42 **Abstract**

43 Maize is currently the most productive cereal crop in the world (www.faostat.org). Maize can
44 form a symbiotic relationship with the Arbuscular Mycorrhizal Fungus MF, *Rhizophagus*
45 *irregularis*. In this relationship, the fungus provides the plant with additional water and
46 mineral nutrients, while the plant supplies carbon compounds to the fungus. Two maize lines
47 were studied, and they exhibited contrasting responses to AMF inoculation based on their
48 physiological and molecular characteristics. Interestingly, the beneficial effects of the AMF
49 were observed mainly under conditions of limited N fertilization. Under such conditions, the
50 AMF helped maintain plant biomass production even when there was a significant reduction
51 in N supply. The availability of nitrogen was found to be a crucial factor influencing all the
52 traits studied. This suggests that the level of N supply plays a pivotal role in determining how
53 the maize plants interact with the AMF. Despite the two maize lines showing different
54 transcriptomic and metabolomic responses to *R. irregularis*, their agro-physiological traits
55 remained similar. This indicates that while there may be genetic differences in how the plants
56 respond at the molecular level, the overall growth and productivity outcomes are comparable.
57 Both the plant and fungal transcriptomes were more significantly influenced by the level of N
58 nutrition rather than the specific maize genotype. This suggests that N availability has a more
59 profound impact on gene expression in both organisms than the genetic makeup of the
60 maize plant. To understand the metabolic implications of this symbiotic relationship, we
61 integrated transcriptomic data into a multi-organ Genome-scale metabolic model (GSM)
62 called iZMA6517 based on a stoichiometric approach. This modelling approach highlighted
63 nucleotide and ureides metabolism as previously unrecognized factors contributing to the
64 symbiotic N nutrition facilitated by *R. irregularis*, thereby enhancing maize growth.

65 **Introduction**

66 Nitrogen (N) is the fourth most abundant component of plant biomass, which explains its
67 pivotal role in agriculture (Hirel *et al.*, 2011; Hirel and Krapp, 2020). Indeed large inputs of N
68 fertilizers are necessary to ensure optimal crop productivity (Hirel *et al.*, 2007, 2011).
69 However, only 30 to 50% of the N available in the soil is taken up by most crops, resulting in
70 important N losses which can cause damage to the environment such as water pollution and
71 increased greenhouse effect (Schlesinger, 2009; Lassaletta *et al.*, 2016). It is urgent to
72 minimize these impacts while simultaneously meeting the increasing demand for food
73 production resulting from population growth. Ensuring crop productivity while minimizing N
74 supply can be monitored by measuring nitrogen use efficiency (NUE). A better understanding
75 of how to enhance NUE is a major challenge in the context of agroecology as it represents
76 the capacity of the plant to produce grains or vegetative biomass per unit of available N (Hirel
77 *et al.*, 2007; Lea and Mifflin, 2018; Wang *et al.*, 2018; Liu *et al.*, 2022). Three physiological
78 processes contribute to NUE: (Masclaux-Daubresse *et al.*, 2010; Lea and Mifflin, 2018) : 1) N
79 uptake efficiency involved in acquisition N from the soil by means of root-specific inorganic or
80 organic N transporters (Fan *et al.*, 2017; Wang *et al.*, 2018); 2) N assimilation efficiency
81 which is the incorporation of inorganic N into organic N-containing molecules necessary for
82 plant growth and development (Hirel *et al.*, 2011; Hirel and Krapp, 2020; Wani *et al.*, 2021);
83 and 3) N remobilization efficiency which represents the capacity of the plant to remobilize N
84 and transfer it to storage organs (Masclaux-Daubresse *et al.*, 2010; Kant, 2018). Direct
85 uptake of minerals including N and P from the soil by plants is ensured by transporters
86 known to drive the so called “direct transport”. Interestingly, to fulfil their N-associated
87 metabolic needs, plants can establish symbiosis with beneficial soil microbes which help to
88 improve their N nutrition by different mechanisms, some of which are well characterized.
89 Exploiting the capacity of a crop to benefit from beneficial microbes in terms of N nutrition in
90 order to maintain yields while reducing chemically synthesized N input is challenging in the

91 context of a more sustainable agriculture (Gianinazzi *et al.*, 2010; Verzeaux *et al.*, 2017; Wipf
92 *et al.*, 2019; Dellagi *et al.*, 2020; Gojon, 2022; Xie *et al.*, 2022).

93 The best characterized symbiosis which improves legume N nutrition occurs when symbiotic
94 bacteria from the Rhizobiaceae family allows fixation of atmospheric N₂ and its reduction to
95 NH₄⁺ readily usable by the host plant (Udvardi and Poole, 2013; Masson-Boivin and Sachs,
96 2018). Nitrogen can also be transferred from the soil to the roots when the plant is colonized
97 by Arbuscular Mycorrhizal Fungi (AMFs), a symbiotic process occurring in 80% of land plants
98 including cereals (Gianinazzi *et al.*, 2010; Chen *et al.*, 2018a; Gojon, 2022; Xie *et al.*, 2022).
99 AMFs are obligate biotrophs, meaning that they rely on their living host plants to complete
100 their life cycle. The early steps of AMF symbiosis involve signal exchange between the host
101 roots of the host plant and the fungus. This signalling process leads to establishment of a
102 physical contact between the partners during which the fungus develops structures like a
103 hyphopodium on the root epidermal cell followed by its growth inside these cells up to the
104 cortical cells where it differentiates into highly branched structures called “arbuscules”.
105 Around these arbuscules, the cortical cells undergo strong reorganization leading to the
106 formation of a structure called “periarbuscular membrane” (PAM). Dual nutritional exchange
107 occurs at the interface of this membrane where the transfer of carbon containing molecules
108 derived from photosynthesis such as hexoses and lipids feed the fungus, which in turn
109 provides minerals such as N and P (Smith and Read, 2002; Gianinazzi *et al.*, 2010; MacLean
110 *et al.*, 2017; Choi *et al.*, 2018; Dellagi *et al.*, 2020). The extra-radical mycelium which
111 represents an extension of the arbuscular structures, allows the fungus to explore the
112 surrounding rhizosphere and to take up minerals further translocated to the periarbuscular
113 interface to be finally delivered to the host plant. In many case, an AMF symbiotic association
114 is able to increase tolerance to abiotic and biotic stresses (Choi *et al.*, 2018; Berger and
115 Gutjahr, 2021).

116 It is well established that phosphorus (P) deficiency is the main driver for the establishment
117 of mycorrhizal symbiotic associations (Breuillin *et al.*, 2010; Smith *et al.*, 2011; Balzergue *et*

118 *al.*, 2013; Wang *et al.*, 2017; Paries and Gutjahr, 2023). Phosphorus deficiency triggers
119 exudation from roots of signaling molecules such as strigolactones that stimulate AMF
120 hyphal branching (Lanfranco *et al.*, 2018; Hull *et al.*, 2021). In addition, isotope tracing
121 experiments have shown that AMF provide phosphorus to their hosts (Sawers *et al.*, 2017;
122 Das *et al.*, 2022). In contrast, the benefit of a mycorrhizal symbiosis in terms of N uptake
123 and utilization by the host plant, remains to be fully characterized (Chen *et al.*, 2018a; Dellagi
124 *et al.*, 2020; Gojon, 2022; Xie *et al.*, 2022). It is known that N can be transported to the plant
125 by AMF (Courty *et al.*, 2015; Garcia *et al.*, 2016; Chen *et al.*, 2018a). Two transporters that
126 mediate the mycorrhizal N transport pathway have been identified so far. For example, in
127 rice, a transporter specifically involved in the transfer of nitrate to the roots of the host plant
128 via the AMF has been described (Wang *et al.*, 2020). In maize, an ammonium transporter
129 enabling the uptake of inorganic N has recently been characterised (Hui *et al.*, 2022).

130 Maize is currently the most productive cereal crop in the world (www.faostat.org) with a
131 global yield exceeding that of rice (Liu *et al.*, 2020). Maize is grown for several purposes
132 including animal feed, food and biotechnological applications (Ranum *et al.*, 2014; Revilla *et*
133 *al.*, 2022). Different maize genotypes are able to develop a symbiotic association with AMF
134 (Sawers *et al.*, 2018a; Berger and Gutjahr, 2021). Several studies have shown that AMF can
135 supply substantial amount of N to maize (Quiroga *et al.*, 2020; Hui *et al.*, 2022). However,
136 physiological and molecular characterization of maize's interaction with AMF under different
137 N supply levels has never been undertaken. We reasoned that utilizing AMF to reduce N
138 fertilization requires investigating the maize physiological responses to AMF under different
139 levels of N fertilization. In the present study, we have studied in an integrated manner the
140 impact of N nutrition on the interaction between maize and the AMF *Rhizophagus irregularis*
141 both at the physiological and molecular levels. Using phenotyping, transcriptomic and
142 metabolomic approaches, we have characterized such interaction using two maize lines
143 which benefit from symbiotic association with the fungus in terms of agronomic performance.

144 Genome-scale metabolic modeling (GSM) is a computational tool to model plant metabolism
145 and can highlight potential key metabolic pathways in plant in response to environmental

146 cues (Morris *et al.*, 2023). Initial efforts on maize metabolic models were limited to its leaf
147 (Simons *et al.*, 2014) and root (Chowdhury *et al.*, 2022b) GSMs, which showed excellent
148 agreement with existing literature regarding phenotypical predictions. Most recently, a multi-
149 organ GSM of maize line B73, *iZMA6517* (Chowdhury *et al.*, 2023), is proposed which
150 includes full scale GSMs of root, stalk, kernel, and leaf; connected via phloem tissue.
151 *iZMA6517* predicted organ-specific metabolic bottlenecks accurately and explored symbiotic
152 relationship with *R. irregularis*. Thereby, apart from experimental works, we used *iZMA6517*
153 to predict plant agronomic performance. Interestingly, *iZMA6517* identified purine and
154 pyrimidine biosynthetic pathways as key physiological processes involved in the efficiency of
155 N utilization in the symbiotic association.

156 **Material and methods**

157 **Plant material, growth conditions and inoculation**

158 The maize inbred lines used in this study B73 and Lo3 are described in Supplementary table
159 1. The reference maize genotype B73, for which the genome was fully sequenced,
160 represents the reference genome for the maize species (Schnable *et al.*, 2009). Additionally,
161 B73 is known to be responsive to AMF, resulting in increased biomass (Ramírez-Flores *et al.*,
162 2019; Berger and Gutjahr, 2021). Lo3, was selected due to its enhanced biomass response
163 following inoculation with *R. irregularis*. This selection was based on the outcomes of two
164 rounds of screening aimed at identifying maize lines that exhibit increased biomass in the
165 presence of AMF under limiting N conditions. These screening rounds were performed on the
166 core collection previously described (Cañas *et al.*, 2017). The purpose was to identify maize
167 genotypes which benefit from AMF inoculation (data not shown). The fungal strain used is
168 the highest quality of purity strain *Rhizophagus irregularis* DAOM197198 (Agronutrition,
169 Toulouse, France). Inoculum was prepared in distilled water and the required volume of
170 spore suspension was added next to the germinated seed or plantlet with a pipette.

171 In all experiments, seeds were surface-sterilized as follows. Seeds were first incubated in
172 ethanol for 5 minutes at 28°C followed by rinsing with distilled water. Then they were
173 incubated for 45 minutes in a 15% commercial bleach solution with 0.01% Triton x100 then
174 rinsed in distilled water. They were placed on wet sterile Whatman paper in Petri dishes
175 closed with parafilm and incubated in the dark for 48-72h at 20°C. Germinated seeds were
176 selected and then sown in pots of 4 litres containing a mix of sterilized unfertilized peat (40%
177 Baltic blond peat 0-10 mm, 60% Brown peat 0-10 mm, 75 g oligoelements, pH CaCl₂ 5.3 –
178 5.8, Stender, France) and dried clay beads (reference: 17831050 BILLE ARGILE LIA 8/16,
179 Soufflet, France) 1:1/v:v. The experimental design and the different steps of growing and
180 harvesting of the experiment in 2020 and 2021 are presented in Supplementary Figure 1 and
181 2 respectively. Meteorological conditions within the greenhouse during 2020 are depicted in
182 Supplementary Figure 3. For each condition 9-10 plants were used. Three inoculations with
183 spores of *R. irregularis* were performed as follow: The first inoculation with 500 spores/plant
184 at sowing, second inoculation 1 week after sowing with 200 spores/plant and a third
185 inoculation 2 weeks after sowing with 200 spores/plant. Control plants were treated with
186 distilled water. Plants were grown under three different nitrogen regimes: low N (LN, 1mM
187 NO₃⁻), medium N (MN, 5 mM NO₃⁻) and high N (HN, 10 mM NO₃⁻). The specific composition
188 of these regimes is provided in Supplementary Table 2. For each N regime, plants were
189 irrigated for the first three weeks with the solution corresponding to the chosen N regime with
190 low P (named P-) containing 10 µM phosphate in order to trigger AMF colonization. Then, at
191 dates indicated in Supplementary Figure 1 and 2, irrigation was changed to the same N level
192 but 300 µM P (named P+, Supplementary Table 2). Increasing P level in the irrigation
193 solution was necessary to allow plants reach the maturity stage. To determine ¹⁵N uptake,
194 ¹⁵N labelling was performed at indicated dates (Supplementary Figure 1). 100 mL of 45 mM
195 KNO₃ solution enriched at 2% ¹⁵N was applied to each plant in order to provide 1,25mg of
196 ¹⁵N.

197 **Harvesting procedures**

198 Plants grown in 2020 were used for the phenotyping, metabolomics, RNA-seq and RT-qPCR
199 experiments. Plants grown in 2021 were to monitor fungal colonization and RT-qPCR
200 experiments. For RNA and metabolite extractions, leaf and root samples were harvested and
201 frozen in liquid nitrogen before RNA extraction. Depending on the experiment and the
202 biological question asked, one, two or three developmental stages were chosen for tissue
203 harvesting. Those stages were determined based a combination of two criteria: (i) the
204 presence of arbuscular symbiotic structures in maize roots and (ii) plant developmental
205 stages. The first one is the vegetative stage (VS) corresponding to the 7- to 8-leaf stage
206 (Cañas *et al.*, 2017). This stage is an indicator of a highly metabolically and
207 photosynthetically active leaf tissue but only few fungal structures start to be visible in roots.
208 The second stage corresponds to 15 days after the Vessel Tasselling stage (VT+15 stage)
209 where root colonization is clearly established and plant is in the early phase of flowering. This
210 stage was chosen because it allows harvesting roots without imposing too great a stress on
211 the plant in order to make sure kernels are not affected. The third stage is maturity stage
212 (MS) and corresponds to plants displaying mature ears. Dates of harvesting for VS, VT+15
213 stage and MS differed depending on the condition and the year of experiment
214 (Supplementary Figure 1 and 2). For leaf tissues, harvesting consisted in cutting a piece of
215 1 cm x 10 cm of leaf mesophyll along the midrib from the 6th fully emerged leaf for the VS.
216 For VT+15 stage and MS, a piece of 1 cm x 10 cm leaf surface from the leaf below the ear of
217 each individual plant was harvested. The leaf below the ear was chosen for providing a good
218 proxy of the sink-to-source transition during grain filling (Prioul and Schwebel-Dugué, 1992).

219 Roots were harvested at VS, VT+15 stage or MS depending on the type of experiment. For
220 each treatment/condition, roots were collected from 5 plants. Thin secondary roots were
221 harvested from the surrounding root system, close to the pot borders. They were washed
222 with distilled water, then frozen in liquid nitrogen or stored in distilled water. Following root
223 harvesting, the plants grown in 2020 were left to grow until maturity. Thus, the roots used for

224 the different omics analyses corresponded to the same plants as those that produced grains
225 and were phenotyped for physio-agronomical traits.

226 **Quantification of yield, biomass, C, N, ¹⁵N and P**

227 Plant organs were harvested then oven dried at 80°C for 3 to 5 days then ground to fine
228 powder. Yield was quantified by weighing dry grains. Biomass of the aerial parts including
229 stalks, leaves, and cobs were weighed after drying. The upper regions of the root system
230 was harvested. This did not allow to quantify the whole root biomass since it was impossible
231 but allowed to quantify the percentage of C, N and P. For each plant and each organ, 5,000
232 µg of dry powder was placed in tin capsules to quantify the total N and C concentrations
233 using the FLASH 2000 Organic Elemental Analyzer (Thermo Fisher Scientific Villebon,
234 France) and the ¹⁵N enrichment using the Delta V Advantage isotope ratio mass
235 spectrometer (Thermo Fisher Scientific, France). Supplementary Table 3 indicates the
236 calculations of different traits with C and N content. A% (Atom percent) represents the ¹⁵N
237 enrichment in the sample [¹⁵N/(total N)]. Since the natural ¹⁵N abundance in N unlabeled
238 samples was 0.3663 (A% control), specific enrichments due to the ¹⁵N uptake were
239 calculated as E% = (A% - 0.3363). The P concentration of shoots, grains and roots was
240 measured using the molybdate blue method on a Shimadzu UV-160 spectrophotometer
241 (Shimadzu Biotech) after acid digestion (Murphy and Riley, 1962).

242 **Quantification of root colonization level by AMF structures**

243 Thin secondary roots were harvested as indicated above and carefully washed in distilled
244 water. They were incubated in 10% KOH overnight at room temperature. They were then
245 rinsed in distilled water and incubated in 5% black ink (Sheaffer Skrip Bottled Ink, France)
246 solution for 10 min at 70°C. Washing was performed by incubating roots in 8% acetic acid for
247 25 min. For the quantification of % of AM colonization (total, arbuscules, vesicles) 50 pieces
248 of 1 cm length each were mounted on a slide for observation of AM structures under light

249 microscope using the slide method (Giovannetti and Mosse, 1980). Quantifications were
250 performed on roots collected from 5 plants for each condition.

251 **RNA extraction for RT qPCR and RNAseq**

252 RNA extraction was performed with TRIzol (Thermo Fisher Scientific, USA) protocol. Fresh
253 tissue of leaves or roots (100 mg) were frozen in liquid nitrogen then ground to fine powder
254 that was homogenized in 1 mL of TRIzol. Two glass beads are added to the extract in the
255 tube which was then vortexed for 5 minutes, then the samples were incubated for 5 minutes
256 at room temperature (RT). Two hundred microliters of chloroform were added then the
257 sample was vortexed for 5 minutes and incubated 3 minutes at RT. Samples are centrifuged
258 at 12,000 g for 15 minutes at 4°C. The aqueous phase (approximately 500 µL) was
259 transferred to a new tube with an equal volume of ethanol (100%). Samples mixed with
260 ethanol were then transferred to a column (Zymo-Spin™ IC, Germany); for purification
261 following manufacturer's instructions.

262

263 **cDNA synthesis and RT-PCR**

264 1 µg of RNA was first treated with DNase (Thermo Fisher Scientific, USA) in a 10 µL total
265 volume. 1 µg of DNase treated RNA was then used for reverse transcription using oligo-dT
266 and the reverse transcriptase Revert aid (Thermo Fisher Scientific, USA) following the
267 manufacturer's instructions. Quantitative PCR reactions were carried out as described (Verly
268 *et al.*, 2020). For each sample, a cycle threshold (Ct) value was determined and converted
269 into Starting Quantity (SQ) also named Arbitrary Units (AU) values based on a standard
270 curve equation. The AU values obtained for each gene of interest was then divided by the
271 mean of AU values obtained for the chosen reference gene (indicated in each dataset)
272 leading to the normalized transcript level value. Primer sequences are described in
273 Supplementary table 4.

274 **RNAseq and Bioinformatic Analysis**

275 RNA-seq libraries were constructed by the POPS platform (IPS2) using the Illumina Stranded
276 mRNA Prep kit (Illumina®, California, U.S.A.) according to the supplier's instructions.
277 Libraries were sequenced by the Genoscope (Évry-Courcouronnes, France) on a Novaseq
278 6000 instrument (Illumina) with 150 base paired-end sequences.

279 **Raw Data cleaning**

280 The raw data were treated as follow:

281 1- Illumina filter. Performed as described with chastity cutoff of 0,6.

282 To remove the least reliable data from the analysis, the raw data were filtered to remove any
283 clusters that have "too much" intensity corresponding to bases other than the called base.
284 The purity of the signal from each cluster was examined over the first 25 cycles and
285 calculated as $\text{Chastity} = \frac{\text{Highest_Intensity}}{\text{Highest_Intensity} + \text{Next_Highest_Intensity}}$ for
286 each cycle. The default filtering implemented at the base calling stage allows at most one
287 cycle that is less than the Chastity threshold (0,6).

288

289 2- Genoscope filter. An in-house procedure was used in order to remove adapters and
290 primers on the whole read and low-quality nucleotides from both ends (while quality value is
291 lower than 20) and then continue next steps with the longest sequence without adapters and
292 low-quality bases. Remove sequences between the second unknown nucleotide (N) and the
293 end of the read. This step is done on trimmed (adapters + quality) reads. Discard reads
294 shorter than 30 nucleotides after trimming. Remove read pairs that come from the low-
295 concentration spike-in library of Illumina PhiX Control. Reads pairs corresponding to
296 ribosomal RNA were removed using sortMeRNA (v2.1, (Kopylova *et al.*, 2012).

297 These previous two steps were performed by the sequencing facility at Genoscope. Cleaned
298 reads from Genoscope were adapter trimmed again by the POPS platform with BBduk from
299 the BBmap suite (v38.84, Bushnell, 2014) with the options `k=23 ktrim=r qtrim=r`

300 useshortkmers=t mink=11 trimq=20 hdist=1 tpe tbo minlen=30 using adapter sequences file
301 included in the BBTools package.

302 *Mapping and Gene expression quantification*

303 Filtered reads were then mapped and counted using STAR (v2.7.3a, (Dobin *et al.*, 2013))
304 with the following parameters --alignIntronMin 5 --alignIntronMax 60000 --
305 outSAMprimaryFlag AllBestScore --outFilterMultimapScoreRange 0 --outFilterMultimapNmax
306 20 on a combined reference genome made by concatenating the files of the *Zea mays* B73
307 (V4.49) and *Rhizophagus irregularis* (V2) reference genomes and the associated GTF
308 annotation files (also combined). Between 75.3 and 96.1 % of the reads were uniquely
309 mapped (median = 91.9%). Between 68 and 88 % of the reads were associated to annotated
310 genes (median = 85.3%).

311 Statistical Analyses of Expression Data

312 Statistical analyses were conducted on R v3.6.2 (R Core Team, 2020) using the script-based
313 tool DiCoExpress (Lambert *et al.*, 2020; AU - Baudry *et al.*, 2022). DiCoexpress used the
314 Bioconductor package edgeR (v 3.28.0, (Robinson *et al.*, 2010; McCarthy *et al.*, 2012).The
315 raw count file used for the statistical analyses only contain the reads of the *Zea mays*
316 organism. Dicoexpress DiCoExpress analyse RNAseq projects with at most two biological
317 factors. For this reason and to answer biological questions of interest, 4 separate statistical
318 analyses were conducted on samples from (i) B73 leaves, (ii) B73 roots, (iii) Lo3 leaves, (iv)
319 Lo3 roots.

320 Gene Filtering and Normalization

321 For the four analyses, low counts genes giving low counts were filtered using the
322 "FilterByExpression" feature available through the edgeR package with a minimum count
323 threshold of 15. Raw counts were normalized with the trimmed mean of M values (TMM)
324 method implemented in edgeR package.

325 *Differential Expression Analysis*

326 The differential analysis is based on a negative binomial generalized linear model. For the 4
327 *Zea mays* analyses, the log₂ of the average normalized gene expression is an additive
328 function of a condition effect (LN or HN), a treatment effect (Rhizo equivalent to *R. irregularis*
329 inoculation) or Ctrl (equivalent to control treatment), an interaction between the condition and
330 the treatment and the technical replicate factor (3 modalities). To make the processing of
331 these multifactorial designs easier, Differential Expression (DE) analyses were performed
332 using the `DiffAnalysis_edgeR` function of `DiCoExpress` to generate automatically the
333 contrasts. In each analysis, we considered the difference between the two treatments at
334 each condition and averaged on the two conditions, the difference between the two
335 conditions given a treatment and averaged on the two treatments and the interaction effect
336 defined as the difference between the two treatments at a given condition (HN) minus the
337 difference between the two treatments at the second condition (LN). It leads to a total of 8
338 contrasts per analysis and only biologically meaningful contrasts were interpreted. For each
339 contrast a likelihood ratio test was applied and raw p-values were adjusted with the
340 Benjamini–Hochberg procedure to control the false discovery rate. The distribution of the
341 resulting p-values followed the quality criterion described by Rigaiill *et al.* (Rigaiill *et al.*, 2018).
342 A gene was declared differentially expressed if its adjusted p-value was lower than 0.05.

343 For the fungal transcripts, expression ratios were considered relative to the N nutrition
344 condition. Fungal transcripts displaying a FC higher or lower than 1.5 in LN compared to HN
345 conditions were considered. Each transcript ID was converted into the protein ID using the
346 fungal genomic resource MycoCosm at the JGI website:
347 https://mycoCosm.jgi.doe.gov/pages/search-for-genes.jsf?organism=Rhiir2_1 (Tisserant *et*
348 *al.*, 2013; Chen *et al.*, 2018b). Based on KOG (euKaryotic Orthologous Groups), functional
349 classes to which the genes belong were determined. Over-represented functional KOG
350 categories of these fungal genes were determined using the 'KOGMWU' 1.2 R package

351 (Date 2019-02-19. Author Mikhail V. Matz). The fold enrichment value is based on a Mann-
352 Witney, U-test that uses for each gene, a combination of the FC and the KOG category.

353 **Metabolomic analyses**

354 All extraction steps were performed in 2 mL Safelock Eppendorf tubes. The ground dried
355 samples (5 mg DW) were resuspended in 1 mL of frozen (-20°C)
356 Water:Acetonitrile:Isopropanol (2:3:3) containing Ribitol at 4 mg/L and extracted for 10 min at
357 4°C with shaking at 1500 rpm in an Eppendorf Thermomixer. Insoluble material was removed
358 by centrifugation at 13500 rpm for 10 min. 700 µL were collected and 70 µL of myristic acid
359 d27 at 0.3 g/L was added as an internal standard for retention time locking. After
360 centrifugation, aliquots of each extract (100 µL) were dried for 4 h at 35 °C in a Speed-Vac
361 and stored at -80°C. Two Blank tubes underwent the same steps as the samples.

362 Sample derivatization and analysis : All steps of GC-MS analyses were done as described in
363 Fiehn et al. (Fiehn, 2006; Fiehn *et al.*, 2008). Agilent literature PUB: 5989-8310EN (Agilent
364 G1676AA Agilent Fiehn GC/MS Metabolomics RTL Library User Guide. June 2008. Agilent
365 P/N: G1676-90000, Agilent Fiehn GC/MS Metabolomics RTL Library Product Note. May
366 2008). Samples were taken out of -80°C, warmed 15 min before opening and speed-vac
367 dried again for 1 hour at 35 °C before adding 10 µL of 20 mg/mL methoxyamine in pyridine
368 to the samples and the reaction was performed for 90 min at 30°C under continuous shaking
369 in an Eppendorf thermomixer. 90 µL of N-methyl-N-trimethylsilyl-trifluoroacetamide (MSTFA)
370 (REGIS TECHNOLOGIES 1-270590-200 -10x1g) were then added and the reaction
371 continued for 30 min at 37°C. After cooling, 90 µL were transferred to an Agilent vial for
372 injection.

373 4 hours after derivatization 1 µL of sample was injected in splitless mode on an Agilent
374 7890B gas chromatograph coupled to an Agilent 5977A mass spectrometer. The column was
375 an ZORBAX DB5-MS from Agilent (30 m with 10 m integraguard column - ref 122-5532G).
376 An injection in split mode with a ratio of 1:30 was systematically performed for saturated
377 quantification compounds. Oven temperature ramp was 60 °C for 1 min then 10 °C/min to

378 325 °C for 10 min. Helium constant flow was 1.1 mL/min. Temperatures were as follows:
379 injector: 250°C, transfer line: 290°C, source: 230 °C and quadripole 150 °C. The quadrupole
380 mass spectrometer was switched on after a 5.90 min solvent delay time, scanning from 50-
381 600 μ . Absolute retention times were locked to the internal standard d27-myristic acid using
382 the RTL system provided in Agilent's Masshunter software. Retention time locking reduces
383 run-to-run retention time variation. Samples were randomized. A fatty acid methyl esters mix
384 (C8, C9, C10, C12, C14, C16, C18, C20, C22, C24, C26, C28, C30) was injected in the
385 middle of the queue for external RI calibration.

386 Data processing and quantification: Raw Agilent datafiles were analyzed with AMDIS
387 <http://chemdata.nist.gov/mass-spc/amdis/>. The Agilent Fiehn GC/MS Metabolomics RTL
388 Library (version June 2008) was employed for metabolite identifications. This library is the
389 most comprehensive library of metabolite GC/MS spectra that is commercially available. It
390 contains searchable GC/MS EI spectra and retention time indexes from approximately 700
391 common metabolites. Peak areas determined with the Masshunter Quantitative Analysis
392 (Agilent) in splitless and split 30 modes. Because automated peak integration was
393 occasionally erroneous, integration was verified manually for each compound in all analyses.
394 Resulting areas were compiled in one single Excel file for comparison. Peak areas were
395 normalized to Ribitol and Dry Weight. Metabolite contents are expressed in arbitrary units
396 (semi-quantitative determination).

397 **Amino acid quantification by OPA-HPLC**

398 Extraction procedure was identical that one described for metabolomics. Here 200 μ L of the
399 extraction solution was taken and dried in a Speed-Vac evaporator for 2 h at 30°C before
400 adding 1,3 mL of H₂O milliQ. The o-phthalaldéhyde (OPA) reagent was made 48 h before
401 first use by dissolving OPA at 12mg/mL in 200 μ L of methanol and adding 1.8 mL of sodium
402 borate 0.5M (pH 9.5) and 40 μ L of 2-mercaptoethanol. The reagent was filtered into an
403 autosampler vial and used for up to 3 days. Precolumn derivatization was performed in the
404 injection loop by automated mixing of 10 μ L sample and 10 μ L OPA reagent, followed by a

405 delay of 2 min prior to injection. The HPLC (Alliance Waters 2695, Waters Corporation,
406 Massachusetts, USA) fitted with a fluo detector (Multi λ Fluorescence Detector 2475) was
407 used. Compounds were measured at λ excitation of 340 nm and λ emission of 455 nm. The
408 chromatographic separation was performed with Symmetry C18 column (3.5 μ m, 4.6*150
409 mm) by gradient elution at 40 °C using buffer A (20% methanol, 80% sodium acetate, 1%
410 tetrahydrofuran, pH 5.9) and buffer B (80% methanol, 20% sodium acetate, pH 5.9). Buffer
411 flow rate was 0.8 mL/min throughout and total run time per injection was 42 min. The
412 chromatography data were analysed by Empower software. Peak identity was confirmed by
413 co-elution with authentic standards. Concentration was calculated with calibration curve
414 using peak area of compound of interest.

415 **Statistical analyses**

416 All statistical analyses were performed with RStudio 2023.06.0+421 "Mountain Hydrangea"
417 under the free software environment R version 4.3.1 (Beagle Scouts). All Anova were
418 implemented with the "aov" R package. All heatmaps were generated with the estimated
419 marginal means that were calculated using the R package "emmeans". Heatmap for physio-
420 agronomical traits was generated with 'pheatmap' 1.0.12 package (Date 2019-01-04. Author
421 Raivo Kolde) by implementing the ward.D2 hierarchical clustering method (Murtagh and
422 Legendre, 2014). Heatmap for physio-agronomical traits was generated with the 'pheatmap'
423 R package 1.0.12 Date 2019-01-04 (Author Raivo Kolde). Heatmaps for metabolomics,
424 including the interactive ones, were generated with "heatmaply" R package (Galili *et al.*,
425 2018)

426 Metabolomics data were analyzed with the R package MultiVarSel (Perrot-Dockès *et al.*,
427 2018) which is the implementation of the variable selection approach in the multivariate linear
428 model proposed in (Perrot-Dockès *et al.*, 2018a), theoretically analysed in (Perrot-Dockès *et*
429 *al.*, 2018b) and applied in several contexts of omics data analyses such as (Grandclaudon *et*
430 *al.*, 2019; Perrot-Dockès *et al.*, 2022). The list of R packages used in this study: Chiquet J,
431 Donnet S, Barbillon P (2023). *sbm: Stochastic Blockmodels*. R package version 0.4.5-9000,

432 <<https://grosssbm.github.io/sbm/>>. Kolde R (2019). `_pheatmap`: Pretty Heatmaps_. R
433 package version 1.0.12, <<https://CRAN.R-project.org/package=pheatmap>>. Lenth R (2023).
434 `_emmeans`: Estimated Marginal Means, aka Least-Squares Means_. R package version
435 1.8.6, <<https://CRAN.R-project.org/package=emmeans>>. Perrot-Dockès M, Lévy-Leduc C,
436 Chiquet J. R package `MultiVarSel` available from the Comprehensive R Archive Network,
437 2017. <<https://CRAN.R-project.org/package=MultiVarSel>>.

438 **Genome-Scale Metabolic Modelling (GSM) and Transcriptomics Data Integration**

439 To investigate the metabolism of maize from systems level, we used *iZMA6517* as the
440 template model (Chowdhury *et al.*, 2023). The model is specific to B73 genotype and consists
441 of organ-specific GSMs of root, stalk, leaf, and kernel. All these individual organ GSMs are
442 connected through a common phloem pool. The model has been described (Chowdhury *et al.*
443 *et al.*, 2023). The model was contextualized with HN Control, HN Rhizo, LN Control, and LN
444 Rhizo using EXTREAM algorithm (Chowdhury *et al.*, 2023). The upper and lower bounds for
445 the mentioned conditions are presented in the Supplementary Table 5. The General
446 Algebraic Modeling System (GAMS) version 24.7.4 with IBM CPLEX solver was used to run
447 FBA and FVA, E-Flux, and the FSA algorithm on the model. Each of the algorithms was
448 scripted in GAMS and then run on a Linux-based high-performance cluster computing
449 system at the University of Nebraska-Lincoln. Instructions for running files in GAMS through
450 NEOS server have been published (Chowdhury *et al.*, 2022a). All the necessary files for
451 COBRApy users can also be accessed through the *iZMA6517* publication (Chowdhury *et al.*,
452 2023).

453 **Metabolic Bottleneck Analysis (MBA)**

454 To determine the metabolic bottlenecks in each of HN Control, HN Rhizo, LN Control, and
455 LN Rhizo conditions, we used Metabolic Bottleneck Analysis (MBA) (Chowdhury *et al.*,
456 2023). MBA expands the flux space of each reaction separately and assesses its impact on
457 the whole plant biomass growth rate. Further details on MBA can be accessed in the original

458 publications. MBA pinpoints plant-wide metabolic bottlenecks, which were further analyzed
459 for biological insights.

460 **Results**

461 **The impact of *Rhizophagus irregularis* on maize growth and yield is strongly** 462 **dependent on the level of N nutrition**

463 To investigate the molecular and physiological mechanisms involved in maize interaction
464 with AMF in terms of N nutrition and have an overview of the diversity of these mechanisms
465 we used two AMF-responsive maize lines B73 and Lo3. In order to find at which level of N
466 fertilization the two lines benefit most from the fungal inoculation, these were grown in a
467 greenhouse under low N (LN), medium N (MN) or high N (HN) corresponding to 1 mM NO₃⁻,
468 5 mM NO₃⁻ and 10 mM NO₃⁻ in the nutrient solution respectively. The impact of *R. irregularis*
469 inoculation on maize physio-agronomic traits was monitored by measuring shoot biomass,
470 grain yield, total N content and ¹⁵N enrichment allowing the calculation of other traits such as
471 NUE as described in Supplementary table 3. In inoculated plants, an increase in the shoot
472 biomass production was only observed under LN in both lines, whereas an increase in grain
473 yield only occurred in B73 (Figure 1A, 1B). A slight negative impact of *R. irregularis*
474 inoculation was observed on B73 grain yield when plants were grown under HN.
475 Interestingly, *R. irregularis* allowed inoculated plants grown under LN to produce a similar
476 vegetative biomass compared to non-inoculated plants fed with 5 times more NO₃⁻. However,
477 AMF inoculation did not influence shoot biomass of either maize genotypes under MN or HN
478 (Figure 1B).

479 In inoculated plants, an increase in NUE for grain was observed under LN and MN
480 fertilization conditions only in B73 (Figure 1D). Aerial parts NUE increased only in LN
481 conditions for both B73 and Lo3 (Figure 1C). Together, these data indicate that benefit from
482 AMF in terms of maize yield and NUE is higher under limiting N supply than under ample N
483 supply and depends on the genotype. When we examined the impact of the AMF on N

484 resource allocation under the three levels of N, a significant increase of biomass allocation to
485 the grain was observed in both B73 and Lo3 only in LN (Figure 1E). Chlorophyll quantities
486 were monitored during the vegetative phase and were also increased by AMF inoculation
487 under LN only (Figure 1F).

488 The grain N content, considered as a proportion relative to dry mass, remains consistent
489 across genotype and the N feeding conditions. However, an exception to this trend is
490 observed in the B73 genotype, where the N content is notably lower in inoculated LN and MN
491 plants (Figure 2A). Both the shoot and the root N contents were roughly proportional to the
492 amount of N provided to the plant. Fungal inoculation did not change N content under LN.
493 However, under higher N supply levels, a significant increase in the N content of aerial parts
494 was observed in response to *R. irregularis* under MN for B73 and under HN for Lo3
495 indicating that these lines are able to store higher levels of N in the vegetative parts upon
496 association with the AMF even under ample N (Figure 2C). The C/N ratio exhibited minimal
497 change, as a slight decrease in B73 inoculated LN plants aerial parts and increase in grains
498 in response to *R. irregularis* under MN for B73 was observed (Figure 2G-H). Changes in
499 carbon (C) content were not statistically significant.

500 To determine whether N uptake is modified during the symbiotic interaction, plants were
501 labelled with a pulse of ^{15}N provided at the vegetative stage. The total quantity of ^{15}N in aerial
502 parts and grains measured at maturity is unchanged whatever the treatment (Supplementary
503 Figure 4). These data indicate that the fungus does not affect N uptake at the vegetative
504 stage. However, under LN conditions, ^{15}N -enrichment in the different organs of the inoculated
505 plants was much lower than in control plants for both B73 and Lo3 in line with a biomass
506 increase resulting in ^{15}N dilution in AMF inoculated plants (Supplementary Figure 4). These
507 data indicate that the higher uptake of N triggered by *R. irregularis* is more likely to occur
508 after the vegetative stage.

509 It is well established that mycorrhizae play a pivotal role in the improvement of plant P
510 nutrition and uptake (Choi *et al.*, 2018; Plassard *et al.*, 2019; Paries and Gutjahr, 2023). To

511 determine if the amount of N supplied to the plant and the presence of *R. irregularis* modify
512 B73 and Lo3 phosphate content, total P content (TPC) was measured by the molybdate blue
513 method. In inoculated plants, an increase in the TPC content was observed under HN
514 conditions both in the grains and in the roots of Lo3, whereas for B73 it was in the shoots
515 and in the roots under HN (Figure 2B-D-F). Together, these data indicate that N supply has a
516 strong impact on *R. irregularis* mediated P nutrition and that this benefit depends on maize
517 genotype.

518 **Inoculation by *R. irregularis* mitigate the physiological impact of N-deficiency**

519 Physio-agronomic phenotyping prompted us to determine if there were traits that could
520 discriminate inoculated and non-inoculated plants. For this purpose, hierarchical clustering
521 analysis (HCA) was performed using the physio-agronomic traits listed in Supplementary
522 Table 3. The HCA presented in Figure 3 shows that the N supply, the genotype, and the
523 symbiotic association had an impact on the monitored traits. All the LN plants were grouped
524 in cluster A. Within cluster A, values for the traits related to N and P uptake including root P
525 content and ¹⁵N enrichment (R_Ppercent and R_15NEpercent respectively), aerial part P
526 content, NUE and ¹⁵N enrichment (AP_Ppercent, AP_NUE, AP_15NEpercent respectively),
527 were higher. LN plants in cluster A were distant from the HN MN plants clustered in group B.
528 In cluster B, genotypes were distributed into two subgroups, B1 and B2. Traits related to
529 yield and biomass were grouped in cluster B irrespective of the inoculation status.
530 Interestingly, in cluster A, traits related to N deficiency exhibited higher values in the control
531 compared to the inoculated plants indicating that *R. irregularis* allowed plants to behave
532 more similarly to group B plants, albeit still under N stress deficiency. These data show that
533 *R. irregularis* inoculation can mitigate the impact of N limitation on physio-agronomic traits.

534 **Marker genes for N uptake and assimilation are differentially regulated in response to** 535 **AMF inoculation and N supply**

536 The finding that several NUE traits, notably those related to NO_3^- uptake were modified by
537 AMF treatment prompted us to investigate further which molecular components were
538 involved. Before investigating in detail, the molecular mechanisms taking place in regard to
539 on N supply we had to identify the time point of the interaction process at which symbiotic
540 markers were expressed at their maximum. For this purpose, the expression levels of
541 symbiotic marker genes were monitored at three stages (see materials and methods). Then,
542 the level of transcripts for the plant genes *ZmAMT3.1*, *ZmPHT6.1* and *ZmNPF4.5* markers of
543 the symbiotic association and representative of NH_4^+ , phosphorus and NO_3^- transport
544 respectively was quantified (Sawers *et al.*, 2017; Wang *et al.*, 2020; Xie *et al.*, 2022; Hui *et*
545 *al.*, 2022). For the three genes, the levels of root transcripts were higher at VT+15 stage in
546 both HN and LN conditions (Supplementary Figure 5). Fungal colonization was greater under
547 HN compared to LN both in B73 and Lo3 (Supplementary Figure 5A). Hence, the VT+15
548 stage was selected for all subsequent experiments.

549 The expression of selected marker genes involved in direct N transport, P and N transport
550 mediated by AMF was then monitored in roots following inoculation by the AMF and
551 according to the level of N supply. By monitoring the level of *R. irregularis* constitutive
552 transcript *RiLSU* we confirmed that high N input led to increased fungal biomass in roots
553 (Figure 4B). The expression level of the four well known symbiotic markers mentioned
554 previously, *ZmPHT1.6*, *ZmNPF4.5*, *ZmHA1*, a proton pump, and *ZmAMT3.1* (Wang *et al.*,
555 2014, 2020; Sawers *et al.*, 2017; Xie *et al.*, 2022; Hui *et al.*, 2022), is up-regulated in
556 response to the fungus in both genotypes and under all N supply conditions. It is interesting
557 to notice that the higher the N nutrition level, the higher the expression of these markers
558 (Figure 4A). To know more about direct N transport and N assimilation genes in those
559 conditions, we investigated expression levels of two maker genes of N starvation stress
560 (*ZmNRT2.1a*, and *ZmNRT2.2*) encoding high affinity transporters, known to be upregulated
561 under N deficiency (Krapp *et al.*, 2014; Wang *et al.*, 2018; Dechorgnat *et al.*, 2019; Hirel and
562 Krapp, 2020) (Figure 4A). As expected, the level of N supply had a drastic effect in both

563 maize genotypes on transcripts levels for the nitrate transporters *ZmNRT2.1a*, *ZmNRT2.2*
564 which were more highly expressed in LN plants compared to MN and HN plants. These data
565 indicate that the presence of the fungus mimics an additional N supply.

566 **Leaf and root transcriptome reprogramming in response to *R. irregularis* colonization**
567 **integrates a genotype and N-availability effects**

568 To further characterize the biological processes involved in maize response to *R. irregularis*
569 colonization as a function of N fertilization, a whole genome transcriptomic approach was
570 conducted in leaves and roots of plants grown under HN and LN conditions. First, we defined
571 the differentially expressed genes (DEGs) as those exhibiting a fold change of the transcript
572 levels in inoculated plants compared to non-inoculated plants that was higher than 1.5 or
573 lower than -1.5 ($p < 0.05$). It is important to note that RNAs used for the transcriptomic
574 approach were obtained from the plants that were phenotyped at the end of their life cycle for
575 physio-agronomical traits. Indeed, root harvesting for molecular studies was not destructive,
576 allowing plants to complete their life cycle.

577 Details for the numbers of DEGs depending on organ, N nutrition level and genotype are
578 shown in Supplementary Figure 6. First, we focused on the DEGs in roots and in leaves
579 irrespective of the genotype and irrespective of the level of N fertilization. In leaves, only 2
580 genes were up-regulated and only 2 genes were down regulated, whereas in roots many
581 more genes were differentially expressed in all conditions in response to the fungus. The two
582 genes up-regulated in all conditions in leaves encode a H(+)-exporting diphosphatase
583 (Zm00001d015569) involved in vacuolar ion transport and a histidine-containing
584 phosphotransferase protein 4 (Zm00001d043505) involved in signalling. The two down-
585 regulated genes encode a Mannan endo-1,4-beta-mannosidase (Zm00001d010039)
586 involved in cell wall remodelling and a Nuclear transcription factor Y subunit (NF-Y)
587 (Zm00001d006835).

588 When considering root DEG genes irrespective of the genotype or N supply, there was an
589 increase in the expression level of 345 genes whereas a decrease was observed for 59
590 genes (Supplementary Figure 6). GO enrichment analysis revealed that for those common
591 up-regulated genes in roots, the biological processes overrepresented were those related to
592 proteolysis inhibition, lipid metabolism, ethylene response and membrane transport. The
593 common down regulated genes were represented by five main functional categories
594 including cell wall biogenesis, metal homeostasis, phosphate transport, stress responses and
595 lipid metabolism (Figure 5).

596 To gain insight into the specific mechanisms taking place in each line (B73 and Lo3) upon
597 symbiotic association as a function of N nutrition, enriched GO functions in DEG under LN or
598 HN in each organ were determined. In B73 roots under LN, main overrepresented categories
599 of up-regulated transcripts are related to plant immunity represented by hormone signaling
600 and phenylpropanoid pathway, cell wall remodeling and nucleotide metabolism, while the
601 main down-regulated categories were enriched in post translational modifications such as
602 histone de-ubiquitination. In B73 roots under HN, the main overrepresented categories in up-
603 regulated genes are related to defense, signaling, glycolysis, lipid metabolism and cellular
604 trafficking while the overrepresented categories in the down-regulated genes are related to
605 sugar and steroid metabolism and cell division.

606 In inoculated Lo3 roots under LN, stress responses, amino acid biosynthesis and autophagy
607 are overrepresented in the up-regulated genes, while in the down-regulated genes, DNA and
608 amino acid metabolism as well as cell wall remodeling are overrepresented. Under HN, *R.*
609 *irregularis* inoculation of Lo3 triggers the up-regulation of root transcripts mainly related to
610 photosynthesis, stress responses, DNA metabolism, water transport, amino-acid metabolism,
611 root development and terpenoid biosynthesis. In roots of HN grown Lo3 plants, the main
612 overrepresented categories of down-regulated genes belong to nitrate assimilation,
613 oligopeptide transport and stress responses categories.

614 We performed the same data analysis in leaves (Figure 5). In response to *R. irregularis*, the
615 B73 leaves main overrepresented categories of up-regulated transcripts under LN conditions
616 are related to translation and auxin signaling, while the main down-regulated categories were
617 enriched in symbiotic interactions, signaling. Under HN, in B73 leaves of inoculated plants,
618 the main overrepresented categories in up-regulated genes are related to redox reactions,
619 carbohydrate transport and defense while the main over-represented categories in the down-
620 regulated genes are related to protein folding and response to inorganic substances.

621 In leaves of inoculated Lo3 plants, under LN, the main overrepresented categories in the up-
622 regulated genes are photosynthesis, cell wall remodeling, cytoskeleton remodeling, stress
623 response, signaling, while in the down-regulated genes, gamma-amino butyric acid (GABA)
624 metabolism and pyrimidine biosynthesis are overrepresented. Under HN, *R. irregularis*
625 inoculation of Lo3 plants triggers the up-regulation of leaf transcripts mainly related to amino
626 acid catabolism, flavin-containing compounds related metabolism and organic acid transport
627 as well as iron homeostasis, while down-regulated genes belong to lipid metabolism,
628 pyrimidine metabolism, and stress response. Taken together, these data show that leaf and
629 root transcriptomic responses to the AMF differ depending on maize genotype and N supply.

630 **Leaf and root metabolomic profiles in response to *R. irregularis* are shaped by N** 631 **nutrition**

632 To further characterize the metabolic responses of the two maize lines to *R. irregularis*
633 inoculation, a primary metabolome profiling was performed on the same leaf and root
634 samples as those studied in the previous section. Metabolic profiles showed that plant organ
635 and N supply had the strongest impact on leaf and root metabolite composition
636 (Supplementary Figures 7A and B). AMF inoculation and maize genotype had globally
637 weaker impacts on metabolite profiles (Figures 6 A and B and supplementary Figure 7C and
638 D). In leaf samples 132 water soluble metabolites were detected of which 103 were
639 significantly different in at least on condition after ANOVA statistical analysis ($P < 0.05$)
640 followed by a Bonferroni post-hoc test and correction. In roots, there were 120 water-soluble

641 metabolites of which 117 were found to be significantly different in at least one condition. The
642 identity of metabolites can be found on the interactive heatmap Supplementary interactive
643 File 1.

644 In roots, fungal inoculation triggered accumulation of lipids such as trans-13-octadecenoic
645 acid and palmitoleic in both lines Supplementary Figure 8. The accumulation of these two
646 lipids was much higher under HN than under LN. We observed that in inoculated roots, there
647 was a global decrease in sucrose, glucose and fructose levels in roots of Lo3 under LN.
648 Several metabolites linked to N metabolism were differentially accumulated in inoculated
649 roots. For example, Glu, Arg, citrulline, Asn and β -Ala levels were increased in response to
650 *R. irregularis* in roots under HN. Glutamine levels remained unchanged in inoculated roots.
651 Some metabolites related to immunity were accumulated differentially in response to the
652 fungus. For instance, shikimic acid was accumulated in LN roots of inoculated B73 plants
653 and trehalose was accumulated in HN inoculated roots of both lines compared to controls.

654 In leaves, lipids and soluble sugars (glucose and fructose) did not show differential
655 accumulation in response to the fungus. Sucrose, however, showed a significant decrease
656 only for HN and this in both lines (Supplementary Figure 9). Gln and Asn accumulated in Lo3
657 leaves under HN in response to *R. irregularis*. Xylulose accumulated in Lo3 R LN leaves.

658 To identify metabolites representative of the plant response to *R. irregularis* under each
659 growth condition, metabolites for which abundance is significantly correlated with specific
660 treatment conditions were identified by using a variable selection approach in a multivariate
661 linear model conducted with the MultiVarSel approach (see materials and methods, Figure 6
662 C and D). For example, we found that under LN, xylulose was accumulated in leaves of Lo3
663 inoculated plants (Figure 6C). In roots, benzoic acid was accumulated in inoculated B73
664 roots of plants grown under LN (Figure 6D). Palmitoleic acid is accumulated to a lower extent
665 in Lo3 HN control conditions compared to all the other conditions. These data indicate that
666 specific metabolites are accumulated depending on the plant genotype and the N supply in
667 response to *R. irregularis*.

668 **Multi-organ metabolic modelling reveals key metabolic processes triggered by *R.***
669 ***irregularis* allowing maize to mitigate N limitation stress**

670 To identify key metabolic reactions involved in yield and biomass reshaping in response to *R.*
671 *irregularis* symbiosis, we integrated the transcriptomic data in a recently reconstructed multi-
672 organ genome scale modelling (GSM) named *iZMA6517* (Chowdhury *et al.*, 2023), This
673 model was built for the B73 maize genotype using the transcriptomic data integration
674 algorithm, EXTREAM (Chowdhury *et al.*, 2023). This was followed by a metabolic bottleneck
675 analysis (MBA) to pinpoint metabolic bottlenecks for biomass production. The B73 leaf and
676 root transcriptomic data were used as input to EXTREAM to contextualized *iZMA6517*. The
677 modelling predicted that growth rates were higher under LN in response to *R. irregularis*
678 inoculation compared to non-inoculated plants, which resulted in grain yield and biomass
679 increase while under HN, a negative impact on maize growth rate was observed (Figure 7A).
680 Strikingly, these data are in agreement with the observed yield and biomass experimental
681 data in Figure 1, confirming the accurate phenotypic prediction of the *iZMA6517*. This result
682 prompted us to determine the metabolic processes that could explain the improved yield
683 under LN B73 plants in response to *R. irregularis* inoculation by identifying the potential
684 metabolic bottlenecks relieved by the AMF under limiting N. For this purpose, we compared
685 the bottlenecks identified in LN control plants to the bottlenecks identified in inoculated LN
686 plants (Figure 7B; Table 1). Four metabolic bottlenecks relieved by *R. irregularis* inoculation
687 were identified : photosynthesis, purine and pyrimidine metabolism, aromatic acid
688 metabolism; and folate metabolism (Figure 7B, Table 1). Interestingly 13 new bottlenecks
689 were emerged following *R. irregularis* inoculation. These new bottlenecks are involved in the
690 metabolism of nicotinate, nicotinamide, purine, aromatic amino acids, Calvin cycle and
691 glycolysis, On the other hand, we found that in HN plants, four metabolic bottlenecks that
692 were present in LN control plants were relieved. Three of them were common with those
693 relieved by *R. irregularis* (photosynthesis, purine and pyrimidine metabolism, aromatic acid
694 metabolism), the fourth one is involved in ascorbate and aldarate metabolism. The HN

695 treatment created 14 new metabolic bottlenecks compared to LN control conditions. These
696 new bottlenecks are involved in glycolysis, TCA cycle, Calvin cycle, metabolism of alanine,
697 aspartate, glutamate, pyrimidine, purine, fructose, mannose, aromatic amino acids. These
698 data indicate that different metabolic processes are modulated by N supply and *R. irregularis*
699 inoculation. The most interesting result is the fact that photosynthesis, pyrimidine
700 metabolism, aromatic amino acid biosynthesis are 3 processes likely to play key roles on *R.*
701 *irregularis* mediated N nutrition in maize.

702 **Transcriptome of *R. irregularis* in inoculated maize roots is driven by N availability**

703 To gain insight into the metabolic cross talk between *R. irregularis* and maize, we
704 investigated the biological processes taking place in the fungal partner according to the N
705 supply conditions. For this purpose, we determined the fungal genes displaying a higher
706 expression in LN roots compared to HN roots and vice versa. This selection was performed
707 for B73 and Lo3 separately. The Venn diagrams in Figure 8A and 8B show that under LN,
708 1251 fungal genes were up-regulated in Lo3 while they were 1247 in B73, including 548
709 transcripts up-regulated in both maize lines. In HN roots, 1596 fungal transcripts were up-
710 regulated in Lo3 and 1359 were up-regulated in B73 roots including 609 genes up-regulated
711 in both maize lines. In both maize lines, the functional categories overrepresented in *R.*
712 *irregularis* DEG were similar in each N nutrition condition Figure 8C. However, an important
713 remodelling in *R. irregularis* overrepresented DEG functional categories in response to N
714 supply was observed. For example, fungal genes up-regulated under LN were involved in
715 nuclear structures, vesicular trafficking, translation and transcription, whereas those up-
716 regulated under HN had a role in metabolic activity of primary and secondary metabolism, in
717 particular nucleotide and lipid metabolism. Only few maize line-specific functional categories
718 could be observed. For instance, defence mechanisms was a functional category of *R.*
719 *irregularis* DEGs specifically expressed in Lo3. These data show that the fungal
720 transcriptome is strongly affected by the nutritional N status of the host and the soil. Among
721 the DEG functional categories, several genes were involved in amino acid and nucleotide

722 metabolism and transport as well as in inorganic transport. We focused on the expression
723 profiles of nucleotide and amino acid metabolism genes and transporter genes as well as
724 phosphate and ammonium acid transport genes. Supplementary Table 7 shows the
725 expression pattern of these fungal genes. Interestingly, fungal ammonia transporters are
726 more highly expressed under LN than under HN. We did not find any fungal nitrate
727 transporter genes in the differentially expressed AMF genes. The fungal amino acid
728 biosynthetic genes up-regulated are mainly involved in asparagine, arginine, glutamine,
729 glutamate and serine pathways. Several fungal amino acid transporter genes were found to
730 be up-regulated either in LN or HN roots. The fungal nucleotide biosynthesis genes up-
731 regulated in HN roots are related to pyrimidine de novo biosynthesis or salvage pathways.

732 **Discussion**

733 To better understand the biological and genetic basis of how AMF improve maize N nutrition,
734 we investigated the physiological and molecular responses of different maize genotypes
735 when they are inoculated with the AMF *R. irregularis* under different N supply conditions. In
736 our study, the first interesting result was to find an increase in kernel yield in the two maize
737 lines B73 and Lo3 inoculated with *R. irregularis* when N nutrition is reduced. We showed that
738 a symbiotic association with *R. irregularis* was able to compensate for decreased maize plant
739 performance when N fertilization is reduced. In the literature, depending on both the N supply
740 level and the form of N supplied, different effects on yield and/or biomass production have
741 been reported, including an increase, no effect, or a reduction in productivity when the plant
742 develops a symbiotic association with an AMF (Ingraffia *et al.*, 2020; Quiroga *et al.*, 2020;
743 Yooyongwech *et al.*, 2022). In the present investigation, we estimated that kernel yield can
744 be maintained with a 2- to 5-fold reduction in N input when two maize lines were inoculated
745 with *R. irregularis*. Such a beneficial impact was previously observed for maize plant biomass
746 production under low N fertilizer inputs (Quiroga *et al.*, 2020). One can, therefore, conclude
747 that the positive impact of AMF on plant performance can be variable depending on the AMF
748 and the host genotype as well as the level and type of available N source (Verzeaux *et al.*,
749 2017; Ingraffia *et al.*, 2020; Xie *et al.*, 2022).

750 Our transcriptome study allowed us to provide an overview of biological processes putatively
751 involved during the establishment of a symbiotic association between the AMF *R. irregularis*
752 and maize. In the leaves of inoculated plants, four maize genes were found to be
753 differentially expressed irrespective of the N-feeding conditions and the genotype
754 (Zm00001d015569, Zm00001d043505, Zm00001d010039, Zm00001d006835). Although
755 these four genes did not allow us to identify a core biological process occurring in inoculated
756 plants, their function was representative and biologically relevant to an interaction with an
757 AMF such as biomass production (Zm00001d015569) (Menadue *et al.*, 2021), cytokinin
758 signaling (Zm00001d043505) (Yonekura-Sakakibara *et al.*, 2004), cell wall remodeling

759 (Zm00001d010039), nitrate transport and flowering (Zm00001d006835) (Su *et al.*, 2018;
760 Cheng *et al.*, 2021).

761 Whatever the level of N fertilization or the maize lines, the core DEGs that were either up or
762 down-regulated in roots were enriched in transcripts encoding proteins involved in a variety
763 of biological functions : defense, hormone signaling (especially jasmonate and cytokinin), N
764 and C metabolism, cell wall and chromatin remodeling, proteolysis inhibition, metal
765 homeostasis, phenylpropanoid and lipid metabolism. Similar results were previously obtained
766 in several other model and crop species, indicating that most of these biological functions are
767 shared when plant develop symbiotic associations with AMFs (Fiorilli *et al.*, 2009; Gallou *et*
768 *al.*, 2012; Schaarschmidt *et al.*, 2013; Meng *et al.*, 2015; Handa *et al.*, 2015; Vangelisti *et al.*,
769 2018; Kaur and Suseela, 2020; Wang *et al.*, 2020; Hui *et al.*, 2022). In particular, the most
770 highly up-regulated genes in roots of B73 and Lo3 under both N nutrition conditions in
771 response to *R. irregularis* inoculation are encoding peptidases, peptidase inhibitors,
772 chitinases and senescence genes (Supplementary Table 10a and b). Interestingly,
773 autophagy genes are overrepresented in Lo3 genes up-regulated in roots under LN following
774 inoculation with *R. irregularis* (Supplementary Table 9, Figure 5). These data suggest that
775 important proteolysis processes are taking place in inoculated roots that may involve
776 autophagy especially in the Lo3 maize line. Autophagy is a process known to recycle N
777 during senescence, and is known to provide N assimilates necessary for maize kernel filling
778 (Li *et al.*, 2015; Masclaux-Daubresse *et al.*, 2017).

779 Changes in the level of expression of genes involved in sugar, amino acid, and lipid
780 metabolism were confirmed by metabolomics analyses (Supplementary Figure 8 and 9).
781 Under HN, the amounts of root soluble carbohydrates sucrose, fructose, and glucose were
782 lower in inoculated plants compared to controls, which is consistent with the export of C-
783 containing molecules to the fungus. As this did not occur under LN, one can hypothesize that
784 the roots and/or the fungus do not constitute an important sink for C or that the plant limits
785 fungal proliferation under N-limiting conditions. Under LN, genes involved in the control of

786 plant immunity were up-regulated in roots of inoculated plants, especially in line B73, which
787 is consistent with the accumulation of shikimic acid (Supplementary Figure 8). Both
788 transcriptomic data and metabolomics data show modifications in lipid metabolism and the
789 accumulation of lipids in roots. In roots, when N fertilization was not limiting, we observed an
790 accumulation of two lipids: trans-13-octadecenoic acid and palmitoleic acid (Supplementary
791 Figure 8). Lipid accumulation in roots colonized by AMFs was already observed (Keymer *et*
792 *al.*, 2017; MacLean *et al.*, 2017), notably in *R. irregularis*, to which their reduction and
793 transfer from the host to the fungus is considered to be a way of fueling the symbiotic fungus
794 with a carbon source other than sugars (Keymer *et al.*, 2017; MacLean *et al.*, 2017). In the
795 present study, lipid accumulation occurred only under HN, which is consistent with the fact
796 that due to higher photosynthetic activity, as revealed by the accumulation of soluble
797 carbohydrates, the plant is able to synthesize more fatty acids to feed the fungus. In
798 inoculated plants, arginine (Arg), known to be a key molecule involved in the transfer of N
799 from the fungus to the plant (Chen *et al.*, 2018a; Kaur and Suseela, 2020; Dellagi *et al.*,
800 2020; Xie *et al.*, 2022), accumulates under HN conditions not only in the roots of line B73 HN
801 but also in the leaves.

802 Unexpectedly, another process that appears to be playing a crucial role in AMF symbiosis is
803 pyrimidine biosynthesis. Our transcriptomic analysis demonstrates that, regardless of
804 nitrogen feeding conditions, pyrimidine biosynthesis processes are consistently
805 downregulated in leaves of inoculated plants (Figure 5). Furthermore, under low nitrogen
806 (LN) conditions, several key genes encoding enzymes involved in nucleotide metabolism,
807 including carbamoyl-phosphate synthase (Witte and Herde, 2020b), are downregulated in
808 both leaves and roots (Supplementary Table 8). For example, maize carbamoyl-phosphate
809 synthase genes *Zm00001d044250* *Zm00001d011192* are downregulated in B73 roots when
810 inoculated with *R. irregularis* under LN conditions (Supplementary Table 8). A critical gene in
811 this context is *Zm00001d023833*, encoding a putative nucleoside diphosphate kinase
812 (NDPK), which participates in pyrimidine and purine nucleotide salvage (Witte and Herde,

813 2020a). This enzyme was identified as a metabolic bottleneck relieved by AMF inoculation
814 (Figure 7). More precisely, the reactions relieved by *R. irregularis* inoculation corresponds to
815 those indicated in Figure 7. In non-inoculated maize plants under LN, this maize *NDPK* gene
816 is up-regulated in leaves compared to HN suggesting that pyrimidine salvage is activated
817 under LN to help plants cope with N Limitation (Supplementary Table 8). On the contrary, in
818 the symbiotic association, *NDPK* gene expression remains unaltered compared to
819 uninoculated LN, suggesting the absence of constraints on this enzymatic reaction in
820 symbiotic plants (Supplementary Table 8). The level of β -Ala, a known product of purine
821 degradation drops in inoculated LN and HN roots suggesting that *R. irregularis* inoculation
822 represses the degradation of nucleotides.

823 In line with these data, fungal transcriptomic analysis by RNAseq shows that pyrimidine and
824 ureide metabolism play a crucial role in the symbiosis with regard to N nutrition. The fungal
825 metabolism appears to differ depending on N supply. The integration of maize and fungal
826 RNAseq and metabolome analyses has allowed us to construct a simplified model depicting
827 the various biological events occurring in the symbiotic association (Figure 9). Under LN,
828 fungal argininosuccinate lyase, carbamoyl-phosphate synthase and arginase genes are
829 upregulated, potentially leading to urea accumulation. However, urea level drops in LN
830 inoculated roots a fact that is consistent with higher expression of *R. irregularis* urease under
831 LN. It is thus likely that under LN, the major way the fungus provides plant with N is based on
832 its urea cycle followed by urea conversion into ammonium which is then transferred to the
833 plant.

834 Under HN, several amino acids accumulate in response to fungal inoculation in roots (Gln,
835 Glu, Asn, Arg, Citr, Orn). Fungal pyrimidine de novo biosynthetic genes and the pyrimidine
836 salvage pathway are upregulated in HN roots. This suggests that under HN, the fungus
837 activates the metabolism of nucleotide monophosphate biosynthesis that may then be
838 transferred to the plant. The transfer of nucleotides from the fungus to the plant could also

839 take place under LN but to a lower extent because metabolic modeling identified the NDPK
840 enzyme as being the metabolic bottleneck relived by *R. irregularis* inoculation under LN.

841 On the other hand, allantoin accumulates exclusively in HN roots and its level remains
842 unaffected by inoculation. This metabolite can be converted into allantoic acid, which may be
843 released into the apoplast (Tegeder, 2014). A fungal allantoicase is upregulated in HN roots,
844 indicating possible conversion of allantoic acid into urea under HN conditions. This transfer of
845 ureides is akin to the process observed in symbiotic associations between tropical legumes
846 and Rhizobia species (Tegeder, 2014). Previous studies have also identified upregulation of
847 genes involved in allantoin synthesis in roots of AMF-inoculated plants (Nanjareddy *et al.*,
848 2017). Consequently, it is plausible that ureide transfer mirrors that occurring in legume
849 nodules.

850 Fungal arbuscules are known to undergo controlled senescence (Choi *et al.*, 2018; Paries
851 and Gutjahr, 2023), our data suggest that autophagy is upregulated in maize roots, with
852 higher expression in Lo3 LN roots (Supplementary Table 9). Autophagy likely contributes to
853 the degradation of fungal cellular products, potentially releasing nucleosides. The fungal
854 nucleotide salvage process can then recycle nucleosides that may repress de novo plant
855 pyrimidine biosynthesis pathways (Tegeder, 2014; Witte and Herde, 2020*b*). This implies
856 that AMF likely supplies the host plant with nucleotides and nucleosides, potentially
857 pyrimidines, to circumvent the deficiency in NDPK activity, thereby alleviating the associated
858 metabolic bottleneck. This observation is consistent with the known role of NDPK in plant
859 survival with respect to pyrimidine salvage (Tegeder, 2014; Witte and Herde, 2020*a*). It is
860 noteworthy that pyrimidine biosynthesis can be an essential process for plant N management
861 (Zrenner *et al.*, 2006; Fernie *et al.*, 2020).

862 Pyrimidine metabolism holds significance not only in crop performance but also in nitrogen
863 use efficiency (NUE) (Tegeder, 2014; Lee *et al.*, 2018; Melino *et al.*, 2022). Recent findings
864 demonstrate a correlation between maize leaf nitrogen accumulation and NDPK protein
865 levels (Urrutia *et al.*, 2023), further supporting the hypothesis that *R. irregularis* stimulates the

866 reprogramming of plant pyrimidine metabolism to enhance maize performance under
867 nitrogen-limiting conditions.

868 In conclusion, we propose that inoculating maize with *R. irregularis* offers a promising
869 strategy to significantly reduce nitrogen fertilizer usage while maintaining maize kernel yield.
870 Our findings highlight a metabolic interplay between the host and AMF, with pyrimidine and
871 ureide metabolism serving as key players in this interaction (BARROSO *et al.*, 1988; Thakur
872 and Garg, 2023). Furthermore, the observed differences in how our two studied maize lines
873 embrace different strategies to benefit from the fungus illustrate the importance of leveraging
874 maize's extensive genetic diversity for a comprehensive understanding of this symbiotic
875 interaction (Schmidt *et al.*, 2016; Sawers *et al.*, 2018*b*; Liu *et al.*, 2020).

Figure 5 : Gene ontology of the enriched functional categories in the common DEGs. A: Leaf genes. B: Root genes. Common DEGs were selected so that they have the same pattern of regulation (up or down) in the different conditions with a fold change (FC) >1.5. FC represents the ration of expression of each gene in *R. Irregularis* inoculated tissues versus the mock control tissues. There were only 2 genes in the common DEGs in leaves thus, they were not included in the GO analyses. Each bar represents the fold enrichment in the indicated category obtained by <https://pantherdb.org/>. Only categories enriched more than 2 fold and displaying more than 2 genes are represented with p -value of enrichment < 0.05.

Figure 7: Genome based metabolic modeling reveals essential impact of AMF on pyrimidine metabolism. **A:** RNAseq data were used to predict different organ growth rates in the B73 maize line. Ctrl: Mock non inoculated control, Rhizo: inoculated with *R. irregularis*, EXTREAM algorithm predicted higher yield under LN in B73. **B** and **C:** Venn diagrams showing the metabolic bottlenecks under indicated conditions highlighting the debottlenecked reactions by uninoculated HN versus uninoculated LN (**B**) and by *R. irregularis* inoculation under LN vs uninoculated LN (**C**). **D:** Metabolic reactions in the pyrimidine pathway de-bottlenecked by *R. irregularis* inoculation and by HN treatment shown in **B** and **C**. P: Plastid compartment. C: Cytosolic compartment.

979
980 **Figure 8 : *Rhizophagus irregularis* transcriptome in maize roots is shaped by N supply.** Plants were grown
981 and harvested as indicated in materials and methods under low nitrate (LN, 1mM NO₃⁻) or high nitrate (HN, 10mM
982 NO₃⁻). Roots inoculated with *R. irregularis* were harvested at VT+15 as indicated in materials and methods. DEGs
983 were selected so that they have a fold change (FC >1.5). **A** : Up in LN indicates *R. irregularis* genes that are more
984 highly expressed in inoculated LN roots compared to inoculated HN roots. **B**: Up in HN indicates *R. irregularis*
985 genes that are more highly expressed in HN compared to LN. **C**: Gene ontology of functional categories
986 enrichment was based on KOG annotations of encoded *R. irregularis* proteins (see materials and methods). Each
987 bar represents the functional category enriched in the given condition. p-value of enrichment was < 0.05; only
988 categories enriched more than 2 fold and displaying more than 2 genes are represented and used to build the
989 heatmap. The color scale indicates the over-representation or the down-representation in red and blue
990 respectively.

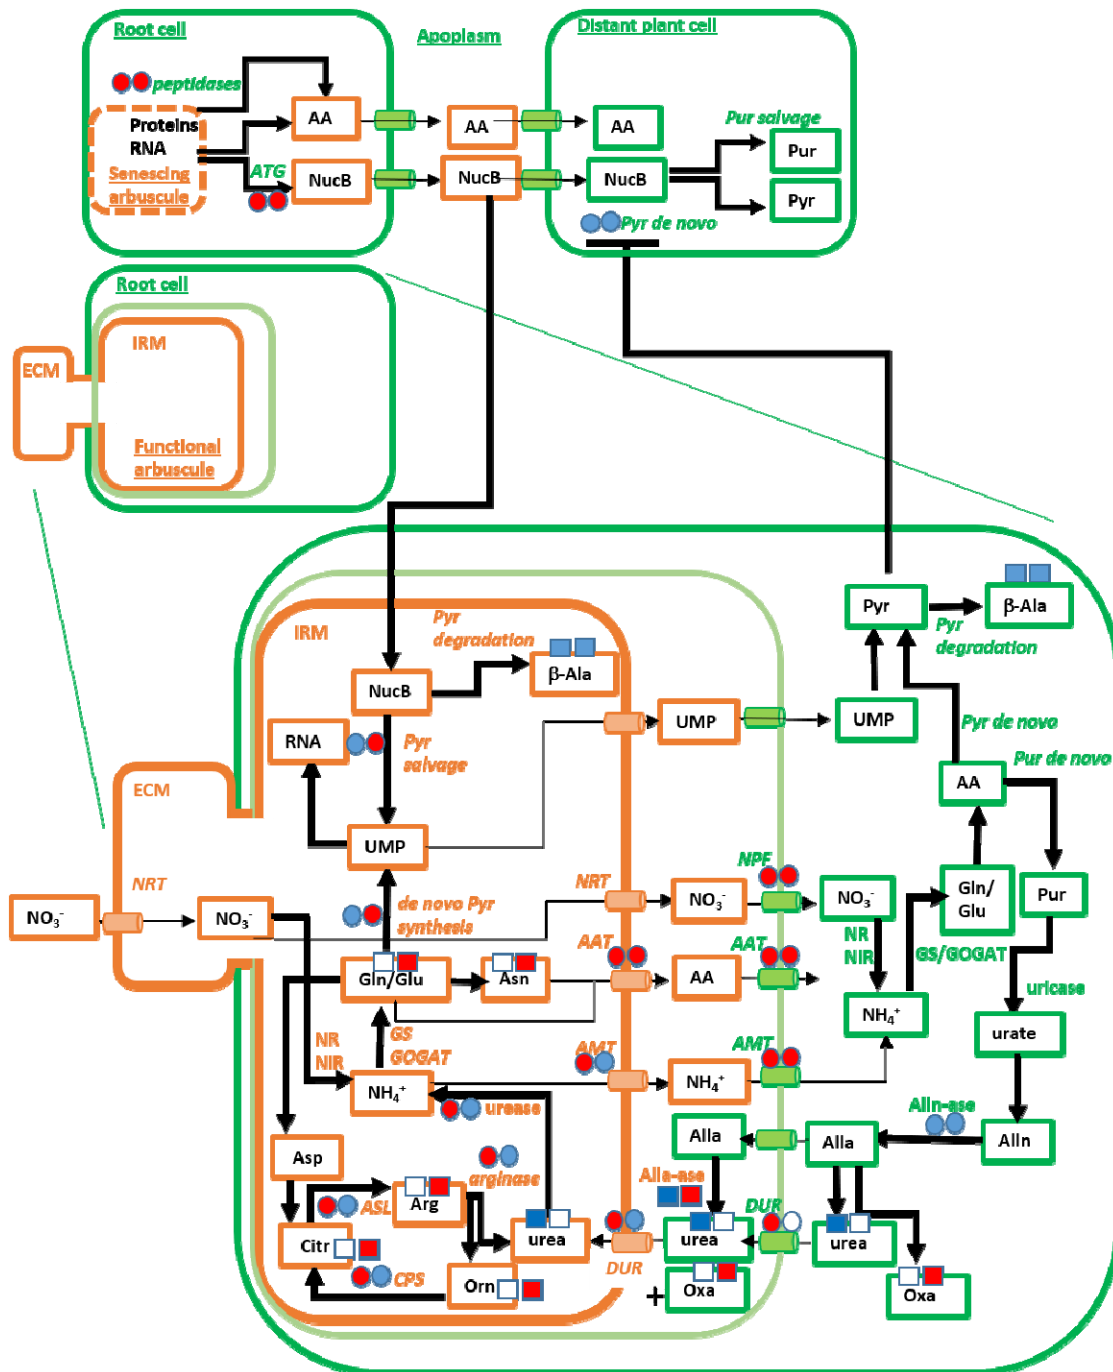

Figure 9: Hypothetical working model for maize and *R. irregularis* N nutrition under LN and HN.

To build the model, the metabolomic data from B73 and Lo3 maize lines were pooled for simplification (Supplementary Figure 10) and we used genes in Supplementary Tables 7 and 8. In some cases genes with multigene families such as Glutamine Synthetase encoding genes have different expression profiles. For simplification purposes, these cases were not considered in the hypothetical mechanistic model below.

- Under LN fungal RNAseq data indicate up regulation of amino acid transporters (AAT) and ammonium transporters (AMT). Fungal argininosuccinate lyase (ASL) and arginase genes are up regulated under LN, which could lead to urea accumulation. A fungal urea transporter (*DUR*) is upregulated under LN, it is likely to be expressed in the IRM but could

991
992
993
994
995
996
997
998
999
1000
1001
1002
1003

1004 also be expressed in the ECM. Usually DUR is an exporter of urea, it remains to be
1005 determined how this *R. irregularis* DUR transporters acts during AM symbiosis. However,
1006 urea is probably further degraded into ammonium by urease since the fungal urease
1007 coding gene is up regulated under LN. This could explain the fact that under LN, *R.*
1008 *irregularis* inoculated roots accumulate less urea. Globally lower amounts of amino acids
1009 are found in LN roots which suggests less assimilation via GS-GOGAT in the fungal and
1010 inoculated plant root cells. The fungal RNAseq data indicate that pyrimidine de novo
1011 biosynthetic genes are down regulated under LN compared to HN but still expressed (for
1012 example, UMP synthase, orototote phosphorybolsyl transferase) as well as the pyrimidine
1013 salvage pathway (for example, dUTPase, allantoicase, deoxycitydylate deaminase,
1014 cytosine deaminase). These data suggest that under LN, the fungus redirects its N
1015 metabolism in order to provide NH_4^+ to the plant cell, but may also provide nucleosides to
1016 plant cells.

1017 -Under HN, high amounts of NO_3^- are available to the fungus and to the plant. Fungal RNAseq
1018 data indicate up-regulation of some amino acid transporters that are different from those
1019 up-regulated in LN, down regulation of ammonium permeases. Fungal argininosuccinate
1020 lyase and arginase genes are down-regulated under HN, which could lead to urea
1021 accumulation. A fungal urea transporter is down-regulated under HN. We observe a global
1022 increase in the amounts several amino acids including Citr, which is a precursor of Arg. Arg
1023 and Asn accumulate in inoculated roots indicating that fungal and/or plant assimilation
1024 via GS-GOGAT are probably upregulated under HN in response to the fungus. The fungal
1025 RNAseq data indicate that in HN roots, pyrimidine de novo biosynthetic genes are up-
1026 regulated (for example, UMP synthase, orototote phosphorybolsyl transferase) as well as
1027 the pyrimidine salvage pathway (for example, dUTPase, allantoicase, deoxycitydylate
1028 deaminase, cytosine deaminase). Allantoin accumulates only in HN roots and not in LN
1029 roots, and its amount is not affected by inoculation in HN roots. Allantoin can be converted
1030 into allantoic acid which can be released in the apoplast. In HN roots a fungal allantoicase
1031 is up-regulated suggesting that urea is produced by this pathway under HN.

1032 -In italics, genes. In boxes: metabolites. In orange : fungal genes or metabolites. In green :
1033 plant genes or metabolites. In front of genes and metabolites there are two squares. The
1034 square at the left indicates the status of the item under LN. The square at the right
1035 indicates the status of the item under HN. The circles at the left indicates the status of the
1036 gene expression under LN. The circle at the right indicates the status of the gene
1037 expression under HN. AA: Amino acids. NucB: Nucleobases. Pur: Purine. Pyr: Pyrimidine.
