum of the *Polyhedra* and the *Symbolic WCET* columns give the global execution time of our technique.

For small procedures, the analysis times are similar for the IPET analysis, the polyhedra analysis, and the symbolic WCET computation. This is because the execution time for the CFG reconstruction dominates the execution time of the actual analysis.

For bigger procedures, the analyses times grow, and unexpectedly the analysis times of IPET and of the Symbolic WCET computation (without considering polyhedra analysis times) are similar. This is because the cache analysis (performed by both) dominates the rest of the analysis. Its complexity is exponential in the depth of loop nesting. In some cases, the polyhedra analysis has higher execution times. This corresponds to programs with many memory accesses, which cause the polyhedra to have many dimensions and constraints. Furthermore, we also noticed that our extensions to support input conditionals have very little to no impact on the symbolic WCET analysis time.

The major difference between our work and IPET concerning analysis time is the abstract interpretation part that extracts input conditionals. There remains a lot of room for improving the scalability of this part of our approach, by adapting the rich set of optimization techniques developed by the community on abstract interpretation over the past decades. Nonetheless, our approach is already capable of producing WCET formulas for programs that are currently out of the scope of other tools in the literature.

8.1.5 Embeddability

The size of the initial and simplified formulae are reported in Figure 9. A simplified formula typically contains between 10 and 50 operands. Its size depends on the number of input conditionals in the non-simplified formula. The largest formula (*minver_minver*) is reduced to 15% of its initial size by our simplification procedure.

Table 4 reports instantiation times (in cycles) for a selection of procedures with various characteristics, in terms of WCET, adaptivity, and formula size. *Instantiation* indicates the WCET of the instantiation program computed by OTAWA. *Max gain* is the difference between the highest and the lowest WCET. *WCET* reports the *Highest* WCET of Table 2. *Op* reports the number of operands in the formula, from Figure 9.

On-line instantiation can be considered only when *Max gain* is significantly larger than *Instantiation*. This is the case for most procedures of Table 2, and the difference is actually quite large. For instance, for *cjpeg_wrbmp_write_colormap*, the instantiation takes 105 cycles while

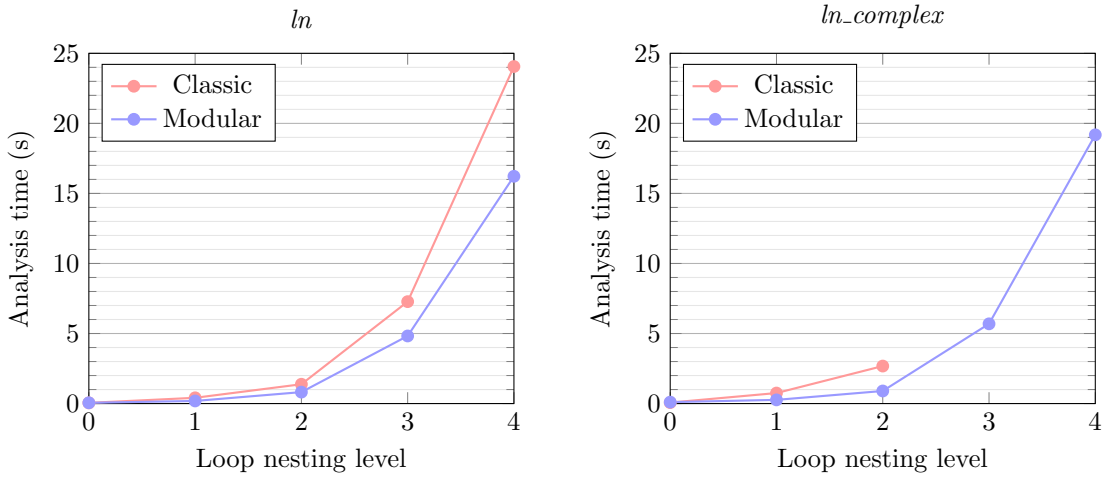

Figure 10: Comparison between classic and modular analysis time (in seconds)

there are 100, 513 cycles that can be reclaimed for other tasks. On the other extreme, the instantiation time of *audiobeam_wrapped_dec_offset* is larger than its WCET, so on-line instantiation has no benefit.

8.1.6 Modular WCET analysis

We use two synthetic programs[8], *ln* and *ln_complex*, to emphasize the benefits of the modular analysis. They call a procedure at different loop nest levels: from *ln0* (no loop, only a procedure call), to *ln4* (loop > loop > loop > loop > procedure call). *ln* calls a simple procedure that performs 4 additions. *ln_complex* calls a procedure that contains conditional statements and performs an addition in each branch. Increasing the loop nest level stresses the analysis, because the number of times the procedure call is analyzed is exponential in the nesting level. Even though widening is applied to speedup analysis convergence, the body of a loop must be analyzed at least two times (possibly more depending on the widening operator).

Figure 10 details the abstract interpretation time for different loop nest levels. *Modular* corresponds to the modular analysis time and *Classic* to the non-modular analysis time. Results show that when there is no loop in the program (*ln0*), the modular abstract interpretation is slightly slower. This is due to the overhead for computing the procedure summary and instantiating it, which is not performed in the non-modular approach. However, when the procedure is analyzed repeatedly (i.e. *ln1*, *ln2*, *ln3* and *ln4*), the modular analysis is significantly faster. This is especially true for *ln3* and *ln4* of *ln_complex*, where the non-modular analysis fails after 5 hours, with a segmentation fault, whereas the modular analysis completes the analysis in less than 20 seconds.

We also ran the complete modular WCET analysis on compatible procedures of TACLeBench. In comparison to the non-modular analysis, resulting WCET values are unchanged. In terms of analysis time, the impact of the modular analysis on the symbolic WCET computation part is negligible, because this part has a low complexity.

8.2 Application to adaptive real-time systems

In this section, we discuss the application of our WCET estimation approach to adaptive real-time systems. Real-time litterature usually focuses on schedulability analysis for such systems. Instead, here we consider on practical implementation aspects.

8.2.1 Semi-clairvoyant mixed-criticality scheduling

Recently, adaptive scheduling has gained interest following work on semi-clairvoyant scheduling for mixed-criticality systems [1]. The system model is based on the *dual-criticality* model of Vestal [37], where a system has two distinct criticality levels, LO (for *low*) and HI (for *high*). The workload consists of a set of tasks $\{\tau_i(\chi_i, [C_i^L, C_i^H]), T_i\}_{0 \leq i < n}$, where:

- $\chi_i \in \{LO, HI\}$ denotes the criticality of the task;
- C_i^L and C_i^H denote the LO-criticality and HI-criticality WCET of the task, such that $C_i^L \leq C_i^H$
- T_i is the *period* of the task and defines the minimum duration between two successive releases, also called *job*, of the task[9].

In *semi-clairvoyant scheduling*, the WCET of a job is estimated at its release. This estimate $\gamma_{i,j}$ equals either C_i^L or C_i^H. The system starts in LO-criticality mode, where every job of must complete before its deadline (the next job released by the same task). Whenever the estimate $\gamma_{i,j}$ of any job equals C_i^H, the system switches to HI-criticality mode, where only HI-criticality jobs need to complete before their deadlines.

Figure 11 depicts a possible implementation of such a system in C. Each job (one step of the loop) first acquires current input values (`getInputs`). Its WCET estimate is obtained by applying the WCET instanciation function of the task to the input values (`fWCET(inputs)`). If it exceeds the LO-WCET of the task, the system switches to HI-criticality. Note that there is no distinction between the code of LO and HI-criticality tasks. However, only LO-criticality tasks are suspended at mode switch (by `suspendAllLo`). Function `doWork` implements the actual task functionnality.

The scheduler function (`schedule`) is called at periodic time intervals (as defined by the scheduler time granularity) and also when a task starts waiting for its next release (when it executes `waitPeriod`). Before switching to the new higher priority task, it tests whether the system can transition back to LO-criticality mode (`goBackToLo`), in which case it does so by resuming all LO-criticality tasks (`resumeAllLo`). Suspended tasks are simply ignored when selecting the next task to schedule. Resuming a task puts it back into the list of tasks ready to be scheduled.

There is a slight difference between the implementation proposed in Figure 11 and the theoretical semi-clairvoyant model: in Figure 11, the WCET estimation occurs at the *start time* of the job (i.e. at the time when it is first selected for execution by the scheduler), while in the theoretical model it occurs at the *release time* of the job. To adhere more closely to the theoretical model, we can simply move L5-7 out of the task function and into the callback function of the periodic timer of the task. This timer is the actual trigger for new job releases; its callback is usually triggered by interruption and is thus not delayed by the scheduler. The pros and cons of both options (at release time or at start time) should be explored in future works.

[9] [1] assumes a more general model of jobs that may or may not be released periodically. We opt for a periodic model to make the discussion more concrete.

```
1  void mixedCritTask() {
2    int inputs[4];
3
4    while(1) {
5      getInputs(inputs);
6      if(fWCET(inputs)>CLo)
7        suspendAllLo();
8      doWork();
9      waitPeriod();
10   }
11 }
```

(a) Task code (LO or HI task)

```
1  void schedule() {
2    saveContext();
3
4    if(goBackToLo())
5      resumeAllLo();
6    selectNextTask();
7
8    restoreContext();
9  }
```

(b) Scheduler code

Figure 11: Implementing semi-clairvoyant mixed-criticality scheduling

```
1  void adaptiveTask() {
2    int inputs[4];
3
4    while(1) {
5      getInputs(inputs);
6      if(fWCET(inputs)>getBudget())
7        simpleWork();
8      else
9        complexWork();
10     waitPeriod();
11   }
12 }
```

Figure 12: Implementing an adaptive control task

8.2.2 Adaptive control

In *adaptive control*, the controller of the system adapts to parameters which vary or are initially uncertain. Such control is commonly used in embedded systems, as illustrated in the simple example of Figure 1. The parameter-space is often large, making control law computation very intensive. Implementing such adaptive control in real-time systems induces a tradeoff between control precision and computation time.

Figure 12 depicts the implementation of an adaptive control task using our WCET estimation approach. The time budget for a job is estimated after input acquisition (`getBudget`). The estimated WCET for the job is compared against its budget. If the estimation exceeds the WCET, the job executes a simplified version of the control law (`simpleWork`), which gives imprecise results but executes quickly. Otherwise, it executes a more refined control law (`complexWork`) that gives better results but takes more time to execute.

9 Conclusion

We presented a parametric WCET analysis that accounts for the effect of procedure argument values on the control-flow of the procedure. It first infers input conditionals by abstract inter-

pretation. Then, based on these results, the analysis produces a parametric WCET formula that depends on the procedure arguments. We also detailed a modular version of the analysis. Experiment show that our approach is adaptive and embeddable. We also illustrated how this approach can be used to implement adaptive real-time systems.

For future works, we plan to extend the modular analysis to support non-pure functions. The main challenge lies in developing an inter-procedural abstract interpretation procedure that supports procedures with side-effects.

A Rewriting rules equivalence proofs

In the following proofs, e_k and e_l are input conditionals, w_1 and w_2 are abstract WCETs, *it* is an integer and l is a loop identifier. For the sake of readability, *true* and *false* values are replaced respectively by 1 and 0. The proofs of all the rules of Figure 6 are presented, except for rules (10), (11) and (12) since those are direct consequences of the application of the $\circledast$ operator semantic and thus are correct by construction. All the proofs are case by case proofs on the possible values of e_k and e_l.

Proof of rule (1). Property: $(e_k \wedge e_l) \circledast w_1 = (e_l \wedge e_k) \circledast w_1$

1. Case $e_k = 0$
$$(0 \wedge e_l) \circledast w_1 = 0 \circledast w_1 = \theta$$
$$(e_l \wedge 0) \circledast w_1 = 0 \circledast w_1 = \theta$$
2. Case $e_l = 0$
$$(e_k \wedge 0) \circledast w_1 = 0 \circledast w_1 = \theta$$
$$(0 \wedge e_k) \circledast w_1 = 0 \circledast w_1 = \theta$$
3. Case $e_k = e_l = 1$
$$(1 \wedge 1) \circledast w_1 = 1 \circledast w_1 = w_1$$

□

Proof of rule (2). Property: $e_k \circledast w_1 \oplus e_l \circledast w_2 = e_l \circledast w_2 \oplus e_k \circledast w_1$

1. Case $e_k = 0$
$$0 \circledast w_1 \oplus e_l \circledast w_2 = \theta \oplus e_l \circledast w_2 = e_l \circledast w_2$$
$$e_l \circledast w_2 \oplus 0 \circledast w_1 = e_l \circledast w_2 \oplus \theta = e_l \circledast w_2$$
2. Case $e_l = 0$
$$e_k \circledast w_1 \oplus 0 \circledast w_2 = e_k \circledast w_1 \oplus \theta = e_k \circledast w_1$$
$$0 \circledast w_2 \oplus e_k \circledast w_1 = \theta \oplus e_k \circledast w_1 = e_k \circledast w_1$$
3. Case $e_k = e_l = 1$
$$1 \circledast w_1 \oplus 1 \circledast w_2 = w_1 \oplus w_2$$
$$1 \circledast w_2 \oplus 1 \circledast w_1 = w_2 \oplus w_1 = w_1 \oplus w_2$$

□

Proof of rule (3). Property: $e_k \circledast w_1 \uplus e_l \circledast w_2 = e_l \circledast w_2 \uplus e_k \circledast w_2$

1. Case $e_k = 0$

$$0 \circledast w_1 \uplus e_l \circledast w_2 = \theta \uplus e_l \circledast w_2 = e_l \circledast w_2$$
$$e_l \circledast w_2 \uplus 0 \circledast w_1 = e_l \circledast w_2 \uplus \theta = e_l \circledast w_2$$

2. Case $e_l = 0$

$$e_k \circledast w_1 \uplus 0 \circledast w_2 = e_k \circledast w_1 \uplus \theta = e_k \circledast w_1$$
$$0 \circledast w_2 \uplus e_k \circledast w_1 = \theta \uplus e_k \circledast w_1 = e_k \circledast w_1$$

3. Case $e_k = e_l = 1$

$$1 \circledast w_1 \uplus 1 \circledast w_2 = w_1 \uplus w_2$$
$$1 \circledast w_2 \uplus 1 \circledast w_1 = w_2 \uplus w_1 = w_1 \uplus w_2$$

□

Proof of rule (4). Property: $e_k \circledast w_1 \oplus e_l \circledast w_1 = w_1$ if $e_l \Leftrightarrow \neg e_k$

1. Case $e_k = 1 \wedge e_l = 0$

$$1 \circledast w_1 \oplus 0 \circledast w_1 = w_1 \oplus \theta = w_1$$

2. Case $e_k = 0 \wedge e_l = 1$

$$0 \circledast w_1 \oplus 1 \circledast w_1 = \theta \oplus w_1 = w_1$$

□

Proof of rule (5). Property: $e_k \circledast w_1 \uplus e_l \circledast w_1 = w_1$ if $e_l \Leftrightarrow \neg e_k$

1. Case $e_k = 1 \wedge e_l = 0$

$$1 \circledast w_1 \uplus 0 \circledast w_1 = w_1 \uplus \theta = w_1$$

2. Case $e_k = 0 \wedge e_l = 1$

$$0 \circledast w_1 \uplus 1 \circledast w_1 = \theta \uplus w_1 = w_1$$

□

Proof of rule (6). Property: $e_k \circledast w_1 \oplus e_l \circledast w_2 = e_k \circledast (w_1 \oplus w_2)$ if $e_k \Leftrightarrow e_l$

1. Case $e_k = e_l = 0$

$$0 \circledast w_1 \oplus 0 \circledast w_2 = \theta \oplus \theta = \theta$$
$$0 \circledast (w_1 \oplus w_2) = \theta$$

2. Case $e_k = e_l = 1$

$$1 \circledast w_1 \oplus 1 \circledast w_2 = w_1 \oplus w_2$$
$$1 \circledast (w_1 \oplus w_2) = w_1 \oplus w_2$$

□

Proof of rule (7). Property: $e_k \circledast w_1 \uplus e_l \circledast w_2 = e_k \circledast (w_1 \uplus w_2)$ if $e_k \Leftrightarrow e_l$

1. Case $e_k = e_l = 0$

$$0 \circledast w_1 \uplus 0 \circledast w_2 = \theta \uplus \theta = \theta$$
$$0 \circledast (w_1 \uplus w_2) = \theta$$

2. Case $e_k = e_l = 1$

$$1 \circledast w_1 \uplus 1 \circledast w_2 = w_1 \uplus w_2$$
$$1 \circledast (w_1 \uplus w_2) = w_1 \uplus w_2$$

□

Proof of rule (8). Property: $e_k \circledast w_1 \oplus (e_k \wedge e_l) \circledast w_2 = e_k \circledast (w_1 \oplus e_l \circledast w_2)$

1. Case $e_k = 0$

$$0 \circledast w_1 \oplus (0 \wedge e_l) \circledast w_2 = \theta \oplus 0 \circledast w_2 = \theta \oplus \theta = \theta$$
$$0 \circledast (w_1 \oplus e_l \circledast w_2) = \theta$$

2. Case $e_l = 0$

$$e_k \circledast w_1 \oplus (e_k \wedge 0) \circledast w_2 = e_k \circledast w_1 \oplus 0 \circledast w_2 = e_k \circledast w_1 \oplus \theta = e_k \circledast w_1$$
$$e_k \circledast (w_1 \oplus 0 \circledast w_2) = e_k \circledast (w_1 \oplus \theta) = e_k \circledast w_1$$

3. Case $e_k = e_l = 1$

$$1 \circledast w_1 \oplus (1 \wedge 1) \circledast w_2 = w_1 \oplus 1 \circledast w_2 = w_1 \oplus w_2$$
$$1 \circledast (w_1 \oplus 1 \circledast w_2) = w_1 \oplus w_2$$

□

Proof of rule (9). Property: $e_k \circledast w_1 \uplus (e_k \wedge e_l) \circledast w_2 = e_k \circledast (w_1 \uplus e_l \circledast w_2)$

1. Case $e_k = 0$

$$0 \circledast w_1 \uplus (0 \wedge e_l) \circledast w_2 = \theta \uplus 0 \circledast w_2 = \theta \uplus \theta$$
$$0 \circledast (w_1 \uplus e_l \circledast w_2) = \theta$$

2. Case $e_l = 0$

$$e_k \circledast w_1 \uplus (e_k \wedge 0) \circledast w_2 = e_k \circledast w_1 \uplus 0 \circledast w_2 = e_k \circledast w_1 \uplus \theta = e_k \circledast w_1$$
$$e_k \circledast (w_1 \uplus 0 \circledast w_2) = e_k \circledast (w_1 \uplus \theta) = e_k \circledast w_1$$

3. Case $e_k = e_l = 1$

$$1 \circledast w_1 \uplus (1 \wedge 1) \circledast w_2 = w_1 \uplus 1 \circledast w_2 = w_1 \uplus w_2$$
$$1 \circledast (w_1 \uplus 1 \circledast w_2) = w_1 \uplus w_2$$

□

Proof of rule (13). Property: $e_k \circledast (e_l \circledast w_1) = e_k \circledast w_1 \qquad$ if $e_k \Leftrightarrow e_l$

1. Case $e_k = e_l = 0$

$$0 \circledast (0 \circledast w_1) = \theta$$
$$0 \circledast w_1 = \theta$$

2. Case $e_k = e_l = 1$

$$1 \circledast (1 \circledast w_1) = w_1$$
$$1 \circledast w_1 = w_1$$

□

Proof of rule (14). Property: $(e_k \circledast w_1)^{it,l} = e_k \circledast (w_1)^{it,l}$

1. Case $e_k = 0$

$$(0 \circledast w_1)^{it,l} = (\theta)^{it,l} = \theta$$
$$0 \circledast (w_1)^{it,l} = \theta$$

2. Case $e_k = 1$

$$(1 \circledast w_1)^{it,l} = (w_1)^{it,l}$$
$$1 \circledast (w_1)^{it,l} = (w_1)^{it,l}$$
