Heatwaves, CMIP6, Model selection, Paris

Abstract

Reaching a surface temperature of 50°C in a heavily populated region, like Paris, would have devastating effects. Although such a high value seems far from the present-day record of 42.6°C, its occurrence cannot be dismissed by the end of the 21st century, due to the continuous increase of global mean temperature. In this paper, we address two questions that were asked by the City of Paris to a group of scientists: When does this event start to be likely? What are the prevailing meteorological conditions? We base our study on the CMIP6 simulation ensemble. Many of the CMIP6 yield biases in temperature. Rather than using methods of bias correction, which are not necessarily adapted to high extremes, we propose a pragmatic approach of model selection in order to seek such high temperature events that are deemed realistic. We analyze the meteorological conditions leading to first occurrences of such hot events and their common atmospheric patterns. This paper describes a simple data mining approach (on a large ensemble of climate model simulations) which could be adapted to other regions of the world, in order to help decision makers anticipating and adapting to such devastating meteorological events.

1 Introduction

Heatwaves have huge impacts on society and ecosystems (Domeisen et al., 2023; Bastos et al., 2020; Yin et al., 2023), and frequently generate thousands of extra deaths per summer in Europe. Western European governments took measures to lower vulnerability, after the European heatwaves in 2003. The Pacific North West American heat wave in June 2021 was a

1 shock with temperatures that came close to 50°C during a couple of days, and were way above
2 previous historical records (Philip et al., 2022). The authorities of a few major cities (in
3 particular in Europe) are in the process of designing adaptation plans to such events, yet
4 unprecedented in Europe, where records since 1950 reach 40-45°C, except for a few
5 Mediterranean cities (Athens, Syracuse, Cordoba), with record nearing or exceeding 48°C. The
6 city of Paris, with a record (2019) of 42.6°C, s preparing an adaptation plan to extreme summer
7 temperatures, and a crisis plan for temperatures in the range of 50°C (Florentin and Lelievre,
8 2023). Scientific questions that have been asked to the (French) scientific community are:

- 9 1. Can temperatures exceed 50°C in Paris and for how long?
- 10 2. What is a likely horizon for the first occurrence of such an event?
- 11 3. How are the 50°C reached?

12 The record shattering event across Western Canada and the US in 2021 (i.e., at a similar
13 latitude as the Paris area) suggests that one could not dismiss that such a hot event could
14 occur in Europe in years/decades to come. Such temperatures were also observed in southern
15 Europe in 2021 and 2023. Therefore, preparing a crisis exercise and adaptation plans for that
16 level of temperatures is important now, as adaptation actions will take time to be effective.

17 When daily temperature records are broken, the increments above the previous record are
18 generally a few tenths of degrees. In the Pacific NorthWest American event in summer in 2021,
19 this was called a “record shattering” event because records were broken by several degrees
20 (Fischer et al., 2021). Such record shattering events can be seen as outliers of observed
21 extreme value distributions (Fischer et al., 2023), and hence can be qualified as surprises.
22 Using data from 1950, Philip et al. (2022) estimated a return period for the event of the order
23 of about 1000 year, accounting for the current global warming level. (Bador et al., 2017) have
24 investigated temperature records in regional climate projections. Based on a single climate
25 model, they found the possibility to exceed locally 50°C in France but not in the Paris region.
26 Here we are interested in hot events that would occur as surprises, similarly to the recent
27 events of 2021 or 2023. Such events are deemed to have a low probability (Philip et al., 2022),
28 which requires large ensemble of data (Bevacqua et al., 2023).

29
30 The objective of this article is to present a method that allows analyzing the possibility of
31 temperatures to reach 50°C in the Paris and provide physically plausible example cases which
32 can serve city managers and planners for adaptation reference using recent climate
33 projections. The recent CMIP6 simulations offer a large multi-model ensemble of data, with
34 several socio-economic scenarios until the end of the 21st century.

35 This paper also aims at succinctly describing the conditions under which temperatures of 50°C
36 can be reached in a highly populated European region like Ile-de-France, surrounding Paris
37 (France). We examine the large-scale atmospheric conditions for such an event, and the global
38 warming level above which such conditions are found with significant probabilities in the
39 simulations, accounting for the interannual and interdecadal variability. We mainly describe a
40 data processing chain, and defer a complete physical analysis to another paper.

41
42 This description can lead to a *climate service*, to analyze a large ensemble of climate
43 simulations, and provide sensible answers to the challenges outlined in this introduction (Is it
44 possible to reach 50°C? When? What climatic and meteorological conditions to expect?). The
45 goal is to be able to replicate our analyses easily and change parameters, so that the
46 computations can be transposed to other regions of the planet. Although those data are
47 publicly available, their volume is huge (peta-bytes of data). Treating an ensemble such as

1 CMIP6 requires scientific computer skills and R&D resources, which are rarely available from
 2 city practitioners whose main interest is not atmospheric sciences. It is hence deemed useful
 3 to propose a simple methodology, easily reproducible by companies providing consulting or
 4 climate services, to treat the three challenges outlined above from available data. Hence, this
 5 processing chain is intended for entities that are capable of processing climate model data,
 6 and communicate results to final stakeholders. To potentially become useful for other cities,
 7 such a methodology should be easy to deploy, reproducible and testable on many regions. We
 8 however restrict here to the Paris city for the presentation.

9
 10 Section 2 presents data and models used in this paper. Section 3 presents results on the
 11 occurrence of events that reach 50°C in the Paris area. Section 4 discusses the caveats of the
 12 analyses. Section 5 the practical applications of this paper, which is concluded in Section 6.

13 2 Data and methods

14 2.1 Data

15 This analysis uses observations (Haylock et al., 2008), reanalyses (Hersbach et al., 2020) and
 16 CMIP6 simulations (Eyring et al., 2016). The CMIP6 simulations include “historical” and four
 17 Shared Socioeconomic Pathway (SSP) scenarios (Riahi et al., 2017): 1-2.6, 2-4.5, 3-7.0 and
 18 5.8.5. Historical simulations run from 1860 to 2014, and are constrained by observed forcings
 19 (natural and anthropogenic). SSP simulations go from 2015 to 2100 (2300 for some models)
 20 and are constrained by economic scenarios of greenhouse gas emissions, pollutants and
 21 changes in land use.

22 Some models provide ensembles of simulations, with slightly perturbed initial conditions. This
 23 helps assessing the role of internal climate variability (Deser et al., 2016).

24 Overall, we considered all simulations that were available to us on August 1st 2023 on the IPSL
 25 computing server, which contains a (large) subset of the simulations on the Earth System Grid
 26 Federation (ESGF) that contains all CMIP6 simulations. We used the models for which
 27 historical runs and the four SSP scenarios are available. This includes 1288 simulations from
 28 26 climate models. Hence this excludes models with fewer scenario simulations. The ensemble
 29 sizes for each model (with historical and four SSP scenario simulations) are indicated in Table
 30 1 below. The ensemble sizes vary from 1 run to more than 50 in SSP simulations, depending
 31 on the model. The size of the ensembles also depends on the SSP scenarios.

1
2 *Table 1: List of CMIP6 models and ensemble sizes for each scenario that are treated in this paper. We only indicate the models*
3 *for which historical and four SSP scenario runs are available. We excluded the models based on MOHC, as they yield*
4 *documented anomalous behavior for TX. The models in boldface characters are those which pass the Kolmogorov-Smirnov*
5 *test of a comparison with ERA5 and E-OBS data.*

6
7 We considered TX (daily maximum temperature), TG (daily mean temperature) and TN (daily
8 minimum temperature) over France, and SLP (sea-level temperature) over the North Atlantic
9 region, in order to investigate the synoptic conditions during heat events in Paris.

10 In the selection of models, we removed simulations of the HadGEM3-GC31-HH, HadGEM3-
11 GC31-HM, HadGEM3-GC31-LL, HadGEM3-GC31-LM, HadGEM3-GC31-MH, HadGEM3-GC31-
12 MM, and UKESM1-0-LL models. For those models, the errata documentation for CMIP6 states
13 that: “An issue has been discovered where isolated and irregular events are leading to spikes
14 (a single time step) in the value of surface air temperature lead to the value of daily tasmax
15 ¹datasets in all MOHC simulations that include the atmosphere. Initial investigations on a
16 single simulation suggest that events over 340K occur once in every 250 days, with events
17 above 350K occurring once in every 1,200 days. We believe the spikes in tasmax are triggered
18 by the model’s surface energy balance, at isolated grid cells, being dominated by sensible
19 heating. For very short periods the accumulated heat appears not to be efficiently mixed away
20 from the surface by the model’s sub-grid scale mixing scheme resulting in the spurious values
21 [...]”. (<https://errata.ipsl.fr/static/view.html?uid=76b3f818-d65f-c76b-bfd8-cae5bc27825c>).

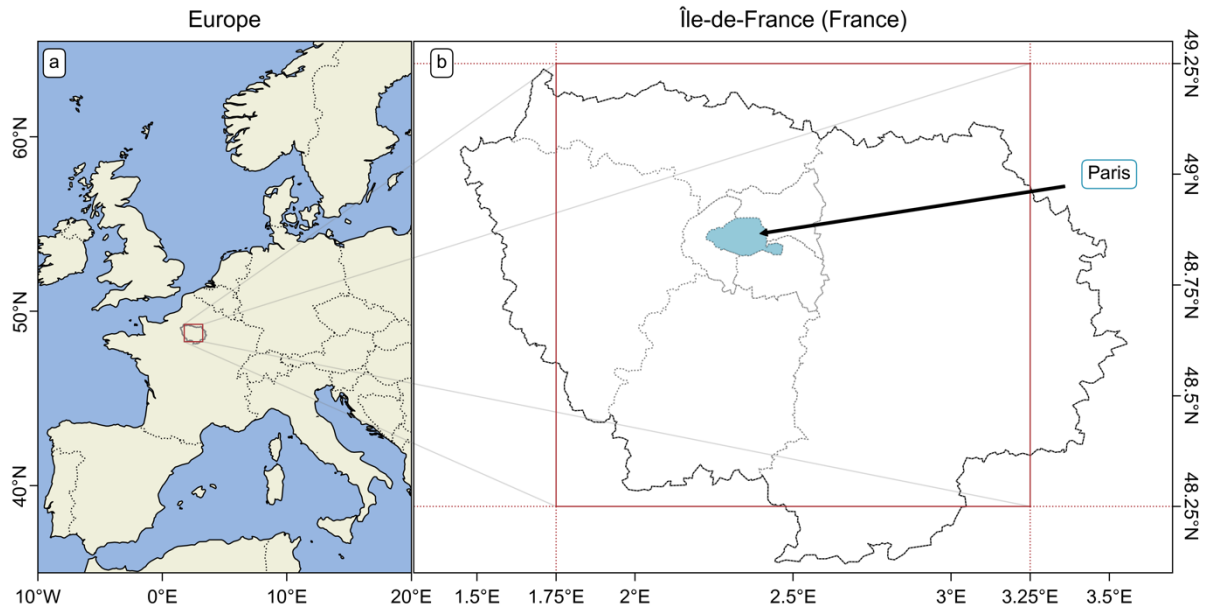

22
23 We extracted TX, TN and TG over the Paris region (Ile de France) outlined in Figure 1. A bilinear
24 interpolation was performed on the model grid cells over the [1.75-3.25°E; 48.25-49.25°N]
25 region, which includes the administrative area of the City of Paris. This interpolation procedure
26 is necessary because Ile de France can be across several model gridcells, whose size can be
27 much larger (~2°) than the area of the region itself. When the spatial average across the region
28 is computed, this interpolation allows weighting the model grid cell that cover the Ile de
29 France region. We note that this computation takes ~28h (for each variable) on the IPSL
30 computing cluster, using 8 parallel CPUs.

31
32 We computed the yearly global mean surface temperature (GMST) for each CMIP6 model. The
33 GMST value between 1950 and 2000 is around ~14.1 +/- 0.5°C (1 sigma) for the CMIP6
34 historical simulations. The mean GMST in ERA5 for these decades is ~13.5°C. We determine
35 global warming increase (GWI) as the difference of a 20-year average GMST with the average
36 value at the turn of the 21st century (1950-2000) or at the turn of the 20th century (1850-1900).
37 A generic code for extracting time series over a given region from the whole CMIP6 archive is
38 provided on github [<https://github.com/pascalgiou/Paris50C.git>].

39

¹ Tasmax is equivalent to TX. The citation is reproduced verbatim.

1 We also used TG from the ERA5 reanalysis (Hersbach et al., 2020) and EOBS (Haylock et al.,
2 2008) data as references to select CMIP6 data (the selection procedure is detailed below). We
3 downloaded the data for the Paris area from the Climate Explorer
4 (<https://www.climexp.knmi.nl>).

6
7 *Figure 1: Ile de France Area in Western Europe (panel a). The red rectangle in panel b refers to the region that is considered in*
8 *the model and reanalysis data. Paris "intra-muros" is indicated in blue.*

9 10 2.2 Pre-processing

11 All CMIP6 models are prone to biases, in particular due to their horizontal resolution (Carvalho
12 et al., 2021). One way to solve this issue is to use bias correction methods (Maraun and
13 Widmann, 2018). Such an approach requires a "sound" reference, like a very high-resolution
14 reanalysis (e.g., SAFRAN (Quintana-Segui et al., 2008)), which is not necessarily available
15 everywhere in the world. In addition, such bias correction methods are rather computer
16 costly, and have only been performed on a small subset of CMIP6 (e.g., only one member per
17 model/group, for arbitrarily selected models). Finally, the bias correction of each individual
18 simulation crunches model statistics towards the statistics of one realization of the true
19 climate variability over a limited time period (the correction training period), the observed
20 one, and may thus artificially reduce the simulated natural variability. This effect can be
21 particularly exacerbated for extremes, because the interdecadal variability at regional scale
22 can be large.

23
24 We chose here an alternative approach consisting of selecting models yielding the smallest
25 biases over Ile de France of the "historical" simulation for TG, taking advantage of the large
26 number of simulations available in CMIP6. We made a comparison of TG in historical CMIP6
27 model simulations with ERA5 and EOBS between 1995 and 2014. We performed a
28 Kolmogorov-Smirnov (k-s) test (von Storch and Zwiers, 2001) between each historical
29 simulation, and ERA5 (and EOBS), to compare the probability distributions of daily summer
30 TG in CMIP6 models and reanalyses or EOBS. The threshold we consider for the k-s test value
31 is 0.1. We opted for an "inclusive" approach for model selection: the whole ensemble of one

1 model is kept when at least one member yields a TG probability distribution between 1995
2 and 2014 that is similar to ERA5 or EOBS.

3 There are two reasons for this strategy:

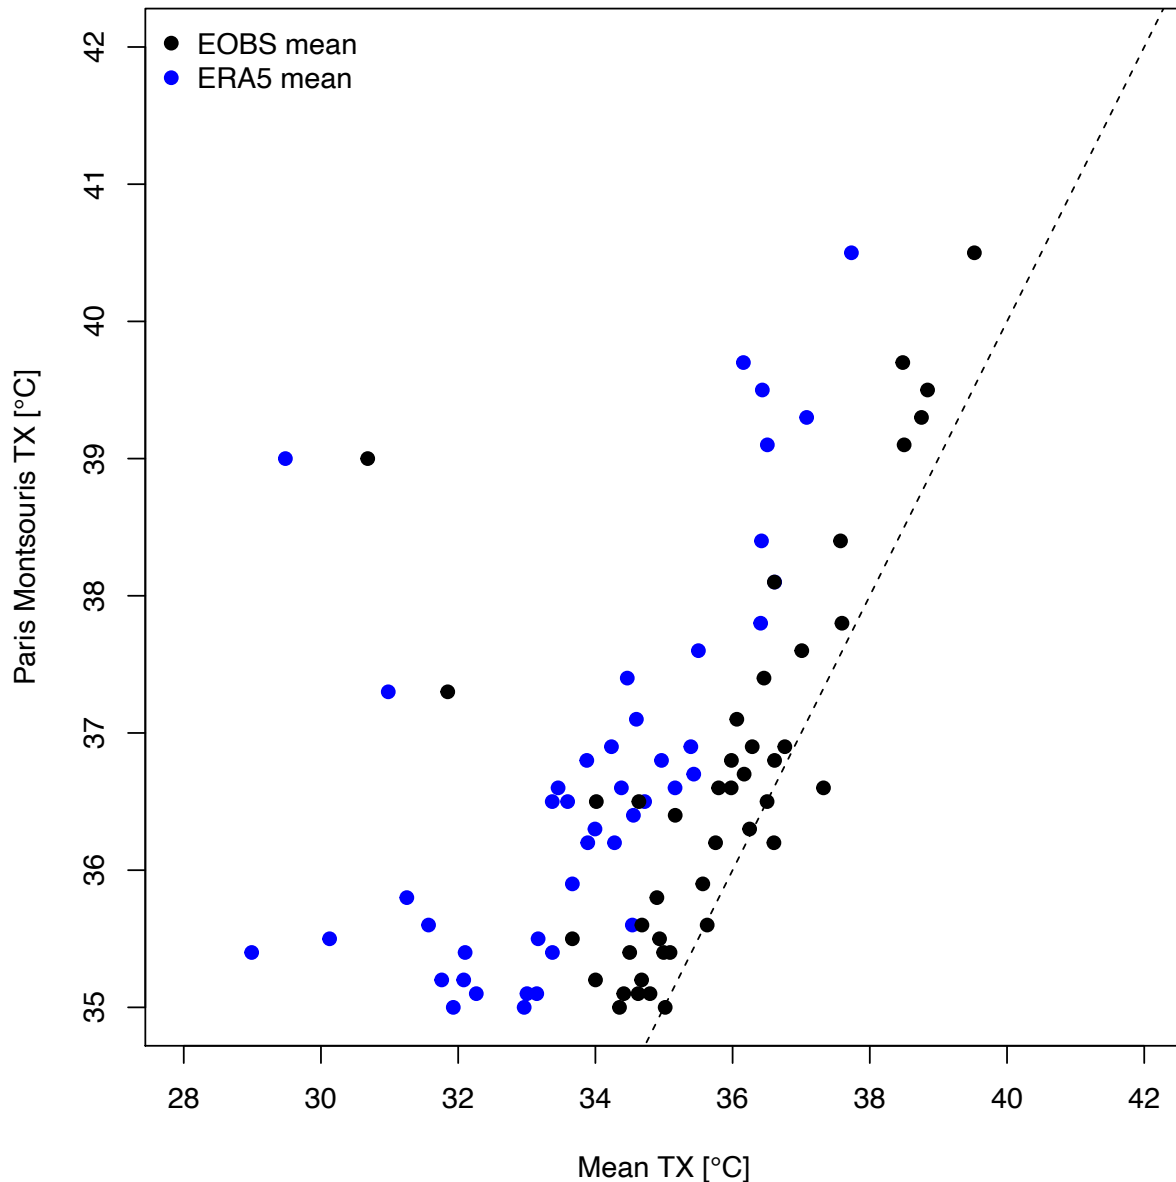

- 4 1. As stated earlier, there is a small offset between TG in ERA5 and EOBS for the Paris
5 area, which means that ERA5 would not pass the Kolmogorov-Smirnov test if EOBS was
6 chosen as a reference (and vice versa). There is no reason to favor EOBS over ERA5,
7 which does not include information in Paris *intra muros* (e.g., the Paris Montsouris
8 station), and it is reasonable to compare CMIP6 with a climate model simulation that
9 best resembles observations.
- 10 2. If a CMIP6 model yields an ensemble to sample internal variability, some of its
11 members could be different from an observation reference during a 20-year period,
12 because model years are not “real world” years. But we do not want to reject them,
13 because if one member is satisfactory, it suggests that the model is able to reproduce
14 observations over a 20-year period of time, so that scenario simulations could bring
15 relevant information. Some models come with only one run, so that this test might
16 exclude them if this only run does not pass a statistical test with observations. This
17 encourages large ensemble approaches, as discussed by (Bevacqua et al., 2023).

18 This selection procedure obviously contains arbitrary elements (k-s test threshold, length of
19 time series for comparisons, period of comparison, reference data, choice of variable for
20 comparison).

21
22 As it is, this procedure selects 819 of the available 1288 simulations (with 585 SSP simulations),
23 and 12 of the 26 CMIP6 models (outlined in boldface in Table 1).

24 25 2.3 Selection of events

26 An event exceeding 50°C is potentially very local and short lived, with an amplification by
27 urbanization and surface water availability. We consider a small region that averages urban
28 areas (Paris *intra-muros*) and suburban areas with forests. Due to the urban heat island effect,
29 we estimate that 50°C can be exceeded within Paris, when TX exceeds 48°C over the Ile-de-
30 France area. This assumption is justified by computing the differences of TX between
31 observation at Paris Montsouris station, and the average over the Ile de France region (Figure
32 2). There is a systematic offset between TX in Paris-Montsouris and the average over the Paris
33 area when TX exceeds 35°C. Therefore, we consider that TX exceeds 50°C in Paris when TX
34 exceeds 48°C over Ile de France. This empirical threshold could be modified. We also verified
35 that for extreme heat days, this temperature variation is typical of intra-region variations, over
36 the last 10 years for which we could have access to more stations (from
37 <https://www.infoclimat.fr>).

1
 2 *Figure 2: Scatter plot of TX in Paris Montsouris versus the average of TX over the region outlined in Figure 1, when TX exceeds*
 3 *35°C in Paris Montsouris. The averages are computed from the EOBS (black circles) data and the ERA5 reanalysis (blue circles)*
 4 *data. The dashed line is the diagonal line.*

5
 6 From a list of 12 models and 585 simulations, we identified the years with at least one
 7 exceedance of 48°C before 2100. The results are summarized in Table 2 (not all model
 8 simulations in Table 1 reach 48°C before 2100).
 9

6 3 Results

7 3.1 Event occurrence in CMIP6

8 We find that 8 models, among those selected to be realistic, exceed, at least once, 48°C
9 between 2020 and 2100. Figure 3 and Table 2 report models for which at least one member
10 in one scenario yields a TX>48°C event. Out of those 232 considered CMIP6 simulations, 81
11 simulations yield at least one TX>48°C event.

12
13 *Figure 3: Time of first exceedance of 48°C in CMIP6 models for four SSP scenarios. The vertical axis indicates the year of first*
14 *occurrence of TX>48°C in the Ile-de-France region, including Paris in model simulations. TX can exceed 48°C at later years, but*
15 *this is not reported in the figure. The colors indicate the GMST for the 20 years around the year of TX>48°C (panel (a) for*
16 *legend).*

17

1 We first consider the four SSP separately. For illustration purposes, we select the model
2 simulations with the earlier dates that reach 48°C in the Paris area. We find that TX never
3 exceeds 48°C in the SSP1-2.6 scenario. Therefore, we focus on SSP2-4.5, SSP3-7.0 and SSP5-
4 8.5 (Figure 3). Only CMCC-ESM2 reaches the threshold with SSP2-4.5 (Figure 3a). This model
5 was run with only one member.

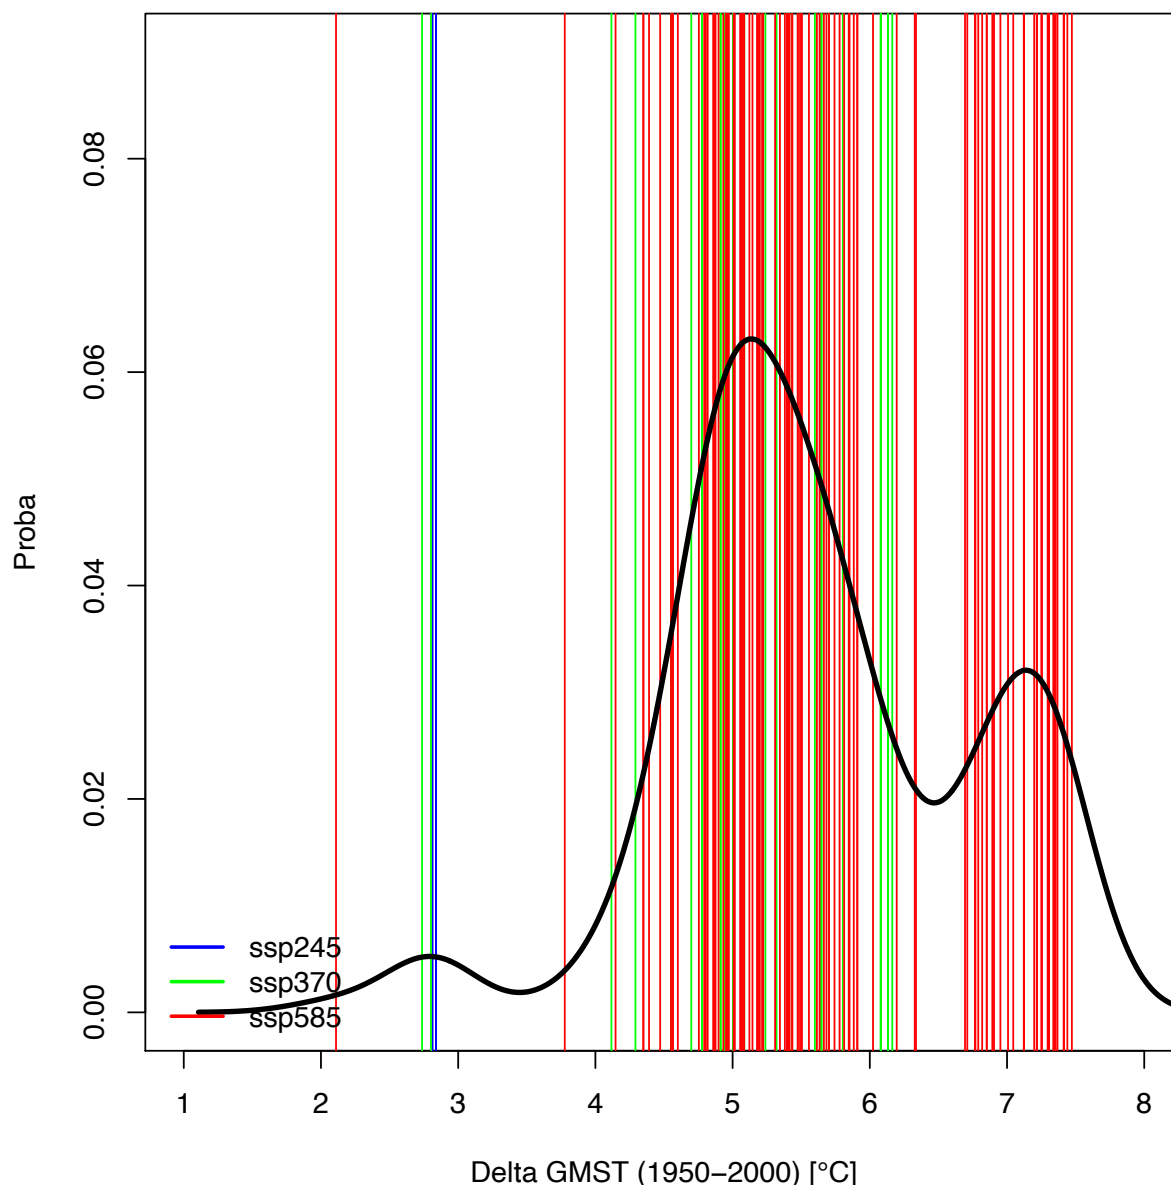

6 We computed the GMST increase (GWI) of the decades around each event since a 1950-2000
7 baselines. From Figure 4, it appears that TX>48°C events in CMIP6 simulations occur when the
8 GWI exceeds 2°C.

9 Most of the selected CMIP6 simulations (with 2 exceptions) do not reach this threshold as long
10 as the GMST does not exceed 16°C (Figure 3), which correspond to a GWI of about 2.5°C since
11 1950-2000 (Figure 4). As reaching this temperature is physically possible (Noyelle et al., 2023;
12 Zhang and Boos, 2023), those simulations will be discussed in this paper.

13 There is a shift of CMIP6 model behavior with SSP3-7.0, where 6 models reach the 48°C
14 threshold between 2079 and 2100 (i.e., within the expected lifetime of the junior authors of
15 this paper). The GWI for those models is larger than 2.7°C (with respect to a 1950-2000
16 baseline: Figure 4).

17 With SSP5-8.5, eight models reach the 48°C threshold between 2049 and 2100, with GWI
18 warming larger than 2.1°C (with respect to a 1950-2000 baseline). Two models (CMCC-ESM5
19 and EC-Earth-Veg-LR) reach this threshold before 2055 (i.e., within the expected lifetime of
20 the senior authors of this paper).

21

1
 2 *Figure 4: Distributions of GMST increase (GWI) values when TX>48°C in Paris, from reference baselines of GMST in 1950-2000.*
 3 *The vertical bars indicate all occurrences of TX>48°C. The colors indicate the SSP scenario of the TX>48°C event occurrences.*
 4 *The black line is an empirical probability density function of the year of occurrence of TX>48°C.*

5 We pooled all 81 simulations for which TX exceeds 48°C and estimated an empirical probability
 6 function for GWI values from a 1950-2000 baseline. The empirical probability was weighted
 7 by the total number of considered simulations (232). This gives a crude idea of the probability
 8 to exceed the 48°C threshold for GWI levels of warming. There are more sophisticated ways
 9 of obtaining such probabilities, in particular using Extreme Value Theory (Coles, 2001; Robin
 10 and Ribes, 2020). We defer such analyses to a future paper.

11 We notice that a peak probability is obtained when GWI (from 1950-2000) is around 5°C
 12 (around 6% chance). If GWI is lower than 2°C, this probability is negligible. It becomes
 13 measurable (1% chance) when GWI reaches ~2.7°C.

14 3.2 Daily summer variations for heat events

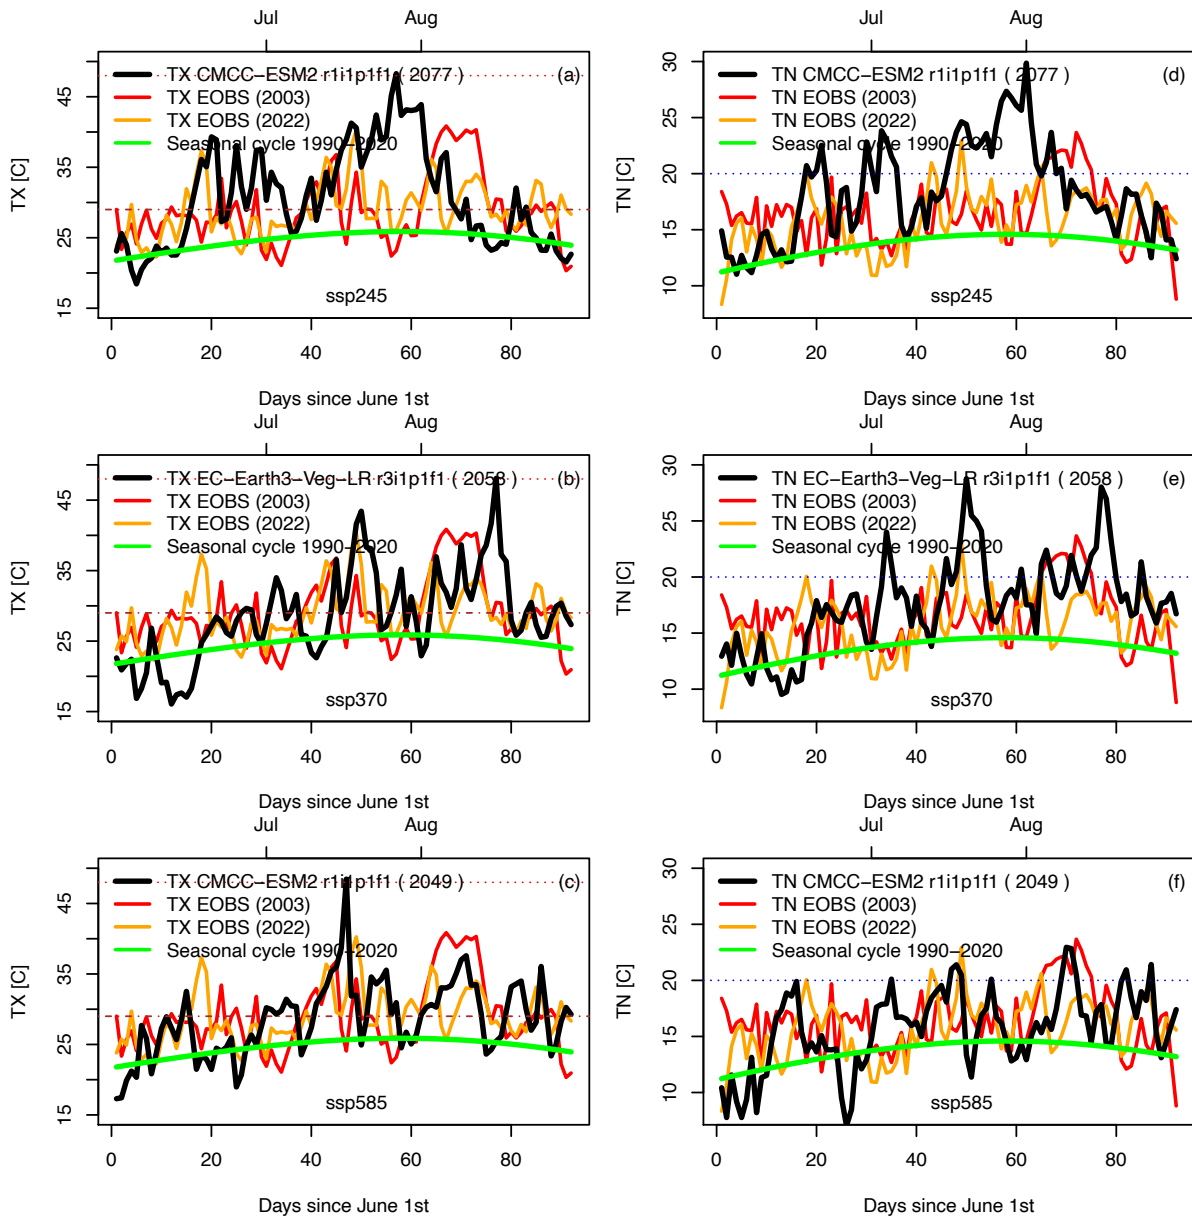

15 We select the first occurrence of TX>48°C for each SSP scenario. We hence retain CMCC-ESM2
 16 for SSP2-4.5, EC-Earth3-Veg-LR for SSP3-7.0 and CMCC-ESM2 for SSP5-8.5 (Table 2). This
 17 choice is obviously arbitrary from the physical point of view. For illustration purposes, we will

1 focus on the earliest occurrences, i.e., the events that the authors of this paper are likely to
2 witness.

3 The summer time series of daily TX and TM (from June 1st to August 31st) are shown in Figure
4 5 for the four selected model, along with the already experienced extremes of 2003 and 2022.
5 Apart from the $T > 48^{\circ}\text{C}$ peaks, the distributions of temperatures are within the variations
6 observed during the hot summers of 2003 and 2022, which shows that the whole summers
7 are already warm. Météo-France defines a heatwave (“canicule”) in Paris when TX exceeds
8 31°C and TN exceeds 21°C [REF]. Such a definition depends on the region, with higher
9 thresholds in the Southern part of France. Due to the urban effects that were identified
10 before, we can lower such a threshold to 29°C for TX, as rough estimates over the Paris region.
11 We retain a 20°C threshold for TN, as it defines tropical nights.

12 We find that reaching a 48°C peak is obtained during warm summers (according to present-
13 day standards: Figure 5), with a large number of days above the mean seasonal cycle. During
14 those summers the values of TX exceed 29°C and TN exceed 20°C on several occasions, which
15 means that several heatwaves (similar to those of 2003 and 2022) also occur during the course
16 of those summers. The peaks of $\text{TX} > 48^{\circ}\text{C}$ correspond to TX anomalies of more than 20°C above
17 the present-day seasonal cycle and last for one day.

18 The selected simulations show periods of tropical nights (i.e., when the minimal daily
19 temperature TN exceeds 20°C). We note that the warmest tropical nights do not necessarily
20 occur on the same day as the warmest TX, although tropical nights do occur when TX is high.
21

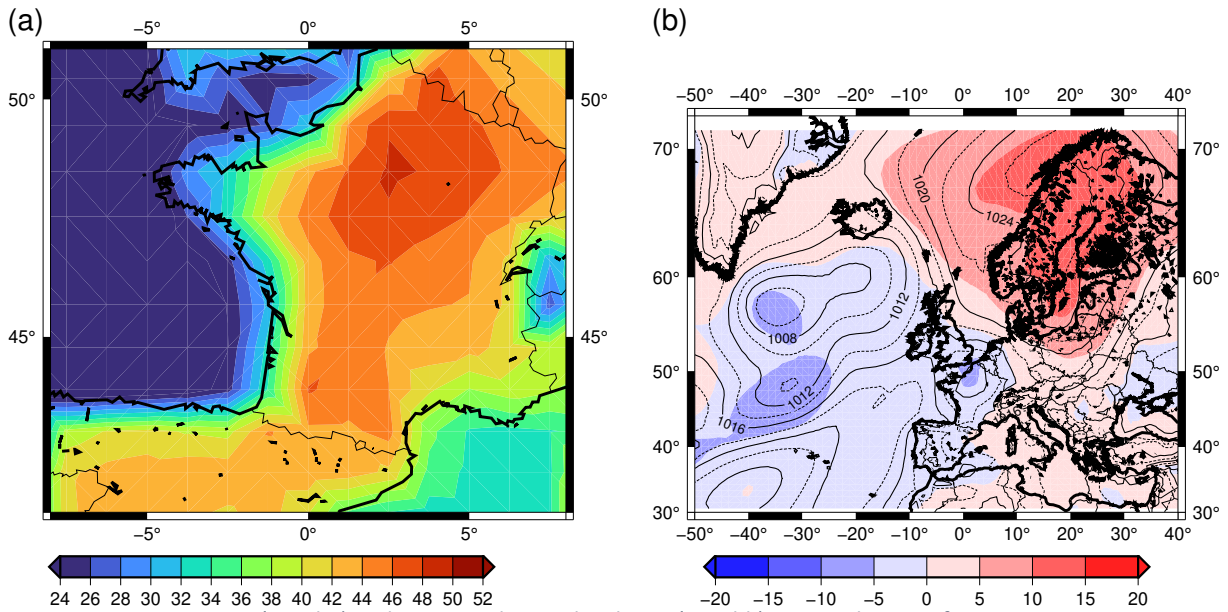

1
2 *Figure 5: Time series of daily maximum (TX: left column) and minimum (TN: right column) temperatures in the Paris area for*
3 *three scenarios. Black lines indicate TX and TN in models. Red and orange lines indicate TX and TN in EOBS for the summers*
4 *of 2003 and 2022 (respectively). The horizontal red dotted line indicates the 48°C threshold for TX. The horizontal dashed*
5 *brown lines indicate the 29°C TX threshold for heatwaves. The horizontal blue dotted line indicates 20°C (TN threshold for*
6 *tropical nights). The green lines indicate the seasonal cycle for TX and TN, computed from the EOBS data (1990-2020).*

7 3.3 TX and SLP patterns

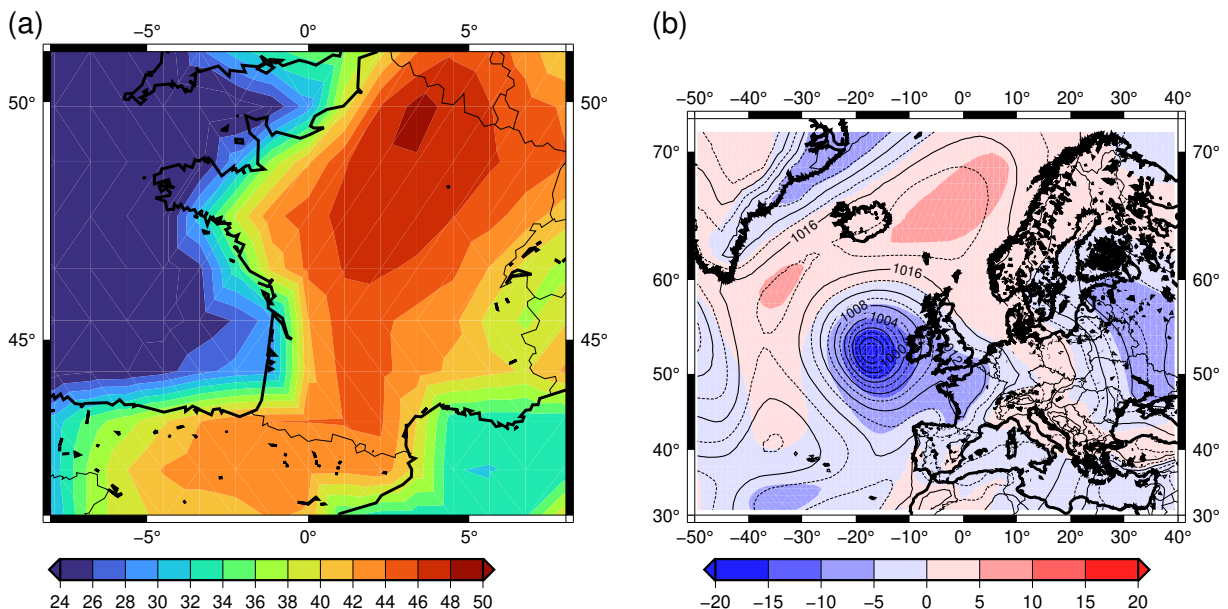

8 The temperature patterns over France and the atmospheric circulation patterns over the
9 Eastern North Atlantic during the four events are shown in Figure 6 to Figure 8.

10
11 For SSP2-4.5, we selected the CMCC-ESM5 model. The TX>48°C event occurs in July 2077, with
12 a GWI of ~2.3°C. The maximum TX anomaly is near the Paris region and TX exceeds 40°C over
13 most of France (Figure 6a). Therefore, the heat event over Paris is also obtained for many
14 gridcells of the model around the Paris region. The atmospheric circulation pattern shows an
15 anticyclone over Scandinavia, and lows over France and west of France (Figure 6b). This
16 atmospheric pattern also corresponds to observed heatwaves of 2003 and 2022 in France
17 [REF].
18

1
2 Figure 6: TX over France (panel a) and SLP over the North Atlantic (panel b) on 27 July 2077, for CMCC-ESM2, in SSP2-4.5
3 (r1i1p1f1). TX (panel a) is expressed in °C. SLP is expressed in hPa (isolines in panel b). Colors in panel (b) correspond to
4 anomalies of SLP (in hPa) with respect to the summer average.

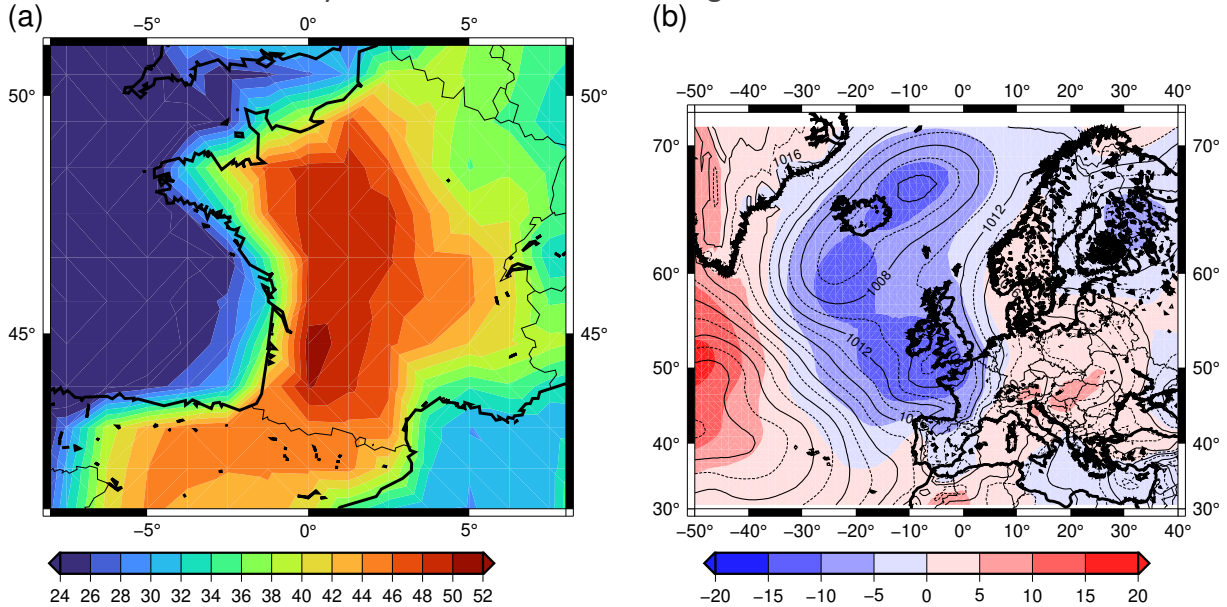

5 For SSP3-7.0, we selected the EC-Earth3-Veg-LR model. TX exceeds 48°C on the 16th of August
6 2077 in the r3i1p1f1 member, i.e. after the apex of the seasonal cycle. The GWI from 1950-
7 2000 is ~2.7°C. The center of the extreme anomaly is located in North East France (Figure 7a).
8 The hot anomaly covers most of France, with TX values above 40°C over most of the country.
9 The atmospheric circulation shows an anticyclonic pattern between Iceland and Scandinavia
10 and in Central Europe. The circulation yields a strong cyclonic pattern west of Ireland (Figure
11 7b). Such a pattern is likely to convey warm air from North Africa into France.
12

13
14 Figure 7: TX over France (panel a) and SLP over the North Atlantic (panel b) on 16 August 2058, for EC-Earth3-Veg-LR, in SSP3-
15 7.0 (r3i1p1f1). TX (panel a) is expressed in °C. SLP is expressed in hPa (isolines in panel b). Colors in panel (b) correspond to
16 anomalies of SLP (in hPa) with respect to the summer average.

17
18 For SSP5.8-5, the early TX>48°C event occurs in July 2049 in CMCC-ESM2 with a GWI of ~2.1°C
19 (since 1950-2000). The center of the event occurs in the South West of France, with

1 temperatures exceeding 50°C (Figure 8a). Most of the country yield TX over 42°C. Northern
 2 Spain is also affected by high temperatures. The heat does not extend to the east of France.
 3 The atmospheric circulation pattern yields an anticyclonic feature east of France (centered
 4 over the Balkans), and a depression between Iceland and Brittany (Figure 8b). In both cases,
 5 the presence of a depression on the west side of the heatwave likely increases temperature
 6 over France via southerly advection or diabatic heating in the frontal area.

7
 8 Figure 8: TX over France (panel a) and SLP over the North Atlantic (panel b) on 07 July 2049, for CMCC-ESM2, in SSP5-8.5
 9 (r1i1p1f1). TX (panel a) is expressed in °C. SLP is expressed in hPa (isolines in panel b). Colors in panel (b) correspond to
 10 anomalies of SLP (in hPa) with respect to the summer average.

11 Out of those three events (from three SSP scenarios, and three different climate models),
 12 three events occur with a GWI between 2.1°C and 2.8°C. Those three events yield atmospheric
 13 patterns that are reminiscent of already observed heatwaves in Paris, albeit with exacerbated
 14 TX values.

15 4 Discussion

16 This paper presents a simple approach to outline extreme temperature events in a large urban
 17 and sub-urban region surrounding (and including) Paris. The methodology is based on data
 18 inspection and does not contain any sophisticated statistical (Parey, 2008; Yiou and Jézéquel,
 19 2020) or physical (Ragone et al., 2018; Gessner et al., 2021) modelling approaches. Those
 20 results serve as a first step for further in-depth studies of extreme heatwaves.

21 Many choices have been subjective (or based on previous experience): threshold of
 22 temperature daily increments, global covariate, and general frequency of extremes. The
 23 results were obtained on the IPSL computing facility, for which a (large) subset of the
 24 simulations of CMIP6 are available. The same computations are possible with access to Earth
 25 System Grid Federation (ESGF) servers throughout the world, although they would require
 26 downloading a large amount of data.

27 We have not discussed in detail the mechanisms leading to hot extremes in Paris, which is left
 28 for further studies. There are fairly substantial differences in the large-scale circulation
 29 patterns occurring those events.

1 5 Practical implications

2 We have identified events corresponding to moderate GMST increase (between 2.1 and
3 2.8°C). Those events come with spates of tropical nights (minimum temperatures over 20°C),
4 which would exacerbate the impacts on health of exceeding 50°C during the day. Some of the
5 Paris events correspond to larger scale events, where temperature exceeds 50°C (e.g., in the
6 south west of France) and large parts of the country have TX above 40°C. Therefore, a crisis in
7 Paris would also be reflected in other regions of France, where temperatures could even be
8 higher, especially in urban areas (in Amiens: Figure 7a; or in Bordeaux: Figure 8a).
9 We have not quantified the probability of exceeding this high threshold, because it is rarely
10 observed more than once in each simulation. This probability is deemed to be negligible for a
11 global surface temperature increase lower than 2°C within the next two decades. It increases
12 to ~1% chance if the global surface temperature increases by 2.7°C. Yet, it cannot be excluded,
13 because Western Europe warms faster than the rest of the world [REF], and temperature has
14 already reached 48.8°C in Sicily (Southern Italy) in August 2023. If global surface temperature
15 (GMST) increases by more than 4°C since 1950-2000, the probability of such hot events
16 increases dramatically in the CMIP6 database.

17 6 Conclusion

18 This paper aims at exploring how a temperature of 50°C could be reached in the Paris area, by
19 examining the CMIP6 database. The general questions where: when? what level of global
20 warming? What type of meteorology? Exploring the CMIP6 database poses a few statistical,
21 physical and computing challenges that are tackled in the paper.
22 This paper is meant to provide a data-processing chain for the analysis of extremes in this
23 simulation ensemble, with an illustration for the Paris area. This serves as a demonstrator for
24 a climate service for policymakers, which can be transposed to other regions in the world.
25 We do not propose a complete climate analysis of the events (which would be an entire paper
26 by itself) and focused on extremely simple diagnostics. Hence this data-processing chain can
27 serve as a preliminary step to identify relevant (in the sense that was defined in the methods
28 section) simulations, and avoid sophisticated (and computer costly) steps of bias correction.

29 7 Acknowledgements

30 This paper was motivated by the Groupe régional d'expertise sur le changement climatique et
31 la transition écologique (GREC) in Île-de-France. We thank the ESPRI computing mesocenter
32 at IPSL for making the CMIP6 data available.

33 8 Funding sources

34 This paper received the support of the grant ANR-20-CE01-0008-01 (SAMPRACE). This work
35 also received support from the European Union's Horizon 2020 research and innovation
36 programme under grant agreement No. 101003469 (XAIDA). PY also acknowledges the
37 support from ANDRA and EDF (grant COSTO).

38 9 Code and data availability

39 The codes (in R, cdo and shell scripts) to perform all data processing computations is available
40 from <https://github.com/pascalyiou/Paris50C.git>
41 The CMIP6 data files are available from the IPSL ESGF node: [https://esgf-
node.ipsl.upmc.fr/projects/esgf-ipsl/](https://esgf-
42 node.ipsl.upmc.fr/projects/esgf-ipsl/)

1 ERA5 reanalysis and E-OBS data sets were retrieved from the Climate Explorer:
2 <https://climexp.knmi.nl/> . We extracted tasmax and tasmin over the region outlined in Figure
3 1, directly from the Climate Explorer.

4 10 Declaration of generative AI in writing

5 This manuscript was entirely written by its authors, without any use of generative AI.

6 11 Author contribution

7 RV and NdN initiated the study. PY drafted the manuscript and ran the computations. YR
8 provided Figure 1. RN and FdA provided input on the analyses of the manuscript. All authors
9 contributed to the writing of the manuscript.
