RNAs are essential molecules involved in numerous biological functions. Understanding RNA functions requires the knowledge of their 3D structures. Computational methods have been developed for over two decades to predict the 3D conformations from RNA sequences. These computational methods have been widely used and are usually categorised as either ab initio or template-based. The performances remain to be improved. Recently, the rise of deep learning has changed the sight of novel approaches. Deep learning methods are promising, but the adaptation to RNA 3D structure prediction remains at stake. In this work, we give a brief review of the ab initio, template-based and novel deep learning approaches. We highlight the different available tools and provide a benchmark on nine approaches using the RNA-Puzzles dataset. We provide an online dashboard that shows the predictions made by benchmarked models, freely available on the EvryRNA platform: https://evryrna.ibisc.univ-evry.fr.

RNA 3D structure | *Ab initio* | Template-based | Deep learning

## Introduction

Ribonucleic acids (RNAs) are macromolecules that play diverse biological roles in living organisms. RNAs are involved in numerous physiological processes, such as protein synthesis, RNA splicing, or transcription regulation, as well as in various human diseases. RNAs also have the potential to be used as therapeutic agents for different purposes, like cancer (1). Understanding RNA functions is a challenging task that has been studied for decades.

The biological function of RNA is, like protein, determined by the 3D conformation of the molecule. This folding can be determined by experimental methods like X-ray crystallography, NMR or, more recently, cryo-EM (2). Nonetheless, these methods are costly both in time and resources. On the other hand, sequencing methods (like next-generation sequencing (3)) have progressed, and a large number of sequences has become available, without any structural data. As a result, there is a huge gap between the known RNA sequences compared to the solved 3D structures. Up to December 2023, there are 7,296 solved RNA structures in the PDB (4) compared to 2,924,924 RNA sequences in Rfam (5). Only 136 out of 4,170 RNA families have at least one known structure. Therefore, computational methods have been developed for the past decades to compute RNA 3D structure from the sequence. Two main approaches have emerged: the ab ini*tio* and the template-based. While the first uses molecular dynamics and force fields, the latter relies on a database of known structures. None of these approaches predicts RNA structure perfectly and methods still emerge.

During the CASP (6) competition, AlphaFold (7, 8) from DeepMind recently successfully predicted protein 3D structures. The team used deep learning techniques to predict the atomic positions of each amino acid of the sequence with high precision. Nonetheless, it can not be applied directly to RNAs due to the protein and RNA intrinsic biological differences. Indeed, the sequences are different between RNA and proteins in terms of individual elements (amino-acid compared to nucleotides), diversity of sequence range (RNA sequences range in length from a few tens to several tens of thousands of nucleotides, while proteins are a few hundred amino acids long), the number of available structure data and the stability of the folding (a given sequence of protein can fold into one stable conformation compared to multiple conformations for RNA). As a direct utilisation of AlphaFold for RNAs is not possible, works have emerged to adapt AlphaFold's success to RNAs. The breakthrough success of AlphaFold is not yet found for RNAs (9), but some inspired works have promising performances.

Works have been done to review the state-of-the-art existing methods. A recent study (10) describes up-to-date models while highlighting the need to use probing data. Another review (11) also describes past methods and points out the detailed types of inputs that can be integrated into developed models. On the other hand, a review (12) describes only the *ab initio* methods with the force fields used for each method. A final recent review (13) discusses recent advances in terms of RNA but is not specific to the 3D structures. It sheds light on the machine learning advancements in the RNA field.

In this paper, we aim to give the reader a comprehensive overview of the RNA 3D structure prediction. Through a detailed description of *ab initio*, template-based and deep learning approaches, we detail the available tools and benchmark them on a dataset to compare their performances. The results are easily reproducible and an interface with the predicted 3D structures is provided and freely available on the EvryRNA

platform: https://evryrna.ibisc.univ-evry.fr. The user can interact with the dashboard to select the RNA to visualize and look at the different predictions computed for the benchmark.

The paper is organised as follows: we first provide an overview of the main predictive methods developed through decades for predicting RNA 3D structure. We give a broad overview of the field and include state-of-the-art deep learning approaches, with published or preprint works. Finally, we benchmark the models available on a common dataset to assess their global performances.

# Methods

Computational methods aim to predict the atomistic positions and interactions in the RNA molecule. They tend to follow the same steps: sampling the conformational space (creation of a set of candidate structures) and discrimination of the candidates. The final structure is usually chosen with either the lowest energy or the center of a cluster of lowest energy structures. Methods can be classified as *ab initio*, template-based or deep learning-based. *Ab initio* methods integrate the physics of the system, while template-based methods are based on constructing a mapping between sequences to known motifs. Deep learning approaches use data to feed a neural network architecture that predicts RNA 3D structures from sequence or MSA (Multiple Sequence Alignment).

We present in the following a description of the state-ofthe-art methods for RNA 3D structure prediction. The methods are organised by approach type (*ab initio*, template-based and deep learning) and chronologically. A timeline of all the methods, including the required inputs, is shown in Figure 1.

The availability of a web server and/or a standalone code is provided for each method. A summary of the state-of-theart tools, including information on their implementation, is given in Table S1 of the Supplementary file.

## Ab initio methods

Ab initio (or prediction-based) methods tend to simulate the physics of the system. They also capture the folding dynamics, such as energy landscapes. RNA molecules are represented at the atom level, and forces are applied to simulate real environment conditions. To explore the conformation space, sampling algorithms are used, like Monte Carlo (MC) (14) or molecular dynamics sampling (15). As the simulation can be time-consuming, a key parameter of *ab initio* methods is the granularity of the nucleotide representation. It is defined as the number of beads per nucleotide, where atoms are omitted to be replaced by representative ones. A bead refers to the number of atoms per nucleotide, which defines the granularity of the method. NAST (16), for instance, uses one atom per nucleotide, while other methods like iFoldRNA (17), OxRNA (18), HIRE-RNA (19), SimRNA (20), IsRNA1 (21), IsRNA2 (22) and RNAJP (23) tend to have more atoms per nucleotide. Other methods use different granularity like Ernwin (24) with helix as a base or BARNACLE (25) with a bayesian model.

**iFoldRNA** (17) is a three-bead per nucleotide method with discrete molecular dynamics to simulate the RNA folding process. Another version of iFoldRNA, called iFoldRNA v2 (26), adds clustering on root mean square deviation (RMSD) after simulation to reconstruct the center of founded clusters. Each bead represents a phosphate, sugar or nucleobase. The force field incorporates angle interactions, base pairing, base stacking, or hydrophobic interactions.

A web server is provided, but not the source code. The web server requires having an account. When connected, a user can make predictions from a sequence and, optionally, a 2D structure. The computation time is high: a sequence with less than 100 nucleotides takes more than one day to be processed.

**NAST** (16) models at the one-point-per-residue resolution but considers the geometrical constraints from ribosome structures before discriminating the obtained structures with root-mean-square deviation. It utilizes knowledge-based statistical potential to guide the simulation and cluster-generated structures. The bead is located at the C3' atom.

No web server is provided; the source code is available and written in Python 2.

**BARNACLE** (25) is based on a Bayesian parametrized model using the seven angles characterizing a nucleotide with a hidden Markov chain process. It models marginal distributions for the dihedral angles using a mixture of probability distributions. It links the dependencies between angles with a Markov chain of hidden states. It helps reduce input representation while capturing the length distribution of helical regions.

No web server is provided, but the source code is available. We tried to run the code, but we got errors. We also tried to convert the Python 2 code to Python 3 without success.

**OxRNA** (18) is a 5-bead coarse-grained approach that uses both virtual move Monte Carlo (VCMC) and umbrella sampling (27) to sample the conformational space. It manages to characterize the thermodynamics of RNA molecules. The potential energy of the model splits terms that are nonnearest-neighbour pairs of nucleotide and neighbours. It also incorporates temperature dependence, as the coarse-grained interaction is assumed to be free energy rather than potential energy.

A web server and source code are available. Nonetheless, the source code details the web server. The required inputs for the local or web servers are of a specific format, with configuration and topology files. Therefore, it is not straightforward to properly convert a sequence to server inputs.

**Ernwin** (24) uses Markov chain Monte Carlo (MCMC) with a helix-based model that maps the helices to cylinders and loops to close edges connected to a helix. The force field uses five energy terms like steric clash energy or knowledge-based potential of mean force.

Figure 1. State-of-the-art of the main works for predicting RNA 3D structures. The different inputs are either raw sequence, secondary structure, tertiary structure or multiple sequence alignment (MSA). Dashed methods are preprint works.

A web server and a source code are available. The web server only returns coarse-grained molecules. There is still, up-to-date, no full-atom reconstruction included.

**HiRE-RNA** (19) shows that noncanonical and multiple base interactions are necessary to capture the full physical behaviour of complex RNAs, with a six-bead nucleotide method. It uses a model with geometric parameters determined from 200 structures. The potential integrates stacking and base-pairing terms that consider base orientations. The Replica-Exchange Molecular Dynamics (REMD) simulations are used for sample strategies.

There is no web server nor source code available.

**SimRNA** (20) uses Monte Carlo steps with a five-bead nucleotide approach guided by an energy that considers local and non-local terms. The local term includes bond length or angle interactions, while non-local terms consider base-tobackbone interactions. The sampling procedure is the asymmetric Metropolis algorithm (28). The predicted structures are based on clustering methods of lower energies.

Web server and standalone server are available. The code is well-documented and can be used easily. The web server is hardly usable as it can only have three jobs at a time. Multiple days are required to process a prediction, preventing automation and easy access to the model. When running locally with default parameters, the outputs were always the same and did not relate to any RNA tertiary structure.

**IsRNA** (29), **IsRNA1** (21) and **IsRNA2** (22) are based on a coarse-grained method with five-bead per nucleotide to predict noncanonical base pairs. The energy used includes bond length, bond angle bending and torsion angle energies. The energy also combines covalent energy functions for basepairing interactions. Non-local terms like base-base, basebackbone and backbone-backbone interactions are also included. In the IsRNA1 model, the canonical base-pairing adds interaction distances to consider bond strength compared to IsRNA. IsRNA2 better integrates noncanonical base pairing interactions in large RNAs compared to IsRNA1.

A web server is available for IsRNA1, while the source code can only be downloaded with an account. The installation requires multiple libraries that also require having an account on other websites. The web server takes multiple hours to predict hundreds of nucleotides. No web server is available for IsRNA2, and the web server for IsRNA1 starts its simulation process with structures predicted from IsRNA.

**RNAJP** (23) uses a coarse-grained approach at both atom and helix levels. It represents a nucleotide with five beads to describe the Watson-Crick, Hoogsten and sugar edges in bases. The force field used is a sum of 12 energy terms considering bonded interactions in length, bond and torsion angles, as well as base pairing and base stacking interactions. The energy integrated uses terms for the manipulation of helices and loops. No web server is available and the source code can only be downloaded with an account. We had errors with the *bp\_stk\_paras* folder, where capitalization variations were missing. We managed to get the program running by modifying this folder.

Using physics-based modelling, coarse-grained approaches can predict RNA tertiary structures from raw sequences. The energy-based scoring function helps discriminate or guide predicted structures. Final predictions are usually either the lowest energy molecules or centroid of clusters. Current coarse-grained approaches fail to consider the formation of non-canonical pairs and, even more, the base side of interactions. The size of the considered RNA limits those methods: the longer the sequence, the more timeconsuming the simulation is. The increase in the sequence length is not linear with the simulation time: the number of conformational states grows exponentially with the sequence. Having an efficient sampling method is a challenging task and the key to efficient ab initio methods. The final limitation of those methods is the discriminator function, which is usually energy-based. An inaccurate energy function could result in a non-native predicted structure and bias the sampling method, which often guides the sampling procedure.

#### **Template-based methods**

Template-based (or fragment-assembly) approaches rely on the fact that molecules that have evolution similitude adopt similar structures. A template molecule can be used as a structural basis, where other mutated sequences tend to retain similar and global conformations. A database of known RNA structures is used as a reference. Those structures have a mapping between their sequence and motif/structure/fragment. The size of the fragments considered is a key parameter for the efficiency and accuracy of the method. It can be at the nucleotide level or at the secondary structure elements (SSEs) level, for instance. Methods like RNABuilder (30) and ModeRNA (31) use one nucleotide per fragment, while FARNA/FARFAR (32) and FARFAR 2 (33) use three nucleotides per fragment. MC-Sym (34), RNAComposer (35), Vfold (36), VfoldLA (37), 3dRNA (38), Vfold Pipeline (39) and FebRNA (40) consider as base representation SSEs. The predicted structure can be refined to prevent clashes with energy minimization.

**FARNA/FARFAR** (32) is one of the first template-based methods to predict RNA 3D structures. It is inspired by Rosetta low-resolution protein structure prediction method (41). It uses an energy function of six terms relying on physics-based constraints, a metropolis criterion for fragment assembly using torsion angles replaced at each Monte Carlo step. While energy is computed atomistically with FARFAR, FARNA uses a simplified coarse-grained potential. Both energies can form non-canonical pairs but are limited by size and cannot predict large molecules. FARNA/FARFAR uses short segments as blocks (three-nucleotide segments) and thus needs numerous MC samplings to find a stable struc-

ture. FARFAR 2 (33) was proposed to increase the accuracy and speed. It also adds a clustering method to discriminate the most common structures.

There is a web server for FARFAR and FARFAR 2, but no source code is available. The prediction time is quite high, with multiple days for a single prediction.

**MC-Sym** (34) uses the SSEs, with nucleotide cycle modulus as blocks. It takes as inputs both raw sequence and 2D structures from MC-Fold (34) method to minimize the physics-based force field. It relies on a representation of nucleotide relationships named nucleotide cyclic motif (NCM), incorporating more context-dependent information. This representation is used to infer a scoring function for both secondary and tertiary structure prediction. A database with lone-pair loops and double-stranded NCMs is used in the pipeline and in the scoring function.

The source code is unavailable, but a well-documented web server is provided. The web server is user-friendly, and there is almost no waiting time for a job to run. However, it requires secondary structures from MC-Fold to predict 3D structures.

**RNABuilder** (30) uses multi-resolution modelling (MRM) and multibody dynamics simulation. It is based on a target-template alignment that assigns correspondences between residues and spatial constraints. It is described to predict *Azoarcus* group I intron and can be extended to other structured RNAs. It combines secondary and tertiary base pairing contacts in the force field. It can also solve structures with small connecting regions without a template.

No web server is available but a source code is available, well-documented and usable.

**ModeRNA** (31) searches for fragments in a database to replace the mutated structure before using energy minimization to refine the final structure. It uses atomic coordinates of the template and prevents backbone discontinuities by adding short fragments of other structures. It provides different strategies to build RNA structures that can be modified easily.

A web server and a code are provided. Both of them require a 3D structure as input.

**Vfold3D** (42) constructs 3D structures from fragment databases. It uses the lowest free energy secondary structures converted to known fragments. The reconstruction of fragments is coarse-grained before being converted to allatom. The final refinement of the structures uses AMBER energy minimization (43, 44). **VfoldLA** (37) uses a template database with single-stranded loops or junctions. Instead of searching for whole motifs, its granularity is finer and allows smaller blocks to be integrated. It helps prevent the limit of Vfold3D, which uses whole motifs (instead of smaller blocks) limited by the number of available RNA data. Integration of two previous methods has been done in **Vfold-Pipeline** (39). Given a sequence in input, the pipeline uses

Vfold2D (45) to predict the secondary structure and then uses either Vfold3D or VfoldLA for the final 3D structure prediction.

A web server is available for either Vfold3D, VfoldLA and Vfold-Pipeline. The source code is also available and usable.

**RNAComposer** (35) creates a database (named FRABASE) with fragment mapping 2D elements to 3D motifs before using refinement. The SSEs are used as minimum blocks to assemble the different fragments. The method uses the Kabsch algorithm (46) to assemble the 3D structure elements. The refinement of the structure concatenates two energy minimization methods: torsion angles energy (using CYANA (47)) and atom coordinate with CHARMM (48).

There is a web server accessible, but no source code is provided.

**3dRNA** (38, 49) uses a fragment assembly approach guided by a scoring function, 3dRNAScore (50), where the SSEs considered are improved by more base pairs from connected stems. It uses SSEs as blocks and predicted structures with a clustering approach using 3dRNAScore as criteria. An improvement of the 3D template library is proposed in 3dRNA by an increase of about ten times the number of templates (51).

A web server is provided, and the source code is available only after login. It is required to have other software installed to run the standalone code.

**FebRNA** (40) creates a 3D fragment ensemble and identifies the 3D coarse-grained structure using cgRNASP (52) score, with three-bead per nucleotide. It performs all-atom reconstruction followed by refinement. The building of fragments is executed with secondary structure tree (SST) (53), where each stem is considered as a node of a tree structure. A 3D structure is build through sequential superposition between coarse-grained atoms of a loop and stem according to the SST order.

No web server is accessible, but the source code is available and well-documented. Nevertheless, we did not manage to run the code because we had errors.

Template-based methods allow the prediction of RNA 3D structures with the help of available data. They create a database mapping sequence to fragments (or motifs) before assembling it to refine final structures. However, the number of experimental RNA structures is a bottleneck for the good accuracy of the models. Templates like SSEs tend to be inaccurate or missing in the constituted database, preventing good predictions of structures. They also fail to generalize to unseen structures. As many RNA families have not yet been discovered, such approaches would probably fail to predict new families.

#### Deep learning approaches

In the CASP competition, an end-to-end approach has been introduced and overperformed all previous works for predicting protein 3D structure: AlphaFold (7, 8). It has changed the structural biology field and raised the interest of researchers. Recent works have been done to predict RNA 2D structures (54, 55), as the available data is much higher than solved 3D structures. Other deep learning works try to predict energy function (56, 57), while others infer torsion angles from the sequence (58). Such angles can nevertheless be used to help the prediction of 3D structures. Preprint works have been released like DeepFoldRNA (59), RhoFold (60), RoseTTAFoldNA (61), and NuFold (62) to predict 3D structures with attention-based (63) methods. Three deep learning approaches, epRNA (64), DRfold (65) and trRosettaRNA (66), have recently been published. As advancements in the field are moving fast, we describe both preprint and published works in the following.

**DeepFoldRNA** (59) is a preprint work that predicts RNA structures from sequence alone by coupling deep selfattention neural networks with gradient-based folding simulations. It predicts distance and orientation maps, as well as torsion angles, with transformer-like blocks. It uses MSA and 2D structure as inputs. A BERT-like (67) loss was also implemented to make the model more robust. A self-distillation approach is used to get around the lack of data. It incorporates bp-RNA-1m (68) sequences to predict their structures and integrate them into the training set. To convert the neural network outputs to 3D structures, they use L-BFGS (69) folding simulations with energy defined by the weighted sum of the negative log-likelihood of the binned probability predictions.

A web server and a source code are provided. We tried to predict sequences from the web server but never received the results.

**RhoFold** (60) is a preprint work with an end-to-end differentiable approach for predicting RNA 3D structures. The model's input is the MSA, and features are extracted with a pre-trained model RNA-FM (70) (trained over more than 23 million sequences). RNA-FM gives an MSA coevolution matrix and pairwise residue features. A module called E2EFormer with gated attention layers is applied to predict the main frame  $(C'_4, C'_1, N_1/N_9)$  in the backbone and four torsion angles  $(\alpha, \beta, \gamma, \omega)$ . An IPA (invariant point attention) is used in modelling 3D positions. It predicts each frame's rotation and translation matrices based on the sequence and pair representation from the E2Eformer module. Given the predicted frames and angles, the structure module can generate the full-atom coordinates of an RNA without simulation. It also uses self-distillation with bp-RNA-1m (68) and combines the training process with a loss that takes into account 1D (sequence masking), 2D and 3D (Frame Aligned Point Error (FAPE)) elements.

A web server and a source code are provided. The web server is easily usable, while the standalone code requires more than 500 GB of space to download the database, even for inference.

RoseTTAFoldNA (61) is a preprint work with an endto-end deep learning approach that predicts 3D structure for RNA molecules and protein-DNA and protein-RNA complexes. It incorporates three representations of molecules: sequence (1D) with MSA representation, residue-pair distances (2D) and cartesian coordinates (3D). The 3D representation uses the position and orientation of phosphate, as well as torsion angles. The model can take as input protein, DNA and RNA. It was trained on five types of structures: protein structures, AlphaFold2 predictions, protein complexes, protein/NA complexes and RNA structures. Two losses were used: one for the training process and the other for the finetuning stage. The first loss is a weighted sum of distogram loss, structure loss (averaged backbone FAPE loss (8) over structure layers of the model), torsion prediction loss and pLDDT loss. The second loss incorporates energy terms to ensure model feasibility.

A source code is provided, but no web server exists. The source code requires more than 500Gb of free space to download sequence and structure databases.

**trRosettaRNA** (66) is a published work inspired by two methods for 3D protein structure prediction, AlphaFold2 (8) and trRosetta (71–73). It uses MSA and secondary structure (predicted by SPOT-RNA (74)) as inputs. The network architecture is inspired by AlphaFold2 Evoformer block and thus uses transformer networks. The full atom reconstruction uses energy minimization with restraints from predicted geometries weighted by parameters optimized from random RNA from the training set. The model is trained on PDB data with sequences that have homologs. It uses bpRNA (68) from Rfam (5) for self-distillation to increase the available data. Distillation is regulated with a Kullback-Leibler divergence.

A web server is available, but no standalone code.

**epRNA** (64) is a published work with an Euclidean parametrization-based neural network that predicts RNA tertiary structure from sequence only. It is trained to predict a distance matrix that is then validated with Hoffmann and Noé (75) algorithm and added to the loss. The network uses convolutional networks and uses one hot encoding as input. epRNA uses RNAs from the PDB and splits them into training and test sets (60% for training and 40% for testing). The method achieves E(3) invariance (rotations, translations and reflections) but does not achieve SE(3) invariance. It means that the mirror image of a chiral molecule is chemically distinct, but this distinction is not made in the network.

A source code is available, but no web server. The code is easy to use, and the installation process is straightforward. There is no need to install huge datasets to perform predictions.

NuFold (62) is a preprint work with an adaptation of Al-

phaFold2 work for RNAs. It considers the base frame with four atoms: O4', C1', "C4' and either N1 (for C and U) or N9 (for G and A). It also adds heads to predict the distance between C4' and P, and the dihedral angle between residue pairs. It uses as inputs MSA and secondary structure predicted by IPknot (76). The NuFold network comprises two key components: the EvoFormer block and the structure model. The EvoFormer part is a transformer model that embeds information into single and pair representations. The structure model converts the embedding into 3D structures. It is recycled three times to increase the accuracy of predictions. The network outputs are the translation and rotation of the four base frames and torsion angles. The torsion angles help the reconstruction of full-atom representation.

No web server is available, and no code yet. It is said that the code will be available after a clean-up by the authors.

**DRfold** (65) is a published work with an end-to-end transformer-based approach that takes as input RNA sequence and secondary structure. It uses a three-bead representation for a nucleotide. It converts the inputs into sequence and pair representations before feeding them to transformer blocks. A structure module outputs frames converted to FAPE (frame aligned point error) potential, while a geometry module predicts rotation and translation property converted to geometry potentials. These predicted frame vectors and geometry restraints are aggregated to a potential for structure reconstruction. The final step includes all-atom reconstruction and refinement using Arena (77) and OpenMM (78).

No web server is provided, but a source code is available. It requires the download of numerous libraries.

Deep learning methods are promising and have good performances on testing datasets. Nonetheless, deep learning models need a huge amount of data, which is unavailable for RNA 3D structures. To avoid this bottleneck, methods use self-distillation. They also mainly input MSA representation like AlphaFold. MSA remains a limitation as the number of known RNA families is restricted. The overall quality of the predicted structures remains to be validated with new data from unseen families.

# **Results**

In this section, we detail the results of available methods for RNA 3D structure prediction. To have a fair comparison between existing methods, we benchmark them on a unique test set widely used in the community, RNA-Puzzles (79). We evaluated and compared the predicted structures using standard metrics described in a previous work (80).

#### **Benchmarked tools**

As discussed in the previous section and summarized in Table S1 of Supplementary file, some of the state-of-the-art methods do not have a web server or a standalone code available. It is the case of Hire-RNA (19) and NuFold (62). Among the remaining tools, unfortunately, many are hard to

use or not working. Among the available standalone codes, we only manage to run RNAJP (23). DeepFoldRNA (59), FebRNA (40) or RoseTTFoldNA (61) require the download of databases. Those databases could have more than 500Gb and thus be hardly usable for users. Ernwin (24) and epRNA (64) only return coarse-grained structures and thus increase the use complexity. Among the web servers available, ModeRNA (31) needs as input an initial 3D structure, which we did not have for the benchmark (and would also bias the comparison with the other methods). OxRNA (18) requires a specific input format, which makes it hard for the user to use. SimRNA (20) and FARFAR 2 (33) have web servers with computation time too long to be included (multiple days of predictions). DeepFoldRNA (59) and Drfold (65) have web servers where we did not get the structures after making the request. The server of iFoldRNA (17) is very hard to connect to and failed to perform all the predictions: we were only able to have a few predictions As a benchmark, we thus considered the remaining nine methods described in Table 1. We used RNA-tools (81) to clean the predicted structures and to normalize them. This software enables the operation of RNA structures and allows their standardisation to help better evaluate them. All methods were used with their web servers except for RNAJP, which was used locally. We set a computation limit for RNAJP computation (50  $\times \, 10^6$  steps in the simulation).

Not all tools could predict directly from the sequences, a secondary structure being required. We decided, when needed, to use the secondary structure predicted by MXFold2 (82), a recent deep learning-based tool giving good prediction results. The choice of MXFold2 was arbitrary but should be consistent between the models to have a fair comparison. For MC-Sym, it is required a secondary structure from MC-Fold (34).

Model	Inputs	Method Type
MC-Sym (34)	Seq+2D	Template-based
Vfold3D (42)	Seq+2D	Template-based
RNAComposer (35)	Seq+2D	Template-based
3dRNA (38)	Seq+2D	Template-based
IsRNA1 (21)	Seq+2D	Ab initio
RhoFold (60)	Seq	Deep Learning
trRosettaRNA (66)	Seq	Deep Learning
Vfold-Pipeline (39)	Seq+2D	Template-based
RNAJP (23)	Seq+2D	Ab initio

 
 Table 1. Benchmarked tools. The state-of-the-art tools are listed from the less to the most recent. For each tool is given its inputs and its method type. Seq refers to the raw sequence, and 2D for the secondary structure.

#### Test Set

As an adaptation of the CASP competition, the community created RNA-Puzzles (79) in 2011. It is used as an RNA test set to assess the model's quality on unseen RNA structures. The RNA molecules proposed through the years as a challenge are solved structures that have challenging properties: double-stranded structures, ribozymes, riboswitches and more. We decided to use this dataset as a benchmark.

The dataset contains both single-stranded and multi-stranded RNAs, whereas not all models can predict RNA complexes (multi-stranded RNAs). We decided only to consider single-stranded RNAs for a fair comparison between models. This represents 22 RNAs with a sequence between 27 and 188 nucleotides. More details about the considered RNAs, as well as their families, are given in Table S2 of the Supplementary file.

A collaboration between RNA-Puzzles and CASP teams led to the CASP 15 (83) competition. 12 RNA targets were proposed. We tried to predict these targets with the nine considered methods, but it led to non-realistic predictions. Most models did not predict RNA targets because the RNA sequences were too long. The RNA targets are complex and require more tuning to adjust model prediction. As we did not get a lot of predictions, we decided to not include the CASP RNAs in this study.

#### **Evaluation metrics**

To evaluate and compare the quality of predictions, we used different metrics. We considered the well-known Root-Mean-Square-Deviation (RMSD), which is very sensitive to local differences. The INF (84) metric tries to incorporate RNA key interactions to evaluate RNA 3D structures better. Another tentative to incorporate RNA specificities is the  $\epsilon$ RMSD (85). We also considered the TM-score (86, 87) and IDDT (88), which are, respectively, the normalisation of atom deviation metric and interatomic differences, both inspired by protein evaluation metrics. Finally, we also used the P-VALUE (89), which assesses if a prediction is better than a random one.

RMSD,  $\epsilon$ RMSD and P-VALUE metrics have good results when the values are low, whereas high values are better for INF, IDDT and TM-score.

Each of these metrics has its specificity, which is why it is important to calculate each of them. A description and comparison of all these metrics is provided in (80).

Note that two additional metrics exist in the literature and are described in (80): DI (deformation index) (84) and GDT-TS (90) metrics. However, they return similar measures to RMSD and TM-score, respectively. The results obtained with these two metrics are therefore not shown here but provided in the Supplementary file.

#### **Benchmark results**

We present here the prediction results obtained by each of the tools summarized in Table 1.

The predictions are reported according to the different metrics presented above. The calculation of the metrics is done thanks to RNAdvisor (80), a tool recently developed in our team that helps the automation of RNA 3D structures evaluation.

The distributions obtained by the different tools are given in Figure 2 (mean values are available in Table S3 of the Supplementary file). It shows the outperformance of deep learning methods compared to *ab initio* and template-based methods for almost all metrics except for INF metric. Deep learning approaches give an overall good shape (low RMSD,  $\epsilon$ RMSD and P-VALUE, and high IDDT and TM-score), but do not output all the key RNA interactions. The base interactions seem better reproduced by Vfold-Pipeline than the other methods (higher distribution of INF). *Ab initio* and template-based methods have almost the same distribution in terms of TM-score and  $\epsilon$ RMSD. Vfold-pipeline is slightly better for every metric compared to the other *ab initio* and template-based approaches. The very low IDDT values for MC-Sym, Vfold3D and RNAJP can be explained by calculation errors, as other metrics do not show the same outliers in the distribution. The distributions for GDT-TS and DI metrics are available in Figure S1 of the Supplementary file.

Detailed results of each method for each RNA are available in Figure 3. The figure highlights the good performances of trRosettaRNA for all the metrics. RhoFold also has good performances, especially for puzzle 34 (PDB ID: 7V9E). We observe high P-VALUE on some RNAs for RNAJP, 3dRNA, RNAComposer, Vfold-Pipeline, Vfold3D and MC-Sym. It means that some predictions are close to random ones, whereas deep learning models are more confident and have almost never a high P-VALUE. Some of the tools have computation issues with certain RNAs, especially the longest ones. It is the case of MC-Sym, Vfold3D and IsRNA1. We also couldn't get the prediction result of Vfold-Pipeline on puzzle 12 (rp12). Other missing values are due to the computation of the metrics. It is the case of RMSD,  $\epsilon$ RMSD and P-VALUE that could not be computed on the predictions of RNAJP for the puzzles rp32 and rp11, as well as on the prediction of RNAcomposer for rp11. The results with GDT-TS and DI metrics are available in Figure S2 of the Supplementary file.

To illustrate and compare visually the predictions obtained by each of the considered methods, we arbitrarily selected a structure from the RNA-Puzzles challenge: puzzle rp3, a Riboswitch (PDB ID: 3OWZ). The predicted structures as well as the native structure are shown in Figure 4. We did an alignment to show them on the same scale using the matching tool of Chimera (91). The model that seems to superimpose the reference structure well is trRosettaRNA, with an RMSD of 2.38. We observe good visual folding for the deep learning models and Vfold-pipeline. On the other hand, RNAJP and RNAComposer predictions do not seem to fit well with the native shape. The metric values for each model for this RNA are given in Table S4 of the Supplementary file.

#### Computation time

As stated above, except RNAJP, all benchmarked tools are available only as web servers. Therefore, a precise comparison of computation time performances is not possible. We thus report here for each tool the rough computation time we measure for processing a given RNA.

Table 2 summarizes the rough inference computation time to predict RNA 3D structures for each model. We report the computation time for the RNAs with the shortest and the most extended sequence. Vfold3D and Vfold-Pipeline

**Figure 2.** Distribution of the prediction results obtained by the state-of-the-art methods on RNA-Puzzles set. The results are reported using different metrics: RMSD, INF, P-VALUE,  $\epsilon$ RMSD, IDDT and TM-score. P-VALUE, RMSD and  $\epsilon$ RMSD are decreasing (the lower, the better) while TM-score, IDDT and INF are ascending and range between 0 and 1. Methods are sorted by release date.

Figure 3. Prediction results obtained by the state-of-the-art methods on each RNA-Puzzles challenge. The results are reported using different metrics: RMSD, INF, P-VALUE,  $\epsilon$ RMSD, IDDT and TM-score. The best results are in yellow, while bad results are in dark. Missing values (in white) are due to a failure in predictions by the models or in the metric computation. Challenges are sorted by RNA sequence length. RNA length is provided in brackets.

have similar computation time: Vfold3D and Vfold-Pipeline are almost the same models; the only difference is the use of VfoldLA when Vfold3D does not provide predictions in Vfold-Pipeline. We observe that the *ab initio* methods have a computation time higher than the template-based and deep learning methods. This is due to the simulation processes that require a high number of computation steps. The templatebased methods almost always return a structure with less than 2 hours of computation (including the queue in the web servers). On the other hand, deep learning methods tend to be very fast for inference. RhoFold predicts with high throughput, and what is the most time-consuming is the relaxation of the prediction.

#### State-of-the-RNArt Dashboard

We provide a dashboard (illustrated in Figure 5) with different visualisations of the predicted structures for the nine benchmarked models. The dashboard, called State-ofthe-RNArt, is freely available on the EvryRNA platform: https://evryrna.ibisc.univ-evry.fr. The user can choose which RNA to compare the predictions from among the different challenges of RNA-Puzzles (79). We also included some of the predictions we made on the CASP-RNA (83). We make available all the obtained predictions and their evaluation with the different metrics. The State-of-the-RNArt Dashboard allows thus the reproducibily of our benchmarks and a quick visualization of the obtained 3D structures.

Figure 4. Predicted structures (in blue) for RNAPuzzle 03 (rp03) (id: 3OWZ, length: 84 nucleotides) compared to native structure (in green) using state-of-the-art methods. A: MC-Sym. B: Vfold3D. C: RNAComposer. D: 3dRNA. E: IsRNA1. F: RhoFold. G: trRosettaRNA. H: Vfold-Pipeline. I: RNAJP. Alignment was done using CHIMERA (91) and Needleman-Wunsh algorithm (92).

Figure 5. Screenshot of the Screenshot of the State-of-the-RNArt dashboard. A: The user can choose the RNA (or challenge) with its native structure to process with the different RNA 3D structure prediction tools. The RNAs are from RNA-Puzzles challenges (79) and from some of the CASP-RNA challenges (83). B: Prediction results were obtained by the nine benchmarked tools and evaluated with different metrics. The metrics are computed with RNAdvisor (80). C: 3D visualisations of the different predictions of the benchmarked models. The native structure is coloured in red, while the predictions are in blue. The predictions are superimposed with the native structure for visualisation using the US-align (93) tool. The associated metrics are also shown on top of the structures.

# Discussion

*Ab initio* methods are physic-based approaches that incorporate different levels of granularity in nucleotide representation. The coarse-grained approach is a trade-off between efficiency in the representation and accuracy in the prediction. We found these methods harder to use in practice as the simulation process can be very time-consuming. The standalone codes are usually unavailable or difficult to run, and good results would require high computation time and resources. Further development of *ab initio* models could incorporate a coarse-grained approach with efficient sample procedure and well-chosen force-field. It must be associated with full-atom reconstruction methods, adapted and efficient.

Template-based methods try to map sequences to structural motifs before merging them into a whole structure, which is then refined. These methods are more efficient than the *ab initio* while still being limited. Their usage is easier than *ab initio* methods, but standalone codes remain hard to reproduce locally. Improvement of template-based methods could be based on the addition of existing physics-based methods that can predict structures not already seen. It could alleviate the prediction of unseen structures. Refining the structure after assembling could also be improved to best include fragments.

The performances of deep learning approaches seem promising. By using available data and self-distillation procedures, they perform well on the RNA-Puzzles dataset. Their performances remain incomparable to AlphaFold for proteins, and the next AlphaFold for RNA has not yet been found (9). Their usage in terms of web servers is very userfriendly: only a sequence is required, and the prediction is made very quickly. We regret the standalone codes that often require the download of a huge dataset, which is almost nonfeasible for standard users. These methods are limited by a common neural network drawback: interpretability. Know-

Models	Time (27 nt)	Time (188 nt)
MC-Sym	$\sim 1 \min$	$\sim 2$ hours
Vfold3D	$\sim 10 \min$	$\sim 2$ hours
RNAComposer	$\sim 1 \min$	$\sim 5 min$
3dRNA	$\sim 1$ hour	$\sim 2$ hours
IsRNA1	$\sim$ 40 min	${\sim}15$ hours
RhoFold	$\sim 1 \min$	$\sim \! 10 \min$
trRosettaRNA	$\sim 1 \min$	$\sim 2$ hours
Vfold-Pipeline	$\sim 10$ min	$\sim$ 2 hours
RNAJP	$\sim$ 2 hours	$\sim 8$ hours

**Table 2.** Approximate time for computation of RNA-Puzzles structures. The minimum time is for an RNA of 27 nucleotides, while the maximum time is computed for an RNA of 188 nucleotides. The computation time is an approximation, as it was run on web servers and might be slowed down by other pending jobs. The time reported for RhoFold is with the relaxation (which is slower than the raw prediction). RNAJP computation time is computed locally with a simulation time set to  $50 \times 10^6$  steps.

ing the folding process would highly increase RNA understanding and is a step the community would appreciate. The integration of physics into deep learning methods could help reduce the black box trap as well as prevent models from overfitting.

Hybrid methods are also a direction that is taken by the community with recent solutions (94, 95) proposed in CASP-RNA (83). For instance, the second best solution from CASP-RNA (94) uses structures predicted by template-methods VfoldLA (37) and Vfold3D (42) before using coarse-grained simulations from IsRNA (21, 22, 29) and RNAJP (23). Hybrid solutions are usually a mix of previous methods to take the best of each of them. These recent methods are not yet available to users, so we did not include them in our benchmark.

All the previously discussed models still need to be improved with the possibility of outputting multiple structures corresponding to environment-dependent RNA molecules. Works remain to allow the prediction of long non-coding RNAs. The sequence length is still a bottleneck, where integration of all possible interactions increases the complexity and limits existing models.

#### ACKNOWLEDGEMENTS

This work is supported in part by UDOPIA-ANR-20-THIA-0013 and performed using HPC resources from GENCI/IDRIS (grant AD011014250). It was also partially supported by Labex DigiCosme (project ANR11LABEX0045DIGICOSME), operated by ANR as part of the program "Investissement d'Avenir" Idex ParisSaclay (ANR11IDEX000302).
