Abstract: Freshwater ecosystems are among the most important ecosystems worldwide, however, over the last centuries, anthropogenic pressures have had catastrophic effects on them. Mercury (Hg) is one of the main environmental contaminants which globally affect ecosystems and particularly freshwater wildlife. While Hg originates from natural sources, anthropogenic activities such as agriculture, biomass combustion, and gold mining increase its concentrations. Gold mining activities are the main drivers of Hg emission in tropical ecosystems and are responsible for up to 38% of global emissions. Once in its methylated form (MeHg), mercury biomagnifies through the trophic chain and accumulates in top predators. Due to the toxicity of MeHg, long-lived predators are even more subjected to chronic effects as they accumulate Hg over time. In the present study we quantified Hg contamination in two top predators, the Black caiman *Melanosuchus niger* and the Agami heron *Agamia agami*, and in their prey in the Kaw-Roura Nature Reserve in French Guiana and evaluated the biomagnification rate in the trophic chain. Our results show that despite a TMF in the range of others in the region (4.38 in our study), top predators of the ecosystem present elevated concentrations of Hg. We have found elevated Hg concentrations in the blood of adult Black caiman ($2.10 \pm 0.652 \mu\text{g.g}^{-1} \text{ dw}$) and chicks of Agami heron ($1.089 \pm 0.406 \mu\text{g.g}^{-1} \text{ dw}$). These findings highlight the need to better evaluate the potential impact of Hg in freshwater top predators, especially regarding reprotoxic effects.

Keywords: Freshwater ecosystems, Trace elements, Trophic chain, Agami heron, Black caiman, Top predators

Introduction

Freshwater ecosystems are among the most important ecosystems worldwide as they host more than 10% of the world's fauna and one third of all vertebrates¹, and provide valuable ecosystem services^{2,3}. However, freshwater ecosystems have been profoundly altered over the last centuries due to anthropogenic pressures such as urbanization, extraction of resources, and agriculture, leading to direct habitat destruction, loss of ecosystem services, and environmental pollution^{4,5}.

Among the main pollutants, mercury (Hg) is worrying as it is a pervasive contaminant which is found in all ecosystems worldwide. Mercury originates from natural geological sources and anthropogenic activities⁶, where artisanal small scale gold mining (ASGM) represents the major anthropogenic source of Hg with 38% of global Hg emissions, and up to 80% in tropical ecosystems^{7,8}. In anoxic conditions, inorganic Hg is methylated by microorganisms into methylmercury (MeHg), its most bioavailable and toxic form^{9,10}. MeHg biomagnifies through the food chain and accumulates in tissues of top predators, making them particularly vulnerable to its toxic effects¹¹. The rate of Hg biomagnification in ecosystems is linked to the latitude of these ecosystems, physico-chemical parameters, and the pool of Hg present in the ecosystem¹². In general, tropical ecosystems have lower biomagnification factors than temperate ecosystems¹², however, several studies have showed that Hg concentrations in top predators in tropical regions are high^{13,14,15,16,17,18}.

Mercury toxicity encompasses a large variety of deleterious effects on human and wildlife health. In 1965, Hg toxicity was revealed due to human poisoning through fish consumption contaminated by MeHg, later called the Minamata disease, a major disaster in human history. Further, Hg toxicity on wildlife and the environment has been demonstrated many times and it is well admitted that environmental Hg contamination represents a global threat for

ecosystems and human welfare worldwide^{11,19}. Many countries took steps to monitor and regulate Hg and finally, scientific evidence of the toxicity of this metal for the environment led to the Minamata Convention, which aims to reduce the use and release of Hg into the environment^{20,21}. In 2013, around 140 countries have approved the Minamata Convention on Mercury. In wildlife, Hg is known to disrupt endocrine regulation, brain function, growth, normal cellular function, physiology, reproduction, and behaviour^{22,23,24,25}. Long-lived predators are even more subjected to chronic Hg effects as they bioaccumulate the contamination they are exposed to over several decades. However, chronic effects of Hg contamination in tropical species remain understudied.

French Guiana's Kaw-Roura Nature Reserve, a vast wetland ecosystem, hosts two emblematic top predators: one of the biggest remaining populations of Black caiman *Melanosuchus niger*, and the second one being the biggest breeding population of Agami heron *Agamia agami* in French Guiana²⁶. However, information on Hg contaminations in these two top predators and their know prey is poor. To the best of our knowledge, there is only one recent study on *Melanosuchus niger* in the Guiana Shield, which has revealed the highest Hg concentrations that have so far been documented in South American caimans²⁷. Such elevated Hg concentrations represent a major threat for both Black caiman and Agami heron populations, herons being also prey of caimans. Additionally, natural Hg richness of soil, and intensive gold mining activities in French Guiana are increasing pressure the contamination of this particular ecosystem.

The goals of our study are first to quantify the Hg contamination of these two top predators and their prey and second, to evaluate the biomagnification rate of the trophic chain to better understand the risk related to Hg contamination in this ecosystem.

Material and Methods

Sampling

The study was carried out in the Kaw-Roura Nature Reserve in French Guiana, a vast marsh dominated by floating vegetation, located 40km southeast of Cayenne (Fig. 1). Sampling was performed in one of the permanent open water areas, namely Agami Pond (04° 38' N, 52° 09' W), which is equipped with a floating research platform (6x4m). One of the particularities of the area is that Agami Pond is inhabited by the biggest known population of Black caiman in French Guiana and additionally hosts a large breeding colony of Agami herons during the rainy season.

Sampling of the food web was initially carried out as part of another study²⁸ and included 12 different species, from plankton to adult caimans (Table 1). Briefly, Black caimans were captured at night, and for each individual the body length was determined (total length) and whole blood was collected from the cranial sinus using a syringe with a 30-gauge heparinized needle. Newly hatched Agami heron chicks were taken directly from their arboreal nests and three drops of whole blood from the femoral vein were collected using heparinized capillary tube. Fishes were collected using nets and rods, then we took a sample of dorsal muscle for large species and the entire individual for smaller species.

Mercury analysis

All samples (including whole blood, muscle and whole individual) were freeze-dried for 48h, ground in powder and homogenized. Total Hg was determined using an atomic absorption spectrometer AMA-254 (Advanced Mercury Analyser-254; Altec®). Analyses were made on at least two replicates of 0.8 to 8.0 mg dry weight (dw) for each individual. The reproducibility for duplicate samples was approved when Relative Standard Deviation (RSD) was below 10%.

At the beginning and at the end of each analytical cycle, and every 10 samples, an analysis of certified reference material TORT-3 (Lobster hepatopancreas from the National Research Council of Canada; certified Hg concentration: $0.292 \pm 0.022 \mu\text{g.g}^{-1}$ dw) was performed to validate the method. Measured values for TORT-3 were $0.292 \pm 0.002 \mu\text{g.g}^{-1}$ ($n = 20$), giving a recovery of $100.5 \pm 2.1 \%$. Blanks were included at the beginning of each analytical run and the limit of quantification of the AMA was 0.05 ng. Hg concentrations are further expressed in $\mu\text{g.g}^{-1}$ dw. Hg concentrations in zooplankton were not determined due to insufficient material to carry out the analyses.

Isotope analysis

An analysis of nitrogen and carbon stable isotopes was conducted on samples after being freeze-dried and then grounded to a fine powder. Aliquots of 0.3 – 0.4 mg were placed in tin capsules. Stable isotopes were analysed using a mass spectrometer (IsoPrime 100, Isoprime, UK) associated to C-N-S elementary analyser (Vario MICRO cube, Elementar, Germany). Stable carbon and nitrogen isotope ratios are expressed as $(\delta^{15}\text{N})$ or $(\delta^{13}\text{C}) = \left[\left(\frac{R_{\text{sample}}}{R_{\text{standard}}} \right) - 1 \right] * 1000$, where R is $^{15}\text{N}/^{14}\text{N}$ or $^{13}\text{C}/^{12}\text{C}$ for $\delta^{15}\text{N}$ or $\delta^{13}\text{C}$. The replicate assays of internal laboratory standards indicated maximum measurement errors of $\pm 0.2 \text{ ‰}$ for both the nitrogen and carbon isotope measurements ($n = 10$).

Statistical analysis

All analyses were performed using the software R, v.4.2.2 (*R development Core Team*). The normality and the homogeneity of variance were first checked, and data were log (natural)-transformed for Hg concentration. *Melanosuchus niger* data were separated in four different groups depending on total length of animals, such as neonates < 50 cm (category A), 50 <

juveniles < 120 cm (category B), 120 cm < subadults < 200 cm (category C), and adults > 200 cm (category D), due to the shift in the species' trophic ecology²⁸. Differences in Hg concentrations (Log[Hg]) between species were assessed by ANOVA. Relationship between Hg concentrations (Log[Hg]) and the $\delta^{15}\text{N}$ values was assessed by linear regression.

The trophic level (TL) of each species was calculated according to the equation: $TL_{consumer} = (\delta^{15}\text{N}_{consumer} - \delta^{15}\text{N}_{baseline}) / \Delta^{15}\text{N} + \lambda$

where $\delta^{15}\text{N}_{consumer}$ and $\delta^{15}\text{N}_{baseline}$ are the isotope values of consumers and the lowest $\delta^{15}\text{N}$ of the sampled species (baseline), i.e., zooplankton as primary consumer (trophic level 2). λ is the trophic level of the organism used as $\delta^{15}\text{N}_{baseline}$ (= 2), and $\Delta^{15}\text{N}$ as the trophic enrichment factor in the food web, established at 3.4 ‰¹².

The Trophic Magnification Slope (TMS) value was obtained using the slope (b) of the relationship between Hg concentrations (Log[Hg]) and $\delta^{15}\text{N}$ values¹².

The Trophic Magnification Factor (TMF) was calculated following the equation: $TMF = 10^{(b * 3.4 \text{ ‰})}$, where b is the slope of the linear regression between Hg concentrations (Log[Hg]) and the $\delta^{15}\text{N}$ values, and 3.4 ‰ is an average increase in $\delta^{15}\text{N}$ with each trophic level¹². The TMF provides a mean rate of increase per trophic level in the studied food web and assumes that uptake is directly related to the diet as the main exposure route²⁹, where $TMF > 1$ indicates Hg biomagnification.

Relationships between Hg concentrations (Log[Hg]) and TL were assessed by linear regression.

Results

Mercury has been detected in the tissues of all specimen that were sampled and analysed as part of this study, with the exception of zooplankton, for which only isotopic analysis has been performed. Mercury concentrations were highly variable between species (ANOVA: $F_{13,121} =$

47.17, $p < 0.001$; Table 1), with the lowest Hg concentration in the muscle of the shrimp *Macrobrachium jelskii* (Palaemonidae) ($0.033 \pm 0.010 \mu\text{g}\cdot\text{g}^{-1} \text{ dw}$) and the highest Hg concentration in blood of adult Black caiman *Melanosuchus niger* ($2.10 \pm 0.652 \mu\text{g}\cdot\text{g}^{-1} \text{ dw}$).

Values of $\delta^{15}\text{N}$ ranged from $0.49 \pm 0.41 \text{ ‰}$ for zooplankton to $9.12 \pm 0.72 \text{ ‰}$ for the wolf fish *Hoplias malabaricus*, while $\delta^{13}\text{C}$ values ranged from $-32.81 \pm 2.20 \text{ ‰}$ for the tetra *Hemigrammus sp.* to $-27.07 \pm 1.19 \text{ ‰}$ for the aimara *Hoplerythrinus*.

Results showed a positive relationship between Hg concentrations and $\delta^{15}\text{N}$ values (Linear regression: slope = 0.11 ± 0.09 , $R^2 = 0.266$, $p < 0.001$). Based on the $\delta^{15}\text{N}$ value for zooplankton (i.e., $0.49 \pm 0.41 \text{ ‰}$), which has a TL of 2 as a primary consumer, the TLs of the other species were determined. The calculated TLs are given in Table 1.

The lowest TL was 2.86 ± 0.30 for the spotted silver dollar, *Metynnis lippincottianus* (Serrasalminidae), the highest TL 4.54 ± 0.21 for the wolf fish *Hoplias malabaricus* (Erythrinidae).

TMS obtained via linear regression between the logarithm of Hg concentrations and the $\delta^{15}\text{N}$ values was 0.11. Calculation from TMS has showed that TMF of Hg was 4.38 in the studied trophic food web (TMF: slope = 0.19 ± 0.02 , $R^2 = 0.266$, $p < 0.001$, Fig. 2).

Discussion

Mercury contamination in French Guiana's freshwater ecosystems has been extensively studied in fishes^{14,30,31,32,33}, mainly because fish represent a major source of exposure which poses a threat on local communities. In contrast, quantification of Hg concentrations and biomagnification and the assessment of impacts on top predators, such as birds and reptiles, remain limited to few studies^{34,35,36}. The present study site, Agami Pond, is home to two emblematic top predators of major conservation interest, the Agami heron *Agami agamia* and the Black caiman *Melanosuchus niger*, which underlines the importance to this marsh

ecosystem. Because Hg is highly methylated in the aquatic environment, these predators, which are positioned on top of the food chain, are expected to have high Hg concentrations and to consequently suffer from its deleterious effects.

The trophic magnification factor of Hg which we have found in Agami Pond (TMF = 4.38) is in the range of TMFs found in other freshwater ecosystems in French Guiana (e.g., “Petit Saut” TMF = 4.48, and “Sinnamary River” TMF = 4.38³⁷) and is in accordance with the global TMF in freshwater ecosystems (global TMF = 4.43 ± 4.48 ¹²). However, the TMF was higher than African subtropical wetland (TMF = 2.7)³⁸. Our results show that biomagnification of Hg occurring in Agami Pond is within a normal range when compared with other studies carried out in the region, and worldwide. However, it is important to acknowledge that due to permit restrictions when working in a nature reserve, the recommendation of three TLs to calculate the TMF was not reached and could limit the obtained results.

Mercury contamination in South America originates from natural sources, atmospheric deposition, and anthropogenic activities such as gold mining^{39,40}. In French Guiana, forest soils are known to have relatively high natural concentrations of Hg (mean of $0.3 \mu\text{g}\cdot\text{g}^{-1} \text{ dw}$ ⁴¹), which are increased by atmospheric deposition^{42,43}, and local gold mining activities⁴⁴. At our study site, Hg contamination seems to be mostly related to soil erosion from the mountain range “Montagne de Kaw” and high atmospheric deposition in the region^{12,45}, as recent gold mining activities are not present in this watershed. The Hg content observed in the trophic chain of this particular ecosystem cannot be attributed to specific human activities.

In our study, the shrimp *Macrobrachium jelskii* has the lowest Hg concentrations with $0.033 \pm 0.010 \mu\text{g}\cdot\text{g}^{-1} \text{ dw}$. This value is in accordance with the Hg concentrations found in the shrimp *Macrobrachium amazonicum* ($0.033 \pm 0.001 \mu\text{g}\cdot\text{g}^{-1} \text{ dw}$) in a natural environment in Brazil⁴⁶. In fishes, carnivorous species show the highest Hg concentrations with respectively 1.429 ± 0.688

$\mu\text{g.g}^{-1}$ dw for the wolf fish *Hoplias malabaricus*, and $1.614 \pm 1.093 \mu\text{g.g}^{-1}$ dw for the aimara *Hoplerythrinus unitaeniatus*. These Hg concentrations are in agreement with those reported in other publications on these two species in French Guiana^{33,34}. Although Hg concentrations we have found in fish are not the highest documented in French Guiana, even low Hg concentrations can have adverse effects on behaviour and reproduction, and can cause organ alteration and cellular injury, as numerous studies have shown^{47,48,49,50}, therefore needing further investigation.

As a piscivorous bird, *Agamia agami* shows relatively high blood Hg concentrations ($1.089 \pm 0.406 \mu\text{g.g}^{-1}$ dw) compared to other freshwater birds from the Brazilian Amazon region, where average blood values in adults and chicks range between $0.65 \pm 0.29 \mu\text{g.g}^{-1}$ dw in the neotropical cormorant *Nannopterum brasilianus* to $1.87 \pm 2.30 \mu\text{g.g}^{-1}$ dw in the anhinga *Anhinga anhinga*⁵¹. The Hg concentrations we have found in chicks of *Agamia agami* are worrying but are not exceed the threshold for Hg toxicity in birds (blood Hg concentration $9.6 \mu\text{g.g}^{-1}$ dw., converted from ww. to dw., using moisture content of 79,13%⁵²), for which an impact on physiology, reproduction, and behaviour has been observed^{53,54}. The potential reprotoxic effect of such Hg contamination in this large breeding population needs to be better understood, especially as *Agamia agami* is classified as vulnerable by the IUCN Red List of Threatened Species⁵⁵.

Despite our expectations, results have showed that *Melanosuchus niger* does not have the highest trophic level, though the highest Hg values were found in adults individuals (category D) with $2.100 \pm 0.652 \mu\text{g.g}^{-1}$ dw, while juveniles show low values of $0.365 \pm 0.092 \mu\text{g.g}^{-1}$ dw. To date, these values are the highest reported in a South American caiman species. Hg quantified in blood of vertebrates represents a proxy of MeHg (>80%^{56,57}), the most toxic form of Hg, concentrations found in the species can have drastic effects and therefore represent a

serious threat. It has already been shown that low levels of Hg in other caiman species from the same region can affect physiology ($0.676 \pm 0.414 \mu\text{g}\cdot\text{g}^{-1} \text{ dw}^{37}$), which ultimately stresses the importance of special attention on this Black caiman population.

In tropical ecosystems, efficiency of Hg trophic transfer is reduced at each trophic level, thus reducing biomagnification¹². The present high concentrations of Hg in adult caimans can potentially be explained by the particularity of the Agami Pond. At this site, large caimans feed on Agami herons during their breeding season, which increases their Hg contamination. Selenium (Se) has protective properties against Hg toxicity in organisms^{58,59}, however, blood Se concentrations in the *Melanosuchus niger* population in Agami Pond are low⁶⁰. These results highlight the need to assess Hg and Se in the Agami Pond food web in order to evaluate the potential impact of Hg contamination on this particular ecosystem.

Hg concentrations found in the Agami Pond food web suggest that the bioavailable, environmental concentrations of Hg remain high despite the absence of direct anthropogenic activities that could be responsible for this contamination. A comparative study on museum specimen from Kaw-Roura Nature Reserve to assess the evolution of Hg contamination in this particular ecosystem would be highly interesting. In addition, the levels of Hg found in the trophic chain, and particularly in *Agamia agami* and *Melanosuchus niger*, deserve further studies to assess potential long-term adverse effects of Hg contamination in these two long-lived species, particularly regarding the reprotoxic effect of this contaminant.

Acknowledgements

We would like to thank M. Bacques, S. Charles, V. François, D. Guiral, G. Lepoint, O. Marquis, M. Sarrazin, and N. Sturaro for their help in the field, and the Kaw-Roura Nature Reserve for logistical support. This work was supported by the “Office de l’Eau de Guyane”, the “Office

Français de la Biodiversité”, and the “Direction Générale des Territoire et de la Mer de Guyane“. We are grateful to C. Churlaud and M. Brault-Favrou from the “Plateforme Analyses Elémentaires” of the LIENSs for their assistance during mercury analysis. Thanks are due to the CPER (Contrat de Projet Etat-Région) and the FEDER (Fonds Européen de Développement Régional) for funding the AMA of LIENSs laboratory. PB is an honorary member of the IUF (Institut Universitaire de France).

Data availability statement

Data associated to the study is not deposited into a publicly available repository, however, data will be made available upon request.

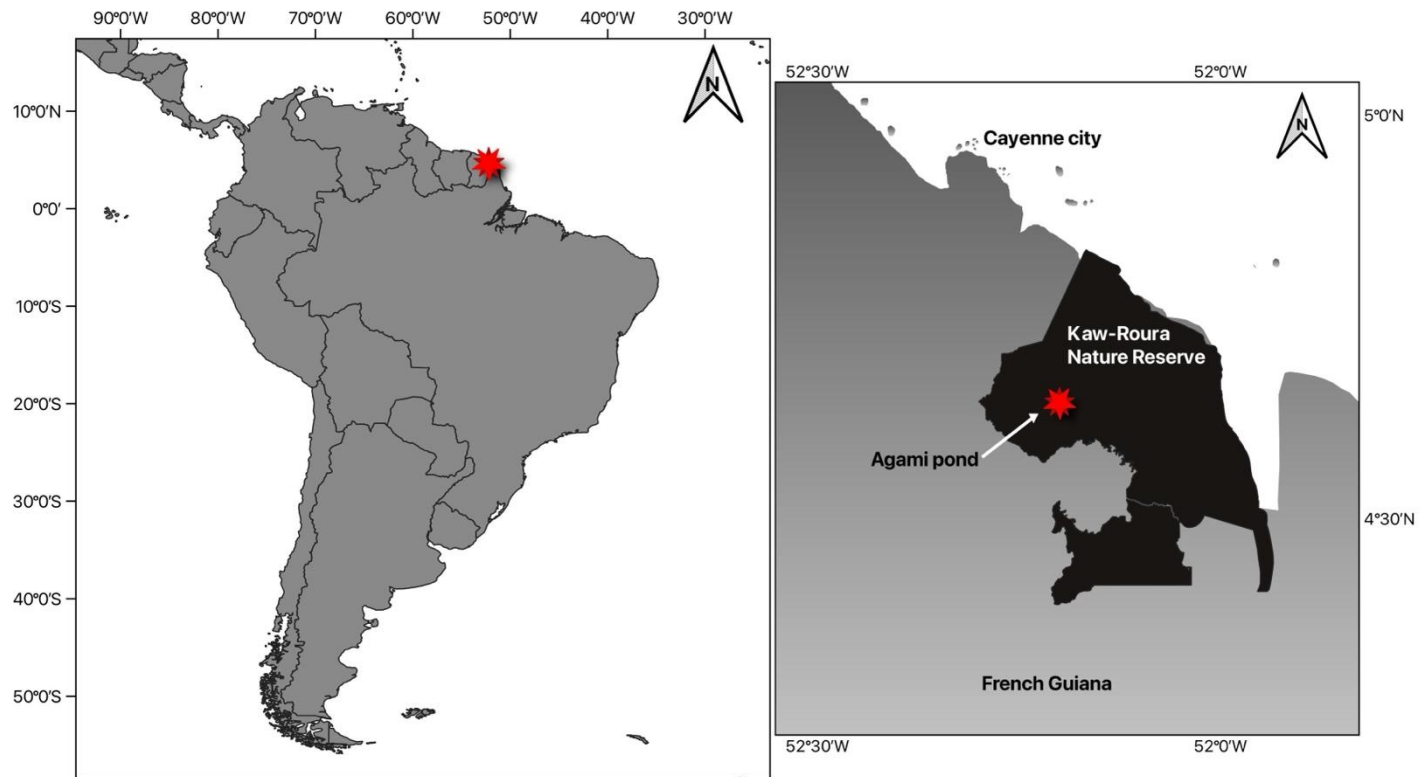

Figure 1. Location of Agami Pond in the Kaw-Roura Nature Reserve, French Guiana.

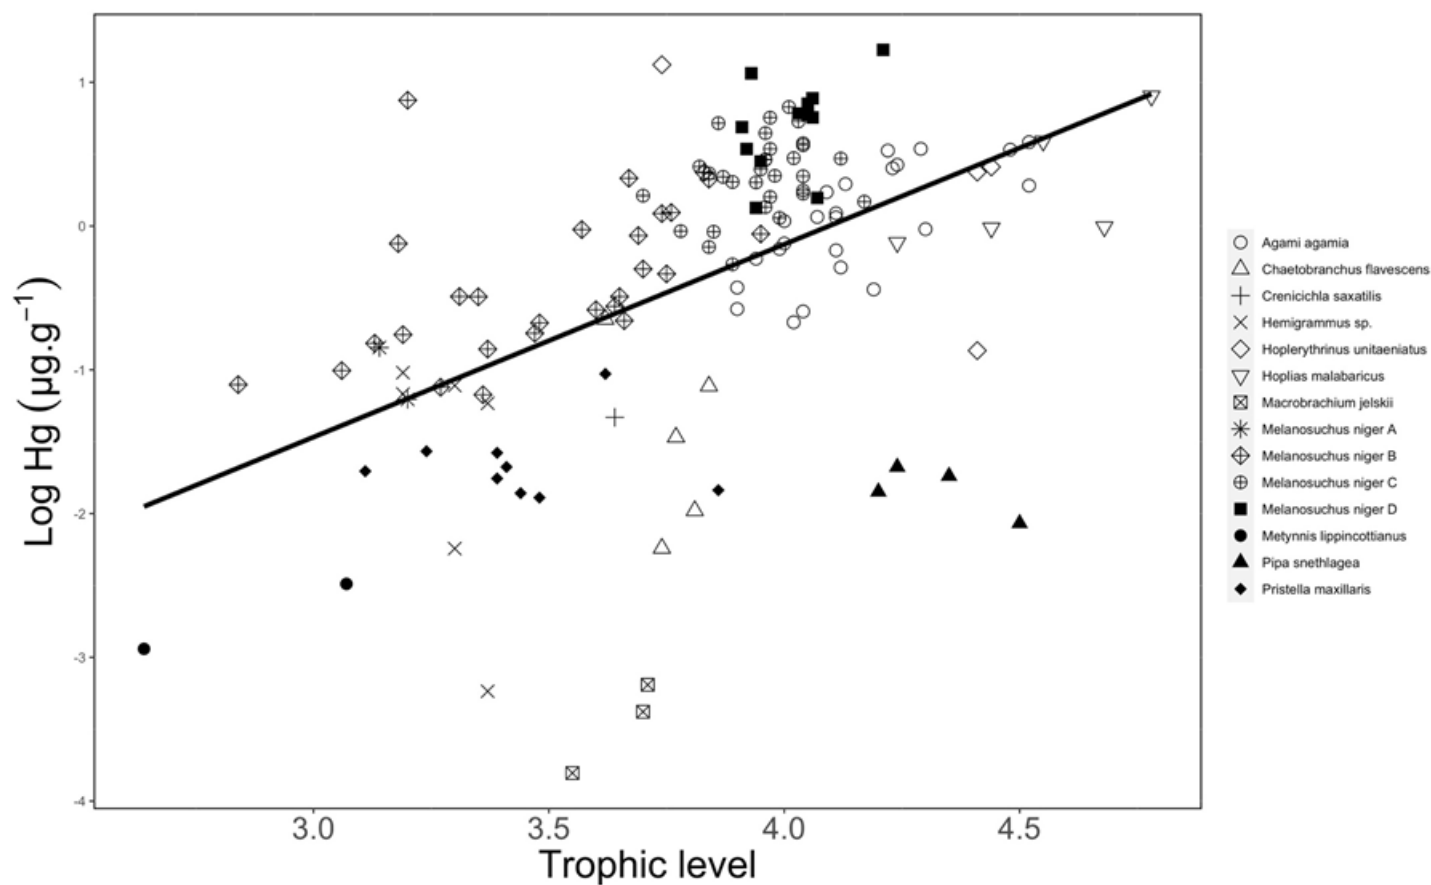

Figure 2. Linear regression between Log of Hg concentration ($\mu\text{g.g}^{-1}$ dw) and trophic level (TL) in the trophic chain of Agami Pond, Kaw-Roura Nature Reserve, French Guiana. Linear regression based on $\delta^{15}\text{N}$ (TMS): slope = 0.11 ± 0.09 , $R^2 = 0.266$, $p < 0.001$) and linear regression based on trophic level (TMF): slope = 0.19 ± 0.02 , $R^2 = 0.266$, $p < 0.001$.

Table 1. Mercury concentration ($\mu\text{g}\cdot\text{g}^{-1}$ dw), $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ (‰) values, and trophic level (TL) in different tissues of the trophic chain of Agami Pond, Kaw-Roura Nature Reserve, French Guiana.

Species	Tissue	n	Hg ($\mu\text{g}\cdot\text{g}^{-1}$)	$\delta^{15}\text{N}$ (‰)	$\delta^{13}\text{C}$ (‰)	TL
Zooplankton	-	-	-	0.49 ± 0.41	-30.30 ± 0.33
