24 **Abstract**

25 In this article, we propose an approach to reconstruct the timing of human activity at Points
26 Cave, an Upper Palaeolithic rock art site located in the middle of the Ardèche River gorge
27 (Rhône valley, France), based on the dating and characterisation of a stalagmite containing soot.

28 Points Cave (“Grotte aux Points” in French), also called the “little sister of Chauvet
29 Cave”, is famous for its parietal art including a series of dots made of palm prints. A large
30 number of stalagmites formed in the cave during the last 500 ka. However, quarrying of the cave
31 floors during historic times led to the partial destruction of the sedimentary deposits, and many
32 of the stalagmites were found lying on the floor. In particular, one of them (STM-18-04) showed
33 the presence of at least four dark layers in cross-section, which appeared as possible remnants of
34 fire-related activities in the cave.

35 Despite being present at the same site, no other specific link between STM-18-04 and the
36 rock art has been documented. This stalagmite, however, allows us to identify phases of human
37 presence, located at the cave entrance. In order to do so, we performed a series of analyses to
38 determine its period of growth and the nature of the dark layers it contains. Scanning electron
39 microscopy and Raman micro-spectroscopy confirmed that the dark layers include soot, and U-
40 series dating indicated that the fire events occurred respectively around 14,200-14,100 and
41 12,500 years ago, in agreement with the radiocarbon ages of charcoal specimens recovered from
42 the excavation areas nearby. We thus highlighted phases of human activity at the site during the
43 Upper Magdalenian and/or beginning of the Epipalaeolithic. By comparing our results with the
44 regional palaeoclimatic record, the soot layers trapped in the stalagmite appear to be synchronous
45 with two cold periods, likely the Older Dryas, and the Younger Dryas.

50 **1. Introduction**

51 Establishing the chronology of human and animal activities in Palaeolithic rock art sites in
52 relation to natural phenomena (climate change, geological and environmental events) is a key
53 issue in rock art research. Following the discovery of Chauvet Cave in 1994 and the publication
54 of the radiocarbon ages obtained on the paintings (starting from ca. 36,000 years cal. BP, Clottes
55 *et al.*, 1995), there has been a major effort to unravel the chronology of events that took place in
56 the Palaeolithic rock art sites of south-eastern France (Valladas, *et al.*, 2001, 2017; Genty *et al.*,
57 2004; Ambert *et al.*, 2005; Cuzange, *et al.*, 2007; Azéma *et al.*, 2012; Sadier *et al.*, 2012; Quiles,
58 *et al.*, 2013; Monney *et al.*, 2014; Guibert *et al.*, 2015; Quiles, *et al.*, 2016; Monney & Jaillet,
59 2019). There is increased interest in understanding the climatic and environmental conditions at
60 the time of human presence at the entrance and/or in the deepest parts of rock art caves during
61 the Upper Palaeolithic, a period that broadly ranges from ca. 50 to 12 ka. In this regard, the
62 analysis and dating of speleothems has proved an essential source of information, especially in
63 the Ardèche River Gorge (Bourdin, *et al.*, 2011; Genty *et al.*, 2004).

64 Uranium-series ($^{230}\text{Th}/\text{U}$) dating is extensively used to date calcium carbonate deposits,
65 in particular cave speleothems (Ivanovich and Harmon, 1992; Richards and Dorale, 2003). In
66 stalagmites, U-series dating can be combined with palaeoclimatic and palaeoenvironmental
67 analyses, including stable isotopes and trace elements. In addition to geochemical information,
68 speleothems may also contain remnants of anthropic activities such as traces of fire, or use of
69 manganese oxides (e.g., Genty, *et al.*, 1997; Vandavelde, *et al.*, 2017; Pons-Branchu *et al.*, 2022).

70 However, applications are successful on well preserved samples, i.e., closed systems, and are
71 limited in the case that U is remobilised due to diagenetic processes (dissolution,
72 recrystallisation), which may distort the ages obtained. This is particularly restrictive when
73 dating thin speleothems (“crusts”) covering rock art (e.g., Aubert et al., 2014; Hoffmann et al.,
74 2016; Pike et al., 2012), thus highlighting the importance of having a clear stratigraphic control,
75 independent dating methods (e.g., radiocarbon) and archaeological context (Pons-Branchu et al.,
76 2014a; 2022).

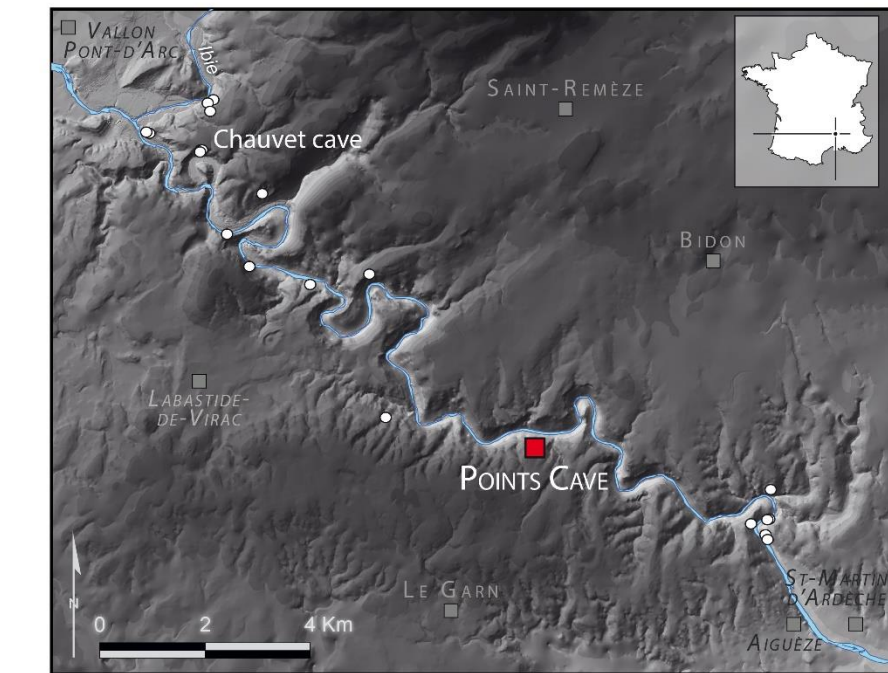

77 Here, we combined U-series and radiocarbon (^{14}C) dating on calcite samples and material
78 characterisation of dark particles trapped in a stalagmite collected on the floor of Points cave
79 (STM-18-04), a rock art site located in the Ardèche River Gorge in France (Figure 1). Our study
80 aimed at connecting chronological data obtained in STM-18-04 with the remnants of fire
81 activities trapped in this stalagmite. These data were compared with the ^{14}C ages obtained on
82 charcoals collected from the stratigraphic context to reconstruct the timing of human activities at
83 the entrance of the cave.

84

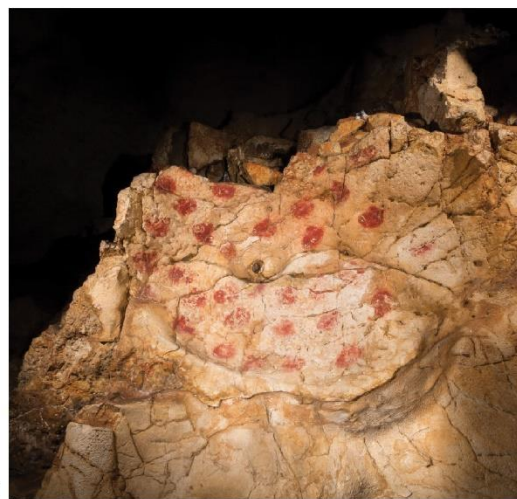

85 **2. Materials and Methods**

86 **2.1. Site description and sampling**

87 Points Cave is a Palaeolithic rock art cave located in the central part of the Ardèche River Gorge
88 (Aiguèze, Gard, France, Figure 1a). Since 2011, it has been subject to interdisciplinary research
89 as part of the “Datation Grottes Ornées” (“Cave Art Dating”) project, coordinated by one of us
90 (Monney, 2018a). The cave is a 110 m-long corridor (Figure 1c). It was successively occupied
91 by cave bears during Marine Isotopic Stage 3 (MIS 3, ca. 57-29 ka, Lisiecki and Raymo, 2005)
92 and modern humans, at least, since the Gravettian (since ca. 32,000 cal BP).

c)

93

94 Figure 1. Location of Points Cave in the Ardèche Gorge (a), an example of palm prints produced

95 by pressing pigment-covered palms onto the rock (b) and map of the cave with location of

96 stalagmite STM-18-04 (c).

97 The rock art, which was discovered in 1993 (Brunel et al., 2008, 2018), is concentrated in
98 an area located in the total darkness zone around 75 m from the entrance. It includes 72 red
99 drawings and paintings, including five animal figures (three ibexes, one horse, one bison), five
100 indeterminate tracings, two bilobed signs, one open-angle sign and 59 palm prints produced by
101 pressing pigment-covered palms onto the rock (Figure 1b, Monney, 2018b). The rock art shows a
102 high colorimetric homogeneity (Lafon-Pham et al., 2022) and is attributed to a single painting
103 phase (Monney, 2018b). Its closest iconographic equivalent is to be found in the entrance sectors
104 of Chauvet Cave, where we also find bilobed signs and palm prints clusters accompanied by
105 small line drawings of animals (Baffier and Feruglio, 1998; Chauvet et al., 1995; Gély, 2005).

106 Material uncovered in SU (Stratigraphic Unit) 1 during archaeological excavations at
107 Points Cave entrance comprises flint, charcoal, faunal remains and colouring material. The
108 preliminary typo-technological analysis of the lithic material revealed the presence of a Noailles
109 burin, microgravettes, probable fragments of unifacial points, covering retouch, etc. (Boccaccio,
110 2018), indicating that humans visited the cave, at least during the Gravettian (ca. 32,000-
111 26,000 cal BP) and Solutrean (ca. 26,000-21,000 cal BP) and possibly up until the
112 Epipalaeolithic (ca. 14,000-12,000 cal BP). During historic times, the floors and sedimentary
113 deposits of Points Cave were affected by extensive quarrying activities that led to the breakage
114 and/or unearthing of speleothems. Archaeological surveys identified 21 stalagmites and
115 one stalactite scattered on the floors and/or embedded in cave sediments (Figure 2).

116 We focused our study on one of the stalagmites, PTS-STM-18-04, whose cross-section
117 revealed a series of dark layers interbedded with calcite (Figure 3). This stalagmite was found in
118 the penumbra zone, 38 m away from the entrance. Following F. Rouzaud (1978), the penumbra
119 zone is described as an area with indirect natural lighting where it is possible to move around

120 without the aid of artificial lighting (grease lamp, torch, etc.). Unlike other speleothems attesting
121 to ancient flood periods inside Points Cave up to the beginning of MIS7, ca. 241 ka (Genuite et
122 al., 2022), STM-18-04 did not show any erosion marks indicative of transport processes, nor
123 traces of burial processes (no red sandy sediments on its outer surface). On the contrary,
124 although found lying on the floor and disconnected from its dripping area, STM-18-04 was
125 found intact. Moreover, remains of the sediment on which it had precipitated were still trapped
126 under its base. Similar sediments were observed under the remnants of a broken, albeit *in situ*,
127 stalagmitic floor located about 3 m away from STM-18-04, suggesting that the stalagmite may
128 have been initially in the continuity of the flowstone and that it would have precipitated close to
129 its finding place (Figure 2).

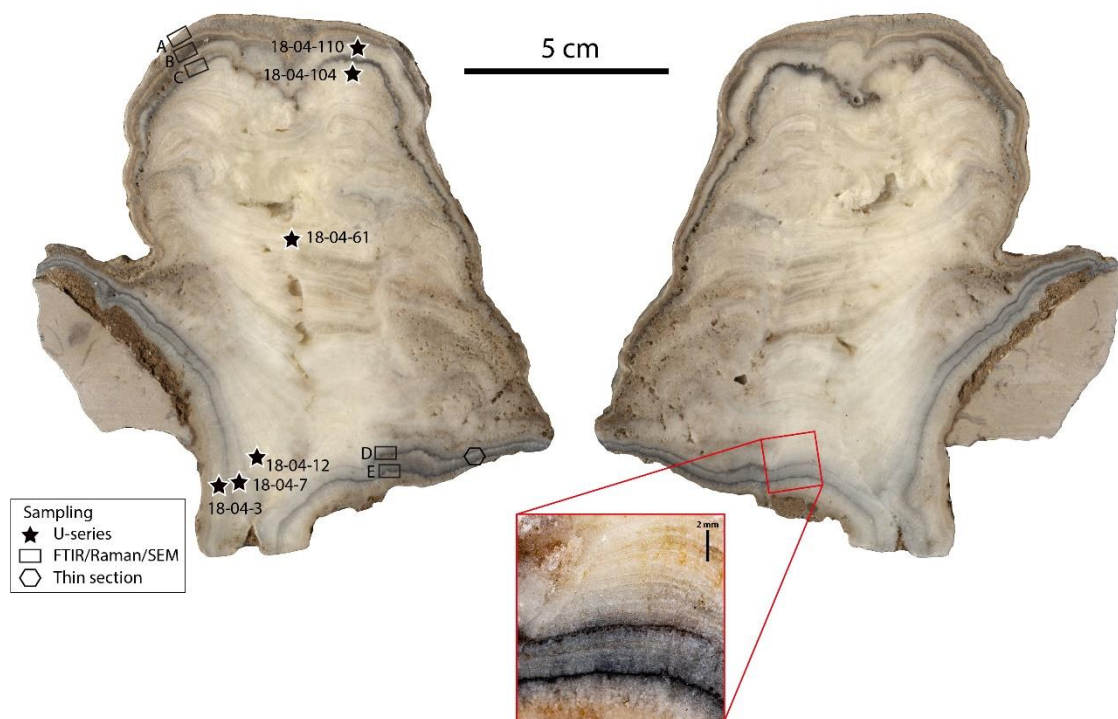

130

131

132 Figure 2. Location of STM-18-04 when found (1), context and floor state at Points Cave (2).

133 In cross-section, STM-18-04 showed a series of dark layers (Figure 3). Two of them,
134 separated by a few millimetres, are located at the base of the stalagmite. A third layer is located
135 less than a centimetre below the top of the stalagmite. A detailed examination of the latter
136 showed that it resulted from the concatenation of at least two different dark horizons. The other
137 dark traces, visible for example at the top of STM-18-04, are too diffuse to attest the presence of
138 any other layer.

139
140 Figure 3. The STM-18-04 speleothem and location of the sampling for U-series, vibrational
141 spectroscopy and optical microscopy. U-series samples were taken from the base to the top of the
142 speleothem: the number after 18-04 refers to the sample depth (in mm).

143
144 These dark layers were observed using stereomicroscopy and characterised using Raman
145 micro-spectroscopy, scanning electron microscopy (SEM), and thin section petrography
146 (Figure 3). Six samples were also collected for U-series analyses to reconstruct the timing of

147 formation of the concretion, including the fire events (Figure 3). The crystalline phase of the
148 samples was determined using Fourier transform infrared (FTIR) spectroscopy. Radiocarbon
149 analyses were also performed on calcite and on charcoals from the immediate archaeological
150 context (stratified deposits).

151

152 **2.2. Chronology**

153 **Uranium-series dating and modelling**

154 U-series dating is based on the radioactive decay of ^{234}U in ^{230}Th within the ^{238}U decay chain.
155 Uranium being soluble in water, it is incorporated to the calcite during the precipitation of the
156 crystal. Thorium being insoluble, it is assumed that the ^{230}Th content measured today is the
157 product of the parent, ^{234}U . However, contamination of exogenous Th is common and needs to
158 be checked in order to assess the reliability of the age results. To do so, ^{232}Th , which does not
159 belong to the ^{238}U decay chain, but has the same chemical behaviour than ^{230}Th , is measured, and
160 the $^{230}\text{Th}/^{232}\text{Th}$ used to assess the level of contamination and to correct the ages (see for example
161 Hellstrom, 2006). The measurement of U and Th isotopes using mass spectrometry allows
162 calculating ages for samples up to ca. 600 ka. Six samples were extracted from STM-18-04 using
163 a dentist drill at the EDYTEM laboratory (Le-Bourget-du-Lac, France) (Figure 3). U-series
164 analyses were conducted at the Laboratory of Science of Climate and Environment (LSCE, Gif-
165 sur-Yvette, France) using the chemical procedure for separation and purification of uranium and
166 thorium isotopes described in Pons-Branchu et al. (2014b). Samples (100-200 mg) were spiked
167 with a ^{236}U - ^{229}Th solution and the U and Th fractions were extracted using U-TEVA resin
168 (Eichrom®). Uranium and Thorium fractions were then recombined for measurements on a
169 Multi-Collector Inductively Coupled Plasma Mass Spectrometer (MC-ICP-MS Thermo Neptune

170 Plus), fitted with a jet interface and an Aridus II desolvating system. ^{238}U , ^{235}U , ^{236}U , and ^{229}Th
171 were measured on Faraday cups, and ^{230}Th and ^{234}U on ion counting following Pons-Branchu et
172 al. (2014b). The ages obtained were modelled using stratigraphic and coevality constraints
173 (STRUT, Roy-Barman and Pons-Branchu, 2016). An age-depth model was then computed from
174 corrected U-series ages and depth measurements using MOD-AGE (Hercman and Pawlak,
175 2012).

176

177 **Radiocarbon analysis of calcite**

178 Aliquots (ca. 10 mg) of the samples collected for U-series analyses were used for radiocarbon
179 (^{14}C) dating at Laboratoire de Mesure du Carbone 14 (LMC14, Gif-sur-Yvette, France). CaCO_3
180 samples were cleaned according to the procedure of Dumoulin et al. (2017). The samples were
181 then hydrolyzed in CO_2 with pure ortho-phosphoric acid (H_3PO_4) and converted to graphite prior
182 to being measured following the standard protocols at the ARTEMIS AMS facility, LMC14
183 laboratory (Moreau et al., 2013; Moreau et al., 2020). The ^{14}C measurements were corrected for
184 isotopic fractionation according to the ^{13}C values measured at the Artemis facility, following
185 international recommendations (Mook and van der Plicht, 1999).

186

187 **Radiocarbon analysis on charcoals**

188 For comparative purposes, ^{14}C dating was also performed on five charcoals taken from the upper
189 part of the stratigraphic sequences of the archaeological excavations previously carried out at the
190 cave entrance. One of these charcoals (Charb-1223) comes from the natural stratigraphy visible
191 in the background in Figure 2. It was collected at the interface between the stalagmitic floor and
192 SU 1, in a stratigraphic position very similar to that of the two black horizons at the base of

193 STM-18-04. Two of the charcoal samples (Charb-1521 and 1525) were prepared in the “Centre
194 de Datation par le Radiocarbone” (CDRC) in Lyon (France) and sent in gas form to the
195 Laboratoire de Mesure du Carbone 14 (LMC14) in Saclay. The chemical pretreatment and the
196 combustion to produce the CO₂ of the three other charcoals (Charb-1140, 1223 and 1548) were
197 done at the LMC14 according to the protocol described in Dumoulin et al. (2017). All the
198 samples were converted to graphite and were measured at the ARTEMIS facilities. The ¹⁴C ages
199 were then calibrated using Oxcal 4.4 (Bronk-Ramsey, 2001) and the IntCal20 calibration curve
200 (Reimer et al. 2020). Note that there was not enough material to perform analyses directly on the
201 black horizons.

202

203 **Stereomicroscopy and thin section petrography**

204 All speleothem fragments (A, B, C, D, and E, Figure 3) were analysed using a Leica
205 stereomicroscope at different magnifications (up to 10x) to identify regions of interest for
206 scanning electron microscopy and Raman micro-spectroscopy. One fragment of the speleothem
207 was mounted on a glass slide and polished to a thickness of 30 µm to obtain a thin section. The
208 thin section was analysed using a Leica DM2500 P polarising microscope at different
209 magnifications (25x, 50x, 100x, 200x, 400x).

210

211 **Scanning electron microscopy (SEM)**

212 Fragment D (Figure 3) was selected for SEM to determine the nature of the black particles
213 embedded in the dark layer. The sample was analysed using a JEOL JSM-IT500HR
214 InTouchScope™ at 5 kV and various working distances™ using a backscattered electron detector
215 for electronic mean density images and a secondary electron detector for topographic images.

216

217 **Fourier transform infrared spectroscopy (FTIR)**

218 Fragments of speleothems ($n=6$) were analysed using FTIR to determine their composition
219 (Figure 3). In addition, two of the fragments were dissolved in 1M HCl to analyse their insoluble
220 fraction. Samples were powdered in an agate mortar and pestle and about 5 mg of each were
221 mixed with 40 mg of KBr and pressed into 7-mm pellets using a hand press. Infrared spectra
222 were collected in transmission mode in 32 scans within the 4000-400 cm^{-1} spectral range using a
223 Bruker Alpha spectrometer operated via OPUS 7.2. Spectra were analysed using OMNIC 9.6 and
224 Macros Basic 8.0, and phase identification was based on standard literature (Farmer, 1974; van
225 der Marel and Beutelspacher, 1976) and on the infrared spectra library of the Kimmel Center for
226 Archaeological Science (<https://centers.weizmann.ac.il/kimmel-arch/infrared-spectra-library>).
227 The degree of atomic order of calcium carbonate crystals was determined following the methods
228 of Regev et al. (2010) and Poduska et al. (2011).

229

230 **Raman micro-spectroscopy (μ Raman)**

231 Fragments of speleothems ($n=3$, #B, D, and E, see Figure 3) were analysed using Raman
232 spectroscopy with a Renishaw micro-spectrometer type RM2000 coupled to a LEICA type
233 DMLM microscope equipped with a x50 large numerical aperture objective and a 633 nm laser.
234 Under 1-2 μm laser spot radius and the chosen optical set, the spatial resolution can be estimated
235 to be around 3 μm along the Z depth optical axis and 2x2 μm^2 at the XY perpendicular matter
236 surface. All the spectra were acquired with a grating blazed at 1200 gr/mm and a 50 μm
237 spectrometer entrance slit, ensuring a high spectral resolution. The acquisitions are a fixed
238 combination between a laser power attenuation and time per point, systematically adapted so that

239 the most intense spectral component neither exceeds the detector saturation (approximately
240 120,000 cts) nor damages the matter under the laser spot. Each spectrum is obtained by a
241 summation of several consecutive acquisitions. Experimental data were processed with WIRE
242 v1.3 Renishaw software for polynomial function background removal and curve fitting
243 deconvolution of Raman spectral components.

244 The archaeological samples were compared with modern reference material including
245 charcoal, burnt carbon fibre, and pencil graphite.

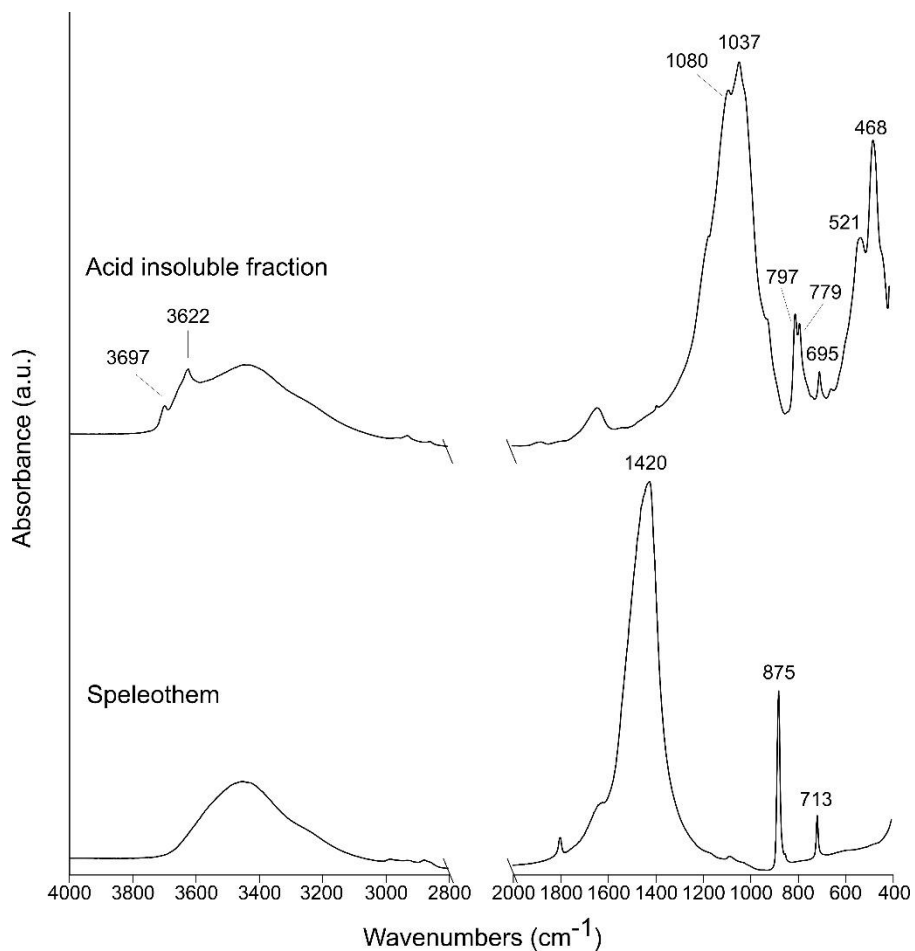

246

247 **3. Results**

248 **3.1. Characterisation**

249 FTIR shows that all the speleothem fragments are composed of calcite, as indicated by the
250 absorption bands at 1420 (ν_3), 875 (ν_2), and 713 cm^{-1} (ν_4) (Figure 4). Despite being the product
251 of a long geological process, calcite crystals show a poor degree of atomic order, similar to the
252 experimental ash and archaeological lime plaster reported by Regev et al. (2010), based on the
253 intensity of the ν_2 and ν_4 absorptions normalised to the intensity of the ν_3 absorption (Table 1).
254 This phenomenon has already been observed in speleothems and is caused by large lattice strain
255 in calcite crystals (Xu et al., 2015). These structural defects may be caused by porosity,
256 inclusions, crystallite size, or morphology, which vary considerably in cave settings. Inclusions
257 were indeed identified in thin section (Figure 5). The insoluble fractions include mainly clay
258 minerals of the kaolinite and smectite groups (absorptions at 3697, 3622, 1037, and 521 cm^{-1})
259 and quartz (1080, 797, 779, 695, and 468 cm^{-1}), whereas organics related to soot were not
260 observed, presumably because of their low concentration (Figure 4).

261

262

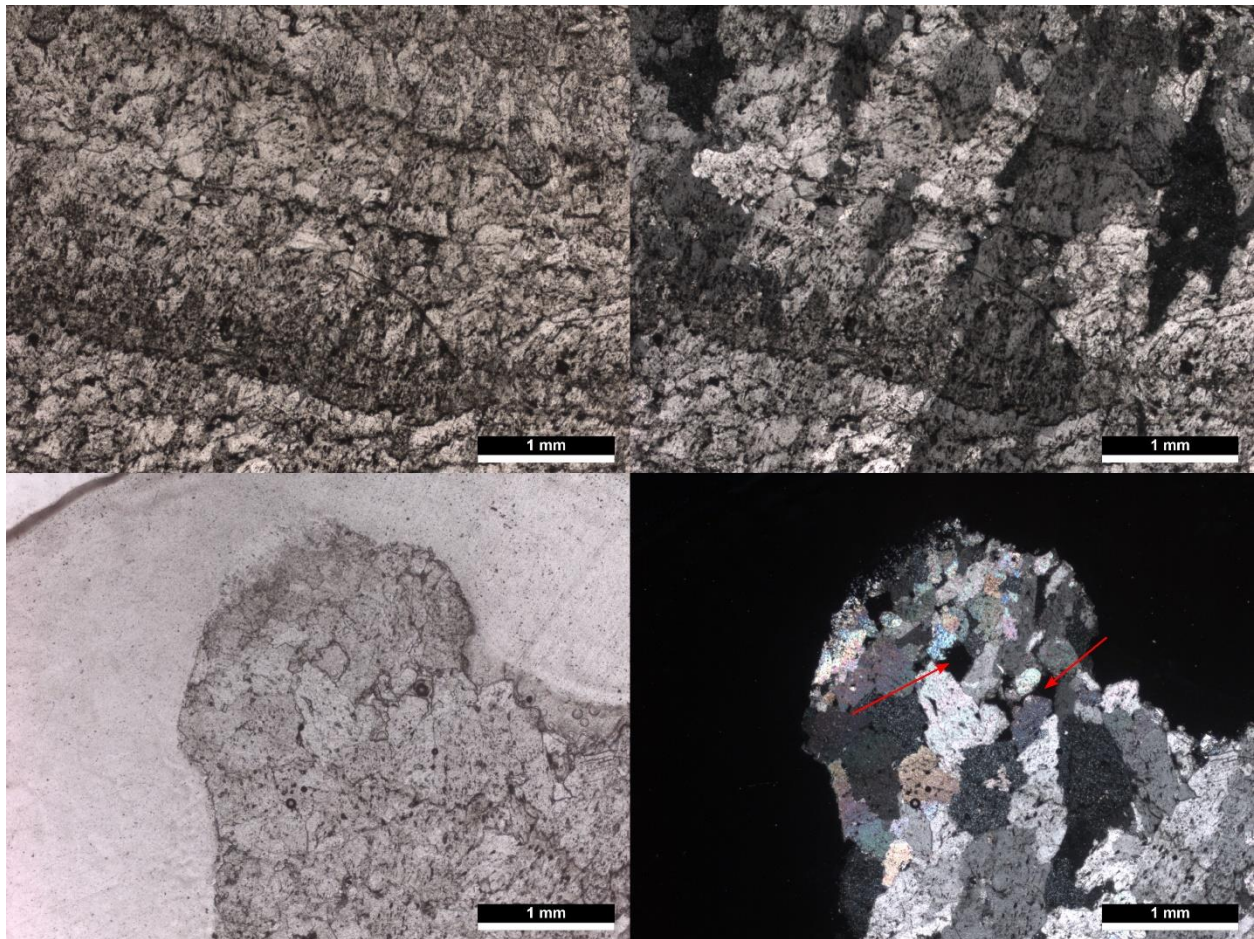

263

Figure 4. Representative FTIR spectra from sample D.

264

Sample number	v2	v4
STM18-04A	424	110
STM18-04B	469	120
STM18-04B+C	435	106
STM18-04C	438	98
STM18-04D	452	108
STM18-04E	456	117

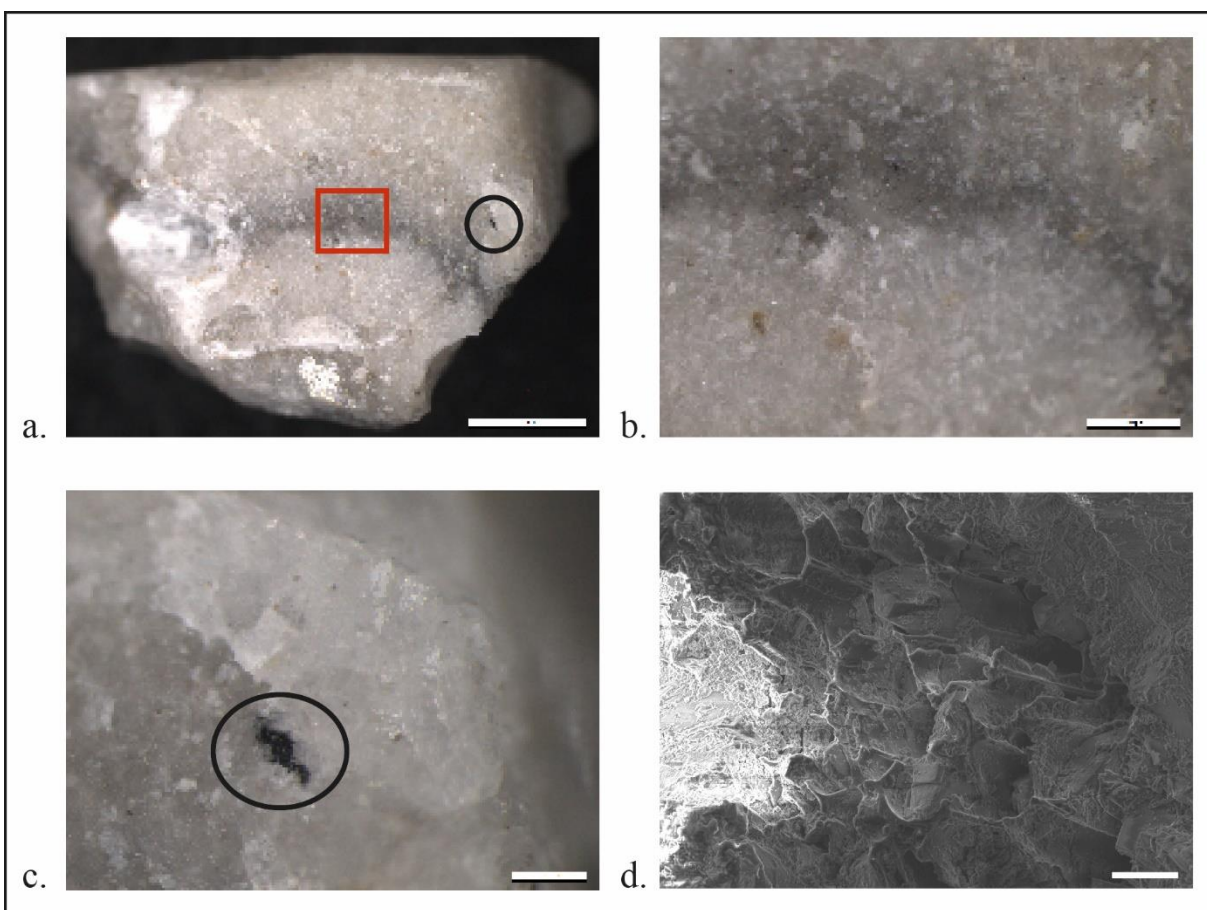

265 Tab. 1. Intensity of the v2 and v4 infrared absorptions of calcite normalised to the intensity of the
 266 v3 absorption.

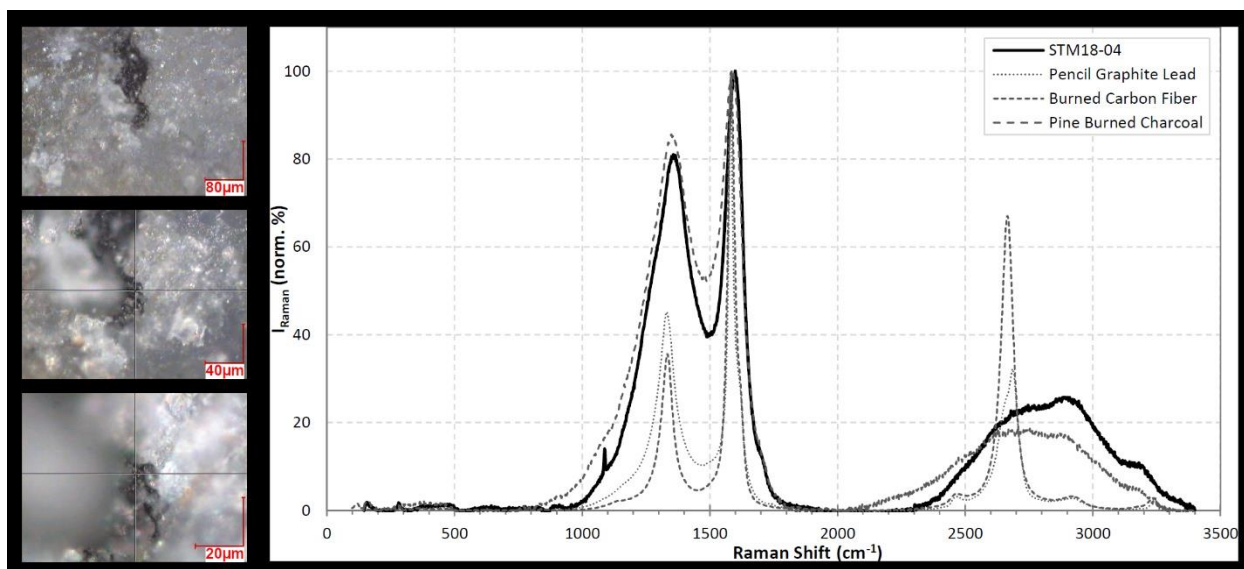

267
 268 Figure 5. Photomicrographs of one of the speleothem fragments (thin section in Figure 3). Top
 269 row shows calcite layers in plane polarized light (left) and cross polarized light (right). The black
 270 spots are inclusions. Bottom row shows the outer portion of the fragment in plane polarized light
 271 (left) and cross polarized light (right). Red arrows indicate porosity.

272
 273 Dark particles identified by stereomicroscopy (Figure 6) were analysed using SEM and
 274 μ Raman to determine their structure and composition. Fragment D exhibits a large black particle
 275 embedded within the dark layer, which is characterised by a regular structure typical of wood
 276 anatomy, as observed in SEM (Figure 6.d). μ Raman revealed that this dark particle, like many
 277 others measuring a few microns across, shows two groups of peaks: the first ranges from 1000 to

278 1800 cm^{-1} , the second between 2200 and 3400 cm^{-1} with an intensity ratio of 1/4 to 1/5 compared
279 to the previous group of peaks (Figure 7, Table 2). The trapped black compound has the same
280 Raman spectral components as burned pine charcoal rather than other carbon compounds
281 (Figure 7). The positions and height ratios of the maxima around 1350 cm^{-1} called D band and
282 around 1600 cm^{-1} called G band can be used as thermometric indicators (Theurer et al., 2021;
283 Deldicque et al. 2023). The spectral curve-fitting of the STM18-04 main black inclusion is
284 reported in SOM Table S1 for further developments.

285
286 Figure 6. Stereomicroscopy (a, b, c) and SEM (d) images of fragment D. Scales are 2 mm (a),
287 800 μm (b), 200 μm (c) and 10 μm (d). The SEM image shows the black particle highlighted
288 with circles in a and c. The red rectangle shows the location of image 2.

297

298 3.2. Chronology

299 As there was not enough material, we did not attempt to date the black soot layers directly from
300 the stalagmite, instead concentrating on dating the calcite above and below these layers.

301 Six U-series ages (2σ) were obtained on STM-18-04: they range from $15,139 \pm 108$ (18-04-03)
302 to $13,170 \pm 158$ years (18-04-61) (uncorrected ages) (Table 3). Similar values of ^{238}U content
303 were obtained for the samples ($\sim 224\text{-}293$ ppb), except for one sample (18-04-104) for which it
304 was significantly lower (~ 148 ppb). Measured $\delta^{234}\text{U}$ ($\delta^{234}\text{U}_M$) values ranged from 22.7 ± 1.5 ‰
305 (18-04-104) to 57.2 ± 1.6 ‰ (18-04-03).

306 There is a stratigraphic inversion at the top of the speleothem: the younger age was
307 obtained for sample 18-04-61, taken more than 40 mm under 18-04-104 ($14,101 \pm 140$ years)
308 and 18-04-110 ($14,790 \pm 100$ years). This can be explained by low $^{230}\text{Th}/^{232}\text{Th}$ ratios, 15.8 and
309 10.6 respectively, for the two uppermost samples, which attest that exogenous thorium
310 contamination is significant. Indeed, the lower the $^{230}\text{Th}/^{232}\text{Th}$ value, the highest is the
311 contamination with detrital Th, i.e. which is not the product of ^{234}U . Ages were thus corrected,
312 assuming an initial $^{230}\text{Th}/^{232}\text{Th}$ activity ratio of $1.5 \pm 50\%$: corrected ages range from $14,437 \pm$
313 456 years for the base to $12,859 \pm 1056$ years for the top (Table 3). A second correction method,
314 based on stratigraphic constraints, the STRUTages algorithm (Roy-Barman and Pons-Branchu,
315 2016), was used. Corrected values using this model did not significantly differ from those
316 corrected using “*a priori*” values, with values ranging from $14,337 \pm 218$ (base) to $12,390 \pm 544$
317 years (top), but the STRUTages algorithm reduces the error range (Table 3). We used the
318 STRUT ages for interpretation and discussion of the stalagmite.

319 Tab. 3. U-series data (2σ) obtained from PTS-STM 18-04. The second column refers to the sample number (see Fig. 2) and is the
320 depth of the sample taken from the base of the speleothem (in mm). Ages (before 2020) were calculated using the following decay
321 constants: $\lambda_{238} = 1.55125 \cdot 10^{10}$ (Jaffey et al., 1971), $\lambda_{234} = 2.82206 \cdot 10^6$, and $\lambda_{230} = 9.1705 \cdot 10^6$ (Cheng et al., 2013).

322 $\delta^{234}\text{U}_M = ((^{234}\text{U}/^{238}\text{U})_{\text{measured}} / (^{234}\text{U}/^{238}\text{U})_{\text{equilibrium}} - 1) \times 1000$. $\delta^{234}\text{U}_{\text{initial}}$ was calculated based on ^{230}Th age (T): $\delta^{234}\text{U}_{\text{initial}} = \delta^{234}\text{U}_M \times$
323
$$e^{\lambda_{234} \times T}$$

324 [†]Ages were corrected using a $^{230}\text{Th}/^{232}\text{Th}$ initial value of $1.5 \pm 50\%$.

325 [‡]STRUT ages were corrected using stratigraphical constraints, assuming 30% of variability, resulting in a $(^{230}\text{Th}/^{232}\text{Th})_0$ of $1.318 \pm$
326 0.213 (Roy-Barman and Pons-Branchu, 2016).

331 Tab. 5. ¹⁴C results on charcoal samples from archaeological excavations at the entrance of the cave. Ages were calibrated using Oxcal

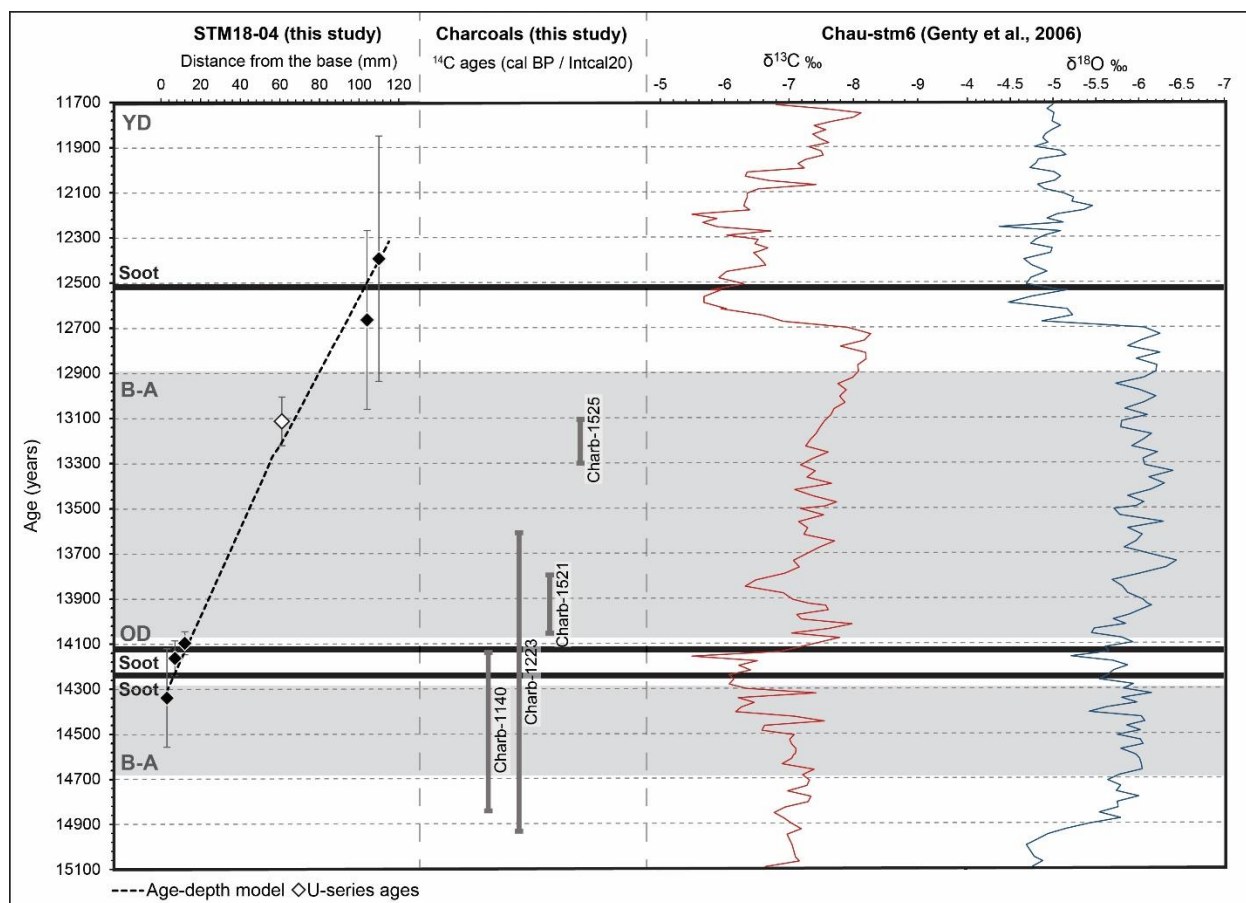

332 4.4 (Bronk-Ramsey, 2001) and the IntCal20 curve (Reimer et al., 2020).

333 These ages fall within MIS2 (29-14 ka, Lisiecki and Raymo, 2005) and are coeval with
334 the Bølling-Allerød, 14.6-12.9 ka, and the Younger Dryas, 12.9-11.7 ka (Rasmussen et al., 2014)
335 (Figure 8). More specifically, samples were taken immediately above and below the dark layers
336 (respectively 18-04-03 and 07; 18-04-07 and 12; 18-04-104 and 110) to bracket the age of the
337 fire events, and thus human presence in the cave. Modelled STRUT ages and their sampling
338 depth within the stalagmite were combined to obtain an age-depth model using MOD-AGE
339 (Hercman and Pawlak, 2012). Using the normal distribution of the U-series ages and depth
340 measurements, modelled ages and depth within the stalagmite were obtained from Monte Carlo
341 simulation (Figure 8). According to our data, the age of the oldest fire event, located at the
342 bottom of the stalagmite, is between $14,337 \pm 218$ and $14,161 \pm 77$ years, and the second event
343 between $14,161 \pm 77$ and $14,094 \pm 51$ years. The third and the fourth events, at the top of the
344 speleothem, are dated to between $12,661 \pm 396$ and $12,390 \pm 544$ years.

345 The ^{14}C ages on calcite allowed us to estimate the dead carbon proportion (DCP,
346 Table 4). They confirm the stability of the dead carbon input over time and the good stratigraphic
347 coherence of the sequence. The DCP was calculated using U-Th ages as “true age”, ^{14}C
348 measurements, and atmospheric ^{14}C values from the IntCal20 calibration curve (Reimer et al.
349 2020) following Genty et al. (2001). DCP display low variation (from 11.9 +1.6 -0.9 % to 14.2
350 +2.2 -1.3 %). These values fall within the typical range of DCP values published for caves with
351 thin soil (Genty et al., 2001; Griffiths et al., 2012; Noronha et al., 2014).

352 Four of the charcoals from nearby archaeological excavations yielded results between ca. 13,105
353 and 14,930 cal BP (Table 5). At 2σ , these results overlap with the period of growth of STM-18-
354 04. In particular two of them (Charb-1140 and Charb-1223) could be related to the same fire
355 event or, at least, one of the two earliest soot horizons at the base of STM-18-04 (Figure 8). This

356 would be consistent, at least for Charb-1223, whose stratigraphic position is similar to that of the
 357 two dark horizons at the base of STM-18-04.

358
 359 Figure 8. U-series (based on STRUT method) and ¹⁴C age results and depth age model (MOD-
 360 AGE, dashed line) presented as a function of the δ¹³C and δ¹⁸O variations recorded in the Chau-
 361 stm6 stalagmite from the Chauvet Cave (data from Genty et al., 2006). The three plain black
 362 lines represent the approximate location of the soot layers identified in STM-18-04 and the black
 363 diamonds represent the U-series ages that bracket the soot layers. YD = Younger Dryas; B-A:
 364 Bølling-Allerød; OD = Older Dryas (ca. 14,150 years, see Figure 11 in Genty et al., 2006).

365
 366

367 **4. Discussion**

368 By combining characterisation tools with dating techniques, we were able to characterise and to
369 reconstruct the timing of human presence during the Tardiglacial era and the Termination I.

370 The hypothesis of an anthropogenic origin for the fire events recorded within STM-18-04
371 is corroborated by the radiocarbon results obtained on the charcoals collected nearby in
372 association with lithic remains in archaeological layers at the cave entrance. The calibrated ages
373 of at least three of these charcoals overlap the timespan of the first two fire events as bracketed
374 by the calcite dating. Assuming that the fire events were related to anthropic activities, human
375 presence at the cave entrance is thus attested during at least two phases, the first one between
376 ca. $14,337 \pm 218$ and $14,094 \pm 51$ years, and the second one between $12,661 \pm 396$ and $12,390 \pm$
377 544 years.

378 The first phase identified falls within the Bølling-Allerød (ca. 14.6-12.9 ka, Rasmussen et al.,
379 2014), and the second one within the Younger Dryas (ca. 12.9-11.7 ka, Rasmussen et al., 2014).

380 These periods of human activity at Points Cave are contemporary with the radiometric
381 results obtained at several archaeological sequences in the Ardèche Gorge. While data are well
382 documented at the regional scale for the Bølling-Allerød, contexts attributed to the Late
383 Tardiglacial are often poorly preserved and/or dated. For example, the site of the Colombier II
384 rock shelter shows evidence of human occupations dated between the Older Dryas and Allerød
385 linked with fireplaces and remains of lithic or bone industry, attributed to the Upper
386 Magdalenian and the Azilian (Onoratini, 1992; Joris, 2002; Bazile, 2014; Beauvais, 2022). The
387 continuous sequence of this site shows similarities with other contemporary contexts such as
388 Saut-du-Loup (Gilles, 1976), which demonstrate recurrent occupations during the Bølling-
389 Allerød. In the Ardèche Gorge, several other sites lacking radiometric results also yielded lithic

390 remains attributed to the same technocomplexes, in particular the Baume d'Oulen (Beauvais et
391 al., 2020) as well as Baou-de-la-Sello and Huchard caves (Combiér, 1967).

392 The results obtained at Points Cave thus fit well into the regional context of use of the central
393 part of the Ardèche River Gorge by human communities at the end of the Upper Palaeolithic
394 and/or beginnings of the Epipalaeolithic, possibly in connection with specialised hunting
395 activities (Lateur et al., 2019).

396 Our age results can be compared with those obtained on other speleothems for which
397 palaeoclimatic data are available. For instance, palaeoclimatic analyses of some of the Chauvet
398 Cave stalagmites (Genty et al., 2004), located upstream in the Ardèche gorges, enable
399 reconstructing the climatic conditions at the time of the human occupation of Points Cave, since
400 they precipitated during the same period. In particular, it is possible to match the ages obtained
401 from STM-18-04 with Chau-stm6, dated between ca. 11,498-32,872 years (Genty et al., 2006)
402 (Figure 8). $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ analyses of this stalagmite give some insights into the regional
403 paleoclimatic record during the last deglaciation. In speleothems, an increase in both $\delta^{13}\text{C}$ and
404 $\delta^{18}\text{O}$ values is interpreted as a cold event: the reduction of vegetation and soil activity due to a
405 decrease in temperature leads to an increase in $\delta^{13}\text{C}$ during cold periods; in turn, an increase in
406 $\delta^{18}\text{O}$ values reflects a decrease in temperature. The palaeoclimatic record of Chau-stm6 shows
407 three peaks in less negative values of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$: at ca. 14,150 years, 12,590 years, and
408 12,200 years (Figure 8), indicating climate degradation for these intervals. A paleoclimatic
409 record at Salamandre cave (Cèze Valley, a few kilometers away from Points Cave) confirms that
410 the Younger Dryas in the region is marked by the degradation of soil activity (Drugat et al.,
411 2019). Interestingly, our U-series ages, which bracket the fire events between $14,337 \pm 218$ and
412 $14,094 \pm 51$ years and $12,661 \pm 396$ and $12,390 \pm 544$ years, match with two of these three

413 events of cold climate, ca. 14,150 years and 12,590 years. Moreover, the cold event observed at a
414 maximum amplitude ca. 14,150 years, recorded within the Bølling-Allerød, is synchronous with
415 the Older Dryas, ca. 14.1 ka (Hughen, et al., 2000) (see discussion in Genty et al., 2006; Genty,
416 2012). We can thus conclude that the humans who produced the fires at Points Cave likely
417 visited the cave during cold events (but sufficiently humid to allow speleothem growth), possibly
418 the Older Dryas, and during the Younger Dryas.

419

420 **5. Conclusions**

421 The study of the stalagmite STM-18-04 showed that proxies such as speleothems are a
422 significant source of information when reconstructing human occupation phases at a cave site.
423 The combination of microscopy and spectroscopy analyses (optical microscopy, SEM, μ Raman,
424 and FTIR spectroscopy) proved to be a valuable toolset to reveal the presence of soot, which can
425 be attributed to fire events within the cave during human occupation. At Points Cave, the analyse
426 of STM-18-04 thus gave new insights into the human activities that took place at the entrance of
427 the cave during the Upper Palaeolithic. Thanks to the characterisation of the soot layers and the
428 dating of its calcite matrix, we showed that the cave was visited several times during the Upper
429 Magdalenian and/or beginning of the Epipalaeolithic, respectively between around 14,200-
430 14,100 and 12,500 years, in agreement with ^{14}C dating of charcoals recovered during the
431 excavations. The comparison of our data with published regional palaeoclimatic records (Drugat
432 et al., 2019; Genty et al., 2006) made it possible to assign these fire events, and thus human
433 presence, to cold phases, likely the Older and Younger Dryas.

434 Ultimately, all of this contributes to refining the overall timing, palaeoclimatic context,
435 and recurrence times of human activities at Points Cave, during the Upper Palaeolithic. However,

436 the relationship between the entrance of the cave, where the fire activities took place, and the
437 cave art, located in the depths of the cave, still needs to be investigated.

438

439 **Acknowledgments**

440 This work was supported by the DRAC Occitanie (French Ministry of Culture) and by the
441 French National Research Agency (ANR-18-CE27-0004 ApART). We would like to thank
442 Robin Furestier, Charlène Girard, and Léo Lacheray (FARPA) for managing the funding, and the
443 municipality of Saint-Martin-d'Ardèche (site owner) for allowing us to carry out research in the
444 cave. Our thanks also go to Patricia Guillermin, Philippe Barth, Françoise Prud'Homme, and
445 Sonia Stocchetti (Aven d'Orgnac – Cité de la Préhistoire) for providing accommodation and
446 technical support. A special thank you to Isabelle Couchoud for providing material resources
447 during sampling at EDYTEM laboratory. Michael Toffolo was supported by a grant from IdEx
448 Bordeaux (ANR-10-IDEX-03-02). We thank Yannick Lefrais for assistance during SEM
449 analysis at Archéosciences Bordeaux, Carlos Sáiz (CENIEH) for preparing the thin section of the
450 speleothem, the PANOPLY platform (Plateforme Analytique Géosciences Paris Saclay) for the
451 use of the MC-ICPMS and the Centre de Datation par le Radiocarbone (CDRC) in Lyon
452 (France).
