Experimental heat-transfer measurements published in the literature seem to be contradictory, some showing a transition at \( \text{Ra} \approx 10^{11} \), some showing a delayed transition at higher \( \text{Ra} \), or no transition at all. New experimental and numerical heat-flux and velocity measurements, both reaching \( \text{Ra} \) up to \( 10^{12} \), are reported on a wide range of operating conditions. In the new measurements the rough cell which reaches Rayleigh numbers, \( \text{Ra} \), up to \( 2.5 \times 10^{12} \), the Nusselt number show a clear \( \text{Ra}^{3/2} \) scaling, hinting a fully turbulent regime. In contrast to the \( \text{Nu} \) vs \( \text{Ra} \) relationship, we evidence that the dimensionless heat-flux, expressed as \( \text{RaNu} \), recovers a universal scaling with Reynolds number, collapses all data and highlights a universal critical Rayleigh number.

Turbulent Rayleigh-Bénard Convection (RBC) is a model system where a layer of fluid is heated from below and cooled from above. It is controlled by three dimensionless parameters: the Rayleigh number \( \text{Ra} \),

\[ \text{Ra} = \frac{g \alpha \Delta T H^3}{\nu \kappa}, \]

(1)

the Prandtl number \( \text{Pr} \),

\[ \text{Pr} = \frac{\nu}{\kappa}, \]

(2)

and the aspect ratio \( \Gamma = L/H \), where \( g \) is the acceleration of gravity, \( \alpha \) the thermal expansion coefficient, \( \Delta T \) the temperature difference across the fluid layer, \( \nu \) the kinematic viscosity, \( \kappa \) the thermal diffusivity, \( H \) the height of the cell, and \( L \) the width of the cell. A long standing endeavor consists in finding universal scaling laws for the heat transfer, expressed as the dimensionless parameter Nusselt number \( \text{Nu} \) [1, 2],

\[ \text{Nu} = \frac{\dot{q} H}{\lambda \Delta T}, \]

(3)

where \( \dot{q} \) is the heat-flux, and \( \lambda \) the thermal conductivity. This would allow extrapolating results from laboratory experiments to natural systems where highly turbulent natural convection plays a role. These include in particular convection in the ocean at the pole or in subglacial lakes [3], resulting in Rayleigh numbers beyond \( 10^{14} \), and in the “ultimate regime” of convection where \( \text{Nu} \sim \text{Ra}^{1/2} \) (with logarithmic corrections) [4]. However, experimental heat-transfer measurements published in the literature for \( \text{Ra} > 10^{11} \) seem to be contradictory, some showing a transition at \( \text{Ra} \approx 10^{11} \) [5, 6], some showing a delayed transition at higher \( \text{Ra} \) [7], or no transition at all [8, 9]. These experiments are within Oberbeck-Boussinesq conditions [10] and share similar geometries, but differ in Prandtl numbers and details in the setup. It now seems clear that the transition to the ultimate regime may be a subcritical process, and may depend on aspect ratio and Prandtl numbers [11–13].

In this letter, we evidence a way to recover universality. We report new velocity data obtained from shadowgraph imaging in parallelepiped Rayleigh-Bénard cells with or without roughness and using either deionized water or Fluorocarbon FC-770 as the working fluid. The cell dimensions are \( 41.5 \text{ cm} \times 41.5 \text{ cm} \times 10.5 \text{ cm} \) for the aspect ratio 1 cell, and \( 20 \text{ cm} \times 41.5 \text{ cm} \times 10.5 \text{ cm} \) for the aspect ratio 2 cell. The details of the cell are described in [14]. The Rayleigh number spans a wide range between \( 10^9 \) and \( 2.5 \times 10^{12} \), the Prandtl number between 4.3 and 7.0 in water, and 11 and 14 in FC-770, and the aspect ratio 1 or 2.

In addition, direct numerical simulations (DNS) were carried out in a similar geometric configuration filled with water. Two cavities with depth aspect ratios \( \Gamma_{xy} \) of one-half and one-quarter, and height to width aspect ratio \( \Gamma_{xz} \) have been modeled. Rayleigh numbers range from \( 5 \times 10^8 \) to \( 10^{12} \). Details of the numerical code can be found in [15].

In these conditions, the flow can be quite different, the scaling exponent of \( \text{Nu} \) versus \( \text{Ra} \) also quite different, and in apparent disagreement with data from Grenoble, Oregon, Brno and Göttingen cited above. And yet, all the data can be collapsed using the appropriate scaling of Reynolds and Prandtl numbers.

The experimental cells can be set up with roughness on the bottom plate, consisting in square roughness elements of height \( h_0 = 2 \text{ mm} \), machined in the plate, as described in [16]. In the DNS, three surface states for the bottom wall have been modeled: smooth or rough wall with two roughness heights (\( h_0/H = 0.04 \) or 0.003). In the rough cases, the cell (later referred to as “RS”), is asymmetrical, with a rough bottom plate, and a smooth top plate. As shown in our previous works [17, 18], this allows to define Rayleigh and Nusselt numbers of the rough and smooth half cells, provided the bulk temperature \( T_{\text{bulk}} \).
is also known. The temperature drop across the boundary layer of the smooth plate, $\Delta T_s = T_{\text{bulk}} - T_{\text{top}}$, and the temperature drop across the boundary layer of the rough plate, $\Delta T_r = T_{\text{bottom}} - T_{\text{bulk}}$ allow to estimate the total temperature difference across a corresponding virtual symmetric cell with identical smooth plates as $2\Delta T_s$, or with identical rough plates as $2\Delta T_r$, from which $Ra_s, Nu_s, Ra_r, Nu_r$ are derived.

The experimental smooth cell (later referred to as “SS”) has entirely smooth boundaries, as described in [14]. We have now operated the experimental rough configuration (RS) with Fluorocarbon FC-770 thus significantly extending the previous heat-transfer results in water [19], see Figure 1. In the Fluorocarbon cell, the thermal boundary layer, estimated as $\delta_{th} = H/(2Nu)$, ranges between 250 $\mu$m and 500 $\mu$m, much smaller than the roughness height $h_0$. The kinetic boundary layer, estimated as $\delta_k \approx \delta_{th} h_r Pr^{1/3}$ ranges between 600 $\mu$m and 1100 $\mu$m, smaller than the roughness height $h_0$. Therefore, the rough cell lies in Regime III as defined by Xie & Xia [20]. By the same definition, DNS configurations can be either in Regime II or Regime III. At $Ra = 10^{10}$, the simulation with the smaller roughness size ($h_0/H = 0.003$) is in Regime II, while the simulation with the larger roughness size ($h_0/H = 0.04$) is in Regime III.

Even when the rough half-cell has a $Ra^{1/2}$ scaling, the smooth half-cell is in good agreement, over more than 3 decades of Rayleigh numbers, with heat-transfer measurements in SS cell, as well as with the Grossmann-Lohse model [2]. This shows that the top and bottom plates remain independent, even very far from the roughness-triggered enhancement threshold, and holds even when the Nusselt number of the bottom half is nearly twice as large as that of the top half. This is a major result that shows how the boundary layers adapt themselves to maintain the heat-flux constant.

We computed the velocity fields using Correlation Image Velocimetry on shadowgraph recordings for all of them, yielding consistent estimates for both the mean and fluctuation velocities, as well as consistent Reynolds number estimates in all configurations. The method consists in deriving velocity estimates from the shadowgraph pattern using the same algorithm we use for Particle Image Velocimetry (PIV) images, i.e. the image is divided into smaller boxes that are correlated at $t$ and $t + \Delta t$, the displacement that produce the maximum correlation is used as an estimate for the local velocity. This method, based on the shadowgraph pattern, has previously been validated against standard PIV in experimental conditions where both were possible [14]. One should be aware that the shadowgraph patterns result from the deviation of light across the cell depth. Therefore, the obtained velocity is integrated over the depth, in contrast to PIV which is computed on a plane.

While we find that the mean flow has the same struct-
fluorocarbon is larger than in the SS case, and additionally is asymmetrical (velocity is larger near the rough plate). This Reynolds number enhancement triggered by roughness was not visible in our previous measurements using PIV in water at lower Prandtl and Rayleigh numbers [24]. Indeed, the Rayleigh number of the new data obtained in fluorocarbon is a decade larger and further from the threshold where roughness-enhanced heat-transfer is triggered than the rough cell using water. The higher Prandtl number also further separates the thermal and viscous boundary layers, which probably plays a role in the boundary layer response to plate roughness.

FIG. 2. Mean (a, c) and RMS (b, d) velocity maps computed from the Shadowgraph recording in smooth cells (SS), and from DNS velocity fields at mid-depth (e, f, g, h). (a, b) Water $Ra = 2.3 \times 10^{10}$, $Re = 5.4 \times 10^{12}$; (c, d) FC-770 $Ra = 1.7 \times 10^{12}$, $Re = 3.3 \times 10^{12}$; (e, f) DNS $\Gamma_{yz} = 0.25$, $Ra = 10^{10}$, $Re = 4.9 \times 10^{12}$; (g, h) DNS $\Gamma_{yz} = 0.25$, $Ra = 10^{12}$, $Re = 6.3 \times 10^{12}$.

One interesting quantity is the friction coefficient, 

$$ \frac{RaNu}{Re^3Pr^2}, \quad (5) $$

which was used by Chavanne, et al. as an indicator of the transition to turbulence in the boundary layers [21], and can alternatively be interpreted as proportional to the ratio between the kinetic energy dissipation rate $\epsilon$ and the bulk energy dissipation rate $\epsilon_{u,bulk}$ [27],

$$ \epsilon = \frac{\nu^3}{H^4} (Nu - 1)RaPr^{-2}, \quad (6) $$

$$ \epsilon_{u,bulk} \propto \frac{\nu^3}{H^4} Re^3. \quad (7) $$

In the range of parameters explored in this work, we evidence a transition at a critical Reynolds number, $Re_c \approx 10^4$. Beyond this transition, the friction coefficient no longer depends on the Reynolds number, or
FIG. 4. (a) Reynolds number measurements in FC-770 (green), water (blue) and from DNS (red), in RS (squares) and SS (circles) cells. Data from [21–23, 25, 26] are plotted for comparison (triangles). (b) Friction coefficient for all data points (same symbols). The heat flux, $RaNu$, collapses for all data with $RaNu \sim 0.2Re^3Pr^2$.

only very weakly, see Figure 4-b. Therefore, we get a relationship between the dimensionless heat-flux, $RaNu$, and the Reynolds and Prandtl numbers, where

$$RaNu = \frac{g\rho^2\alpha Cp H^4}{\mu \lambda^2} \dot{q}.$$  \hspace{1cm} (8)

The phenomenological relationship is,

$$RaNu \approx 0.2Re^3Pr^2.$$  \hspace{1cm} (9)

However, this result does not allow to directly infer whether the kinetic energy dissipation rate is dominated by the bulk energy dissipation rate, or how much dissipation in the boundary layers still contributes, because of prefactors stemming from the non-unique definition for the Reynolds number and of the turbulent dissipation.

It is remarkable that this relationship, Eq. 9, holds for the Grenoble data which evidence a transition to the ultimate regime, as well as data which does not evidence such transition, and also in the case of rough cells in which $Nu \sim Ra^{1/2}$, as well as smooth cells with a classical scaling. This shows that whatever changes are triggered by either the roughness or the transition to the ultimate regime are entirely taken into account in the Reynolds number. While it may seem at first glance that the Reynolds number is only a function of $Ra$ and $Pr$, it really is not. Multiple flows are possible at a given Rayleigh number [10, 28], and it is therefore elusive to try to determine a universal $Nu$ versus $Ra$ relationship. The universal scaling for the heat-flux, Eq. 9, evidenced in this work, has to be taken into account in tentative theoretical models of turbulent thermal convection.
