Abstract:

Methanol (MeOH) is a solvent and cleaning agent used in industry, but it is poisonous when ingested. The recommended release threshold for MeOH vapor is 200 ppm. We present a novel sensitive micro-conductometric MeOH biosensor created by grafting alcohol oxidase (AOX) onto electrospun polystyrene-poly(amidoamine) dendritic polymer blend nanofibers (PS-PAMAM-ESNFs) on interdigitated electrodes (IDEs). The analytical performance of the MeOH microsensor was evaluated using gaseous MeOH, ethanol, and acetone samples collected from the headspace above aqueous solution with known concentration. The sensor's response time (t_{Res}) fluctuates from 13 s to 35 s from lower to higher concentrations. The conductometric sensor has a sensitivity of 150.53 $\mu\text{S}\cdot\text{cm}^{-1}$ (v/v) for MeOH and a detection limit of 100 ppm in the gas phase. The MeOH sensor is 7.3 times less sensitive to ethanol and 136.8 times less sensitive to acetone. The sensor was verified for detecting MeOH in commercial rubbing alcohol samples.

Keywords: Micro-conductometric sensor; Alcohol oxidase; Methanol sensor; Nanofibers; Dendrimer; Rubbing alcohol.

30 **1. Introduction**

31 Methanol, the simplest alcohol, is harmless on its own, but its metabolites formic acid and formate are
32 very hazardous after ingestion [1,2]. It is well known that consuming MeOH may harm the
33 neurological and circulatory systems permanently, leading to blindness, organ failure, or even death. It
34 can be found in alcoholic drinks made by distillation or spontaneous fermentation. Blindness cases
35 have been documented following the ingestion of as little as 4 mL of MeOH. It is often stated that 100
36 mL of consumed MeOH is the least deadly dosage [1]. MeOH is often employed as a cleaning agent
37 and solvent in industry, and it is an alternate energy carrier to hydrogen [3]. For repeated exposure
38 during the working day without experiencing serious health consequences, INRS (the French National
39 Institute of Research and Security) proposes a released threshold for MeOH vapor concentration of
40 200 ppm for an 8 h's exposure. It is thus necessary to create assays and sensors that are sensitive,
41 reasonably priced, and easy to use for industrial laboratories, suppliers, and end users. MeOH has been
42 identified using a variety of methods, such as gas chromatography [4], Fourier transform infrared
43 spectrometry [5], Raman spectroscopy [6], and surface plasmon resonance [7]. These methods are not
44 suited for routine usage because of their limitations, which include high costs and the requirement for
45 skilled personnel. To address the issue, a gas sensor approach has been used to detect MeOH or other
46 volatile organic chemicals (VOCs).

47 Numerous sensors are based on semiconducting metal oxides. For the detection of MeOH,
48 nanostructured metal oxides such as SnO₂, ZnO, In₂O₃, and α-Fe₂O₃ show excellent sensitivity as well
49 as ferrite-type perovskites [8]. The main drawbacks of these nanomaterials are their high working
50 temperature and their rather poor specificity.

51 Taking advantage of the enzyme selectivity, enzyme-based sensors were used as a “bio-sniffer” for
52 the detection of methanol. Alcohol oxidase (AOX) is an oligomeric FAD-dependent enzyme that
53 oxidizes MeOH by accepting electrons from molecules of oxygen (O₂) and generating formaldehyde
54 and hydrogen peroxide (Eq. (1)). Since O₂ has a significant oxidizing effect, MeOH is irreversibly
55 oxidized by AOX:

57 Following the reaction, optical or electrochemical detections can be used to measure either the
58 decrease of O₂ or the increase of H₂O₂ concentration. Until recently, all electrochemical transducers
59 presented have been amperometric or voltametric [9].

60 MeOH in exhaled breath, for non-invasive assessment of intestinal flora, was detected through
61 fluorometry, using a cascade reaction with two enzymes, AOX from *Pichia pastoris* and formaldehyde
62 dehydrogenase from *Pseudomonas sp.*. The dynamic range of the MeOH sensor was 0.32–20 ppm
63 [10].

64 Another AOX-based biosensor was developed for the detection of MeOH in the aqueous phase
65 through photoelectrochemistry with AOX from *Hansenula sp.* immobilized in the presence of
66 cysteine-stabilized cadmium sulphide quantum dots that photocatalyze oxidation of 1-thioglycerol.
67 The detection limit of MeOH was found to be 0.01 ppb. No interference with ethanol was observed
68 [11].

69 An alcohol biosensor was obtained by the immobilization in polyvinyl alcohol of a bienzymatic
70 system (AOX from *Hansenula sp.*+ catalase from bovine liver) on a microconductometric transducer.
71 The biosensor provided a lower detection limit for MeOH (0.5 μM, 16 ppb), compared to that of
72 ethanol, in aqueous solutions [9].

73 In this work, a microconductometric transduction was chosen for the detection of MeOH in the
74 headspace above aqueous solutions through its oxidation by AOX from *Pichia pastoris*. In comparison
75 to other AOX, the active site cavity of this AOX is significantly reduced in size, which could explain
76 the observed preference for MeOH as substrate [12].

77 Polymeric nanofibers have been investigated for application in the construction of sensors due to their
78 unique properties, such as their large surface area, facile surface functionalization, and interconnected
79 porosity, which aid in improved interaction with the surrounding medium and access to the desired
80 analyte [13]. Researchers have preserved enzyme stability by immobilizing them on the surface of
81 nanofibers [14-16]. In this work, we employed PS-PAMAM dendritic polymer blend nanofibers to
82 immobilize AOX. PS is well-known for its distinct properties, such as good shape stability in aqueous
83 media and non-swelling, as well as its low cost and excellent spinnability [17]. On the other hand, PS
84 has been altered using PAMAM, a highly branched polymer, and active amine groups have been

85 designed on the surface of ESNFs to stabilize the AOX. Dendrimers are the perfect matrix for
86 stabilizing biomolecules because of their distinctive properties, including their spherical shape, size
87 controllability, high surface groups, hydrophilicity, and excellent physical and chemical stability.
88 These characteristics boost the sensitivity, selectivity, stability, and reusability of biosensors as well as
89 their capacity to capture target molecules [18]. For instance, the researchers developed an
90 amperometric biosensor based on immobilizing AOX on PAMAM and utilized it to identify ethanol
91 based on the consumption of dissolved oxygen concentration. The sensor's limit of detection (LOD)
92 was 0.016 mM, with a detection range of 0.025 to 1.0 mM. The stability studies of bioanalytical
93 characteristics preservation revealed 67% of the initial sensitivity after 1 month at 4°C [19]. To form a
94 strong covalent link between the AOX and the fiber surface, glutaraldehyde coupling chemistry was
95 employed to form a bond between the PAMAM dendritic polymer groups and the amine groups on the
96 AOX's outer surface. The conductometric sensor, which incorporates an IDEs coated with a thin layer
97 of PS-PAMAM ESNFs on which AOX is immobilized, is shown step by step in Scheme 1. The
98 volatile alcohols are measured directly in the headspace above the aqueous solutions using
99 conductometry. The analytical performance of the novel MeOH sensor was determined. For its
100 validation, the determination of the MeOH content in rubbing alcohol was performed.

2. Materials and Methods

2.1 Reagents and solutions

106 The reagents and solutions were fully addressed in the supplemental material.

2.2 Technology of fabrication of the micro conductometric chips

108 A chrome-on-glass mask was designed for the production of interdigitated gold microelectrodes with a
109 width of 20 μm and an interelectrode distance of 20 μm . The electrical tracks were 500 μm wide. The
110 lithography and deposition steps are carried out on 4-inch (Borosilicate) glass substrates, 1mm thick
111 with two polished sides. The photosensitive resin used for the process was AZ 5214 E resin, which is a

112 reversible resin but, in this case, used in positive mode (the exposed parts were left during the
113 development). In order to improve the adhesion of the resin to the wafer, a primer was used, which
114 was spread with the same program as the resin. The spreading of the primer and of the resin were
115 consecutive. The assembly was then annealed at 120°C on a hot plate for 120 s. The thickness of the
116 resin deposited on the wafer was approximately 1.4 µm. The UV KUB 2 system, working with an
117 LED carpet, was used for insolation. The maximum power of the KUB UV was 23.2 mW/cm² (100%).
118 It was critical that the Cr/glass mask and resin mask made good contact. The insolation parameters
119 were 70% of the maximum power for 10 s. The development was carried out in the AZ 726 MIF
120 developer for 1 min with a slight manual agitation. The reaction was stopped by immersing the wafer
121 in a large volume of DI water, then the wafer was rinsed with DI water, and finally it was dried under
122 a dry air flow. Before carrying out the deposition by electron gun, the wafers were cleaned by plasma
123 using the RIE NGP 80 frame. The process conditions were: 55 sccm O₂, 100 mTorr, 70 W (13.56
124 MHz RF generator), and duration 120 s. The metal deposition was carried out in an EVA 300 vacuum
125 frame. The substrates were fixed to an uncooled rotating sample holder. The high-voltage generator
126 was set at 7.4 kV. A thickness of 20 nm of titanium was deposited, and then a thickness of 150 nm of
127 gold was deposited. At the end of the deposition, lift-off was carried out; the samples were immersed
128 in an acetone bath under ultrasound for 30 min. To remove the last residues, a new plasma cleaning
129 was carried out under the same conditions as before, but for a period of 10 min. The chips were then
130 cut into pairs of electrodes using the DISCO saw. A flow chart of the fabrication process is presented
131 in Figure 1. An excellent reproducibility from one microelectrode to another and excellent gold
132 adhesion was obtained. The glass wafer covered with interdigitated electrodes cut in pairs, and
133 supported on a blue film is presented in Figure S1.

134 The chips were detached from the blue film and rinsed with acetone and ethanol to remove any
135 contaminants that would hinder the encapsulating resin from adhering to the surface. The connections
136 were covered with the encapsulation resin, which was made by combining two EPOTECH polymers
137 (50/50 by weight) to designate the measuring area. The micro-conductometric chips were 5×30 mm in
138 size and consisted of two identical gold interdigitated electrodes.

2.3 Preparation of the methanol sensor

2.3.1 Preparation of PS-PAMAM ESNFs based micro conductometric chips

To create a 20 wt.% PS-PAMAM electrospinning solution, 0.14 g of PAMAM and 0.26 g of PS granules were each individually dissolved in 1 mL of N,N-dimethylformamide (DMF) and agitated overnight at room temperature (RT). Then, the PAMAM was gradually and carefully added to the PS, and the mixture was stirred for an additional 4 h. Following this step, the homogeneous PS-PAMAM solution was used immediately for electrospinning. The solution loaded into a 1 mL syringe was fed to the nozzle head (a laser-cut needle, 22 gauges) with the help of an electrospinning pump through a polytetrafluoroethylene (PTFE) tube (vertical electrospinning device, Spraybase®, Ireland). The electrospinning parameters were 20 kV for the voltage, 0.25 mL/h for the feed rate, and 20 cm for the working distance, and they were optimized in the prior investigation to produce beadless nanofibers with a uniform diameter [20]. PS-PAMAM nanofibers were electrospun on each micro conductometric chip for 1 min by placing the interdigitated electrodes under the vertical spinning device in order to obtain the greatest degree of uniformity across the electrodes in terms of the thickness and quantity of ESNFs deposited. The micro conductometric chips containing nanofibers were stored at RT until the subsequent stages of sensor manufacturing.

2.3.2 AOX Immobilization

The enzyme immobilization on the biosensor surface was carried out by a method of protein cross-linking in saturated glutaraldehyde (GA) vapor, as previously optimized [9]. Typically, the PS-PAMAM ESNFs based sensor was placed in saturated GA vapor for 45 min. In parallel, BSA (2,8 mg/mL) was first dissolved in 10 mM PBS (pH = 7). The solution was mixed with AOX enzyme (2 mg/mL). The mixture containing AOX and BSA was deposited dropwise on the sensitive surface of the PS-PAMAM ESNFs based sensor (working sensor) and then kept dried at 4°C in the refrigerator until further usage. The reference sensor was functionalized only with BSA. After one night in the fridge, it was possible to use the sensor.

166 **2.4 Instrumentation**

167 2.4.1 Physicochemical Characterizations

168 The Characterizations were fully addressed in the supplemental material.

169 2.4.2 Conductometric measurements

170 Conductometric VOC detection was accomplished by applying an alternating voltage (10 mV
171 amplitude, 10 kHz frequency) generated by a very low-frequency wave-form generator to each pair of
172 interdigitated electrodes (working sensor and reference sensor). These parameters enabled reductions
173 in faradaic processes, double-layer charging, and concentration polarization at the microelectrode
174 surface. These parameters had previously been optimized in KCl solutions. A conductometer
175 VigiZMeter was used to record the sensors' differential output signal (COVARIANS Gif-sur-Yvette,
176 France). The working/reference sensor pair was placed in the headspace over a liquid phase in a
177 cylindrical container to accomplish these measurements. The conductance (G) measurement was
178 recorded versus time throughout the insertion of the sensor pair into the headspace and its withdrawal
179 from the headspace.

180 **2.5. Preparation of gas samples**

181 Gaseous MeOH, ethanol, and acetone samples were collected from the headspace above aqueous
182 solutions of known concentrations between 0 and 100%.

183 The concentrations of MeOH and ethanol in the gas phase above the aqueous solutions are determined
184 using the Henry's law constants of the given analytes in water, according the equation reported by
185 Sander [21], at 25°C.

$$186 \quad k_{\text{H}}^0 = c_{\text{a}} / p_{\text{g}} \quad (\text{eq. 1})$$

187 Where k_{H}^0 refers to Henry's law constants for the standard condition; $[k_{\text{H}}^0] = \text{M/atm}$. c_{a} is the
188 concentration of a species in the aqueous phase; $[c_{\text{a}}] = \text{M}$, and p_{g} is the partial pressure of that species in
189 the gas phase; $[p_{\text{g}}] = \text{atm}$.

190 For the listed solvents, MeOH, ethanol, and acetone, Henry's law constants value are respectively $2.2 \times$
191 10^2 M/atm , $2 \times 10^2 \text{ M/atm}$, and $0.2 \times 10^2 \text{ M/atm}$ at 25°C [22].

192 The calculated equilibrium gas-phase concentrations of MeOH, ethanol, and acetone above the
193 aqueous phase are shown in Tables S1, S2, and S3.

194

195

196 **3. Results and discussion**

197 ***3.1. Characterization of the PS-PAMAM ESNFs mats***

198 The homogeneity in the diameter of the nanofibers has a significant impact on the performance of
199 nanofiber-based sensors, including the repeatability of the results and reproducibility of the sensor. An
200 FESEM microscope was used to analyze the nanofibers' morphology. According to the photograph in
201 Figure 2 (A), PS-PAMAM ESNFs have a uniform diameter and a smooth surface without any beads.
202 The main reason for this is the presence of PAMAM in the electrospinning solution, which increases
203 the electrical conductivity of the electrospinning solution and the surface charge of the jet during
204 flight, as a result of which the electrospinning jet is subjected to more instabilities and causes the
205 nanofiber diameter to decrease. The uniformity of the diameter, both along the length of a single fiber
206 and in the average diameter of the fibers, is confirmed by the histogram of Figure 2 (B)'s narrow
207 diameter distribution, which will result in repeatability and reproducibility for the desired sensor. The
208 branching polymer's active sites and the average diameter of 200 nm will give a large amount of
209 accessible surface area for enzymes, leading to a significantly higher level of stability of the enzyme
210 on the fiber surface.

211

212

Figure 2.

213

214 The FTIR test was used to evaluate the chemical structure of PS-PAMAM ESNFs and to validate the
215 presence of PAMAM amine groups in the structure and surface of nanofibers. In all spectra
216 (Figurec3), the characteristic peaks of PS at 696 cm^{-1} and 755 cm^{-1} associated with C–H out-of-plane
217 bending vibration, 1451 cm^{-1} and 1492 cm^{-1} related to CH_2 bending vibrations, 1600 cm^{-1} linked to
218 C=C stretching vibrations, 2846 cm^{-1} , 2920 cm^{-1} , and $3080\text{-}3024\text{ cm}^{-1}$ related to aromatic C–H

219 stretching vibration absorption, and the presence of CH_2 were present. Characteristic bands of
220 PAMAM are also found in the spectra of PS-PAMAM ESNFs at 1372 cm^{-1} , 1551 cm^{-1} , and 1645 cm^{-1} ,
221 corresponding to C–N stretch of amide III, N–H bending and C–N stretch of amide II band, and C=O
222 of amide I band, respectively. Furthermore, the band at 3268 cm^{-1} is associated with N–H stretching
223 vibration (Figure 3. (A)). These bands show that PAMAM is intercalated in the PS fiber structure
224 without any interaction with PS because the FTIR bands of amide I, amide II and amide III remain
225 at the same positions as those of the pristine PAMAM grafted on the surface of PS fibers
226 [13,23]. The spectra of GA-PS-PAMAM ESNFs (Figure 3. (B)) shows two additional peaks at 1644
227 cm^{-1} and 1715 cm^{-1} that are associated to GA. Moreover, the peak at 1674 cm^{-1} is connected to the
228 C=N group, confirming the covalent link between the NH_2 of PAMAM and the C=O of GA [20]. The
229 peak at 1715 cm^{-1} associated to GA has diminished owing to binding between the AOX and GA after
230 immobilization of AOX on the surface of PS-PAMAM ESNFs based micro conductometric chip
231 [24,25] (Figure 3. (C)).

232

233

Figure 3.

234

235 *3.2 Analytical performance of the micro-conductometric methanol sensor*

236 Conductometric detection of numerous VOCs (MeOH, ethanol, acetone, chloroform, and toluene) was
237 carried out in the gaseous phase above pure liquid compounds at 25°C in order to assess the
238 discrimination capacity of an AOX/PS-PAMAM ESNFs-based sensor, as shown in Figure 4. The
239 conductivity signal increased dramatically when exposed to the headspace of MeOH. The nanofibers'
240 large accessible surface area, along with the designed surface chemistry supplied by the PAMAM,
241 permitted very high immobilization of the AOX on the electrode surface, resulting in very high sensor
242 sensitivity. In comparison to ethanol and acetone, the sensor has shown significantly higher sensitivity
243 to MeOH. It should be emphasized that the sensor showed no response following exposure to toluene
244 and chloroform. This demonstrates the proposed sensor's remarkable sensitivity to MeOH.

245

246

Figure 4.

247

248 The response time (t_{Res}) is defined as the amount of time needed to achieve 90% of the total change in
249 conductance following introduction into the headspace, and the recovery time (t_{Rec}) is defined as the
250 amount of time needed to achieve 10% of the total change in conductance following withdrawal from
251 the headspace.

252 As shown in the diagram in Figure S2, the t_{Res} of the AOX/PS-PAMAM ESNFs-based conductometric
253 sensor was from 13 s to 35 s from lower concentrations of MeOH to its higher concentrations. The t_{Rec}
254 was from 6 s to 10 s from lower concentrations to higher concentrations.

255

256

Figure S2.

257

258 The detection of different gas-phase concentrations of MeOH is presented in Figure 5. When the
259 MeOH concentration was zero and the sensor was exposed to pure water, the conductivity that was
260 recorded corresponded to 100% humidity at that time and was 22 $\mu\text{S}/\text{cm}$. The observed signal at
261 9v/v% MeOH concentration was 1100 $\mu\text{S}/\text{cm}$; the contribution of 89v/v% humidity is then 1.8% of
262 this signal, which is within the experimental error range for this concentration. This low contribution
263 of humidity is due to the differential measuring method between the working sensor with AOX and the
264 reference sensor with BSA. The non specific signal for water is then cancelled.

265

266

Figure 5.

267

268 The calibration curves of gas-phase concentrations of MeOH, ethanol, and acetone are
269 presented in Figure S3. The MeOH sensor presents the best linearity of $R^2 = 0.9707$, and the
270 best sensitivity of 150.53 $\mu\text{S}\cdot\text{cm}^{-1}(\text{v}/\text{v})$. The MeOH sensor has a detection limit of 100 ppm,
271 calculated from the formula $3s/S$ where s is the standard deviation of 3 different blanks
272 and S is the slope of the calibration plot. The sensitivities for ethanol and acetone are 20.4

273 $\mu\text{S}/\text{cm}(\text{v}/\text{v})$ and $1.1 \mu\text{S}/\text{cm}(\text{v}/\text{v})$, respectively, showing that the MeOH sensor presents a 7.3 times
274 higher sensitivity than ethanol and 136.8 times higher than acetone. The relative standard deviation of
275 the measurements is 2%. The inter-sensor reproducibility is 5%. The shelf life of the MeOH sensor is
276 one month when continuously used.

277 **Figure S3.**

278
279 A lot of MeOH sensors have been fabricated, mainly based on semi-conducting compounds (SnO_2 ,
280 TiO_2 , CdS) and on Ni phthalocyanine (Table 1). Meanwhile, this is the first time that an AOX/PS-
281 PAMAM ESNFs based sensor is used for the conductometric detection of MeOH. Compared to the
282 other conductometric MeOH sensors, the prepared MeOH sensor works at room temperature, presents
283 a short response time, but it has a rather high detection limit.

284 **Table 1.**

285

286 **287 *3.3 Detection of alcohol content in rubbing alcohol through the gas phase***

288 Rubbing alcohol, a product made from 95% MeOH, is used as a liquid on barbecues or fireplaces or as
289 an antifreeze solvent. In addition, if used at home, it is a powerful cleaner for stubborn dirt, polishing
290 numerous surfaces, and removing stains.

291 After the detection of MeOH in the headspace of absolute MeOH and of an 80% MeOH /water
292 mixture, the detection of MeOH in the headspace of a commercial rubbing alcohol “Alcohol de
293 QUEMAR” was conducted as presented in Figure S4.

294 The conductivity found for the commercial sample was $1282 \mu\text{S}/\text{cm}$. This value corresponds to 10.31
295 $\pm 0.23 \text{ v}/\text{v}\%$. The corresponding concentration in the liquid phase of the rubbing alcohol is $23.60 \pm$
296 1.30 M . This corresponds to $91.17 \pm 1.5 \text{ v}/\text{v}\%$, which is in good agreement with the supplier’s figure
297 of 95%.

4. Conclusion

A highly sensitive MeOH sensor based on AOX/PAMAM dendritic-polystyrene polymer blend nanofibers was successfully developed in this study. The sensitivity for MeOH is 7.3 times higher than for ethanol. The sensor is selective, sensitive, has a short response time, and has a shelf life of one month. The detection limit is lower than the recommended threshold for MeOH vapor concentration for exposed workers.

Reagents and Solutions

Polystyrene (PS, MW = 192,000 g/mol) and N,N-dimethylformamide (DMF) (purity 99.9%) were purchased from Sigma-Aldrich. Poly(amidoamine) dendritic polymer equivalent to the second generation of poly(amidoamine) dendrimer (PAMAM) was provided by the Delta-Innovative Company, Poland. Alcohol Oxidase (AOX) from *Pichia pastoris* (10-40 units/mg protein), Bovine serum albumin (BSA) (96%), glutaraldehyde (GA), phosphate buffer saline (PBS) tablets, methanol (MeOH) (99.5%), ethanol (99.5%), acetone (99.5%), chloroform (99.5%), toluene (99.5%) were purchased from Sigma Aldrich. Ultra-pure water (UPW) (resistivity >18 MΩ cm) was produced by the ELGA System.

566

567 **Figure S1.** The glass wafer is covered with interdigital electrodes cut into pairs and supported on a
568 blue film

569

570 *Characterizations*

571 Field emission scanning electron microscopy (FE-SEM, MIRA3 TESCAN) was used to characterize
572 the morphology of ESNFs. Using the ImageJ analysis program, the average diameters and diameter
573 distributions of ESNFs were calculated from FE-SEM images by randomly picking 100 fibers from each
574 of the ESNFs mats.

575 The surface chemical composition of ESNFs during methanol sensor preparation was characterized by
576 Fourier Transform-Infrared (FTIR) using a NEXUS spectrophotometer (Nicolet-Thermo Fisher, UK)
577 for 256 scans at a resolution of 4 cm^{-1} . The spectra were recorded in attenuated total reflectance
578 (ATR) mode using a Thunder dome (Spectratech) accessory containing a germanium crystal with a
579 mono reflection at 45° .
