Abstract

The correlation of molecular neuroimaging and behavior studies in preclinical PET imaging is of major interest to unlock progress in the understanding of brain processes and assess the validity of preclinical studies in drug development. However, fully achieving this ambition requires performing molecular images of awake and freely moving animals, whereas most of the preclinical imaging procedures are currently performed under anesthesia. To overcome this issue, the MAPSSIC project aims to develop a pixelated intracerebral probe to be implanted into awake and freely moving rats. The aforementioned probe relies on IMIC (Imageur Moléculaire Intra Cérébral), a Monolithic Active Pixel Sensor (MAPS) prototype set to directly detect positrons. The IMIC sensors were produced in 5 different configurations. Measurements using a ²⁰⁴Tl source showed that the sensor parameters can be optimized to boost its performance allowing to increase the sensitivity and reduce the average cluster size. In addition, comparisons between sensor configurations show a clear gain provided by the introduction of CMOS process modifications. Finally, the choice of the optimal sensor configuration will depend on the expected *in vivo* conditions.

Keywords: CMOS image sensors, Monolithic active pixel sensors, Particle detection, Beta Probe, Molecular imaging, Neuroimaging

1. Introduction

Performing neuroimaging on awake and freely moving animals could tighten the links between preclinical and clinical studies in neuroscience and even open the door to a powerful association between behavior studies and real time neuroimaging [1, 2], while the anesthesia remains an inherent limit to this day. Previous works have indeed emphasized that anesthetic drugs impact the ability of PET brain imaging to accurately represent the activity of the awake and freely moving rodent's brain [3, 4]. To overcome anesthesia's potential biases on brain processes, approaches have been developed, mainly focusing on micro-PET devices [5, 6, 7, 8]. A complementary approach

22 consists in using β^+ sensitive implantable microprobes [9]. This kind of device takes advantage of its *in situ* position
23 and good sensitivity to provide images of a radiotracer's distribution in the implanted structures based on a direct
24 detection of positrons. This allows to generate reliable time activity curves based on local measurements and
25 provides precious information about the molecular exchanges in the brain.

26 Various types of β^+ sensitive microprobes using passive pixels have been developed in the past [10, 11, 12, 13] but
27 had some noticeable drawbacks. Among them, a non-negligible sensitivity to γ -rays as well as a high contribution
28 of background noise. Considering these limitations, Monolithic Active Pixel Sensors (MAPS) appear to provide a
29 powerful approach for such instruments as the amplification and the signal conversion are integrated within the pixel,
30 thus reducing the noise and increasing the sensitivity. Furthermore, the low density of the silicon combined with the
31 limited sensitive thickness allows to significantly reduce the γ -ray sensitivity [9]. Finally, previous studies have shown
32 that such a sensor features low energy dissipation, which makes it compatible with an *in vivo* implantation [14, 15].

33 This paper describes the physical characterization of IMIC (Imageur Moléculaire Intra Cérébral), a MAPS array
34 developed for rat brain imaging. It is available in five configurations, which differ in terms of active layer thicknesses
35 as well as in the CMOS processes used for their fabrication. These variations were introduced in order to optimize
36 the charge collection and the sensitivity, aiming to improve their overall performances.

37 **2. Material & methods**

38 *2.1. IMIC sensor description*

39 *2.1.1. General characteristics*

40 The MAPSSIC probe relies on two 610 μm wide, 14700 μm long and 200 μm thick MAPS called IMIC [9, 14, 15].
41 The pixel front-end is derived from the ALPIDE chip developed for the ALICE experiment at the CERN Large
42 Hadron Collider [16]. The sensitive area contains 16×128 pixels of dimensions $30 \mu\text{m} \times 50 \mu\text{m}$ separated in the
43 middle by a 14.73 μm vertical gap accommodating the digital part driving the readout of the pixels. The pixel
44 array is surrounded by a non sensitive silicon area of around 45 μm to 60 μm on the left and right sides and
45 80 μm at the bottom end of the sensor, enclosed by a guard ring. An approximately 10 μm thick CMOS electronic
46 precedes the epitaxial layer that acts as a particle detector. All pixels use a binary readout (1 bit) of hits passing
47 a globally set energy threshold. The readout of the matrix is done in a rolling shutter manner with an adjustable
48 readout frequency. The integration time can vary from 600 μs to 65 s in the current configuration. A pulse injection
49 capacitor allows to make test charge injections in the input of the front-end's electrodes [16, 17] with an uncertainty
50 of 2.7 % determined by the post-layout simulations. Finally, a backside layer of around 150 μm of silicon substrate
51 ensures the mechanical robustness of the sensors. The resulting MAPSSIC probe is made out of two IMIC sensors
52 that are glued back to back and thus has a thickness of less than 450 μm . This two-sensor assembling allows to
53 double the sensitivity of a given probe while recording an information that is not confined only to 180° . On top of
54 that, it ensures a better mechanical robustness of the probe as it doubles the overall thickness. This paper will not
55 discuss measurements on the two-sensor probe but rather on the single-sensor IMIC.

56 2.1.2. IMIC configurations

57 The sensors were designed in five different configurations that vary, in terms of epitaxial layer thicknesses, from
58 25 μm for the standard sensor (IMIC-a) and 50 μm for some modified ones (IMIC-b). Doubling the epitaxial
59 layer thickness was introduced in order to study the potential gains in sensitivity, especially by increasing the
60 detection efficiency of particles entering the sensitive layer from the lateral edges of the sensors. In addition to
61 the variations in epitaxial layer thicknesses, the sensors also differ due to modifications of the CMOS process
62 used for their fabrication [18]. These variations were introduced in order to maximize the charge collection. The
63 modifications of the CMOS process were also meant to increase the radiation hardness of the MAPS which is
64 relevant for applications in high-energy physics. However, the radiation hardness should not be a limiting factor for
65 neuroimaging applications even in longitudinal studies which consist in repeated measurements to follow particular
66 individuals over prolonged periods of time, as the activities used should be fairly low (around 10 MBq).

67 The standard CMOS process and the modifications introduced are shown in figure 1 (illustrations derived
68 from [18]). In the standard configuration, the depletion zone is not fully extended laterally in the epitaxial layer
69 between deep p-well and substrate. This effectively creates a gap between pixels that can cause a loss in sensitivity
70 due to a part of charge which will be collected by slow diffusion instead of drift in the depleted region. To overcome
71 this issue, the addition of a deep low-dose n-type implant has been introduced (figures 1.b and 1.c) to help create
72 a full depletion of the epitaxial layer thanks to a planar junction under the collection electrode. This extends the
73 depleted zone over the full pixel area in depth as well as laterally, regardless of the reverse bias used.

74 Although charges can be created anywhere in the epitaxial layer, their collection depends on the direction and
75 magnitude of the electric field [18]. A uniform and high electric field is indeed a key to avoid charge diffusion that
76 causes charge sharing and would ultimately mean a loss in sensitivity. This is due to the fact that even though the
77 energy lost by a given particle is supposedly higher than the pixel threshold globally set, if charge sharing occurs,
78 the amount of charge collected by each pixel electrode may fall below the threshold. As a result, no pixel is activated
79 despite the energy initially deposited being enough to trigger a detection. This is particularly problematic as the
80 energy range of incoming positrons is continuous. As showed in a previous Monte Carlo study on a sensor with the
81 same architecture and comparable sensitive layer thickness [9], the energy loss spectrum for ^{18}F is expected to be
82 up to 100 keV with a most probable energy loss being below 7 keV. In such a sensor, the interaction of a particle
83 in the sensitive layer usually leads to the activation of not one but a group of pixels called cluster (figure 1.d).
84 The number of activated pixels and therefore the size of the clusters is greatly influenced by the electric field. For
85 instance, a weak electric field will induce the activation of more pixels for a given recorded event resulting in larger
86 clusters. This will make the event identification more difficult and error prone at high count rates due to pile-up,
87 with the binary readout on 1 bit used to satisfy space constraints and to limit the power consumption down to
88 55 nW/pixel according to simulations [14]. At high count rate, there can be an accumulation of counts on pixels
89 that have already been activated during the integration. Because of the binary readout, such pixels cannot give

90 information about additional events thus complicating the identification of events. The pile-up probability increases
91 with the size of the clusters.

92 A major contributing factor to the charge sharing for sensors using a small collection electrode, such as IMIC,
93 is the non-uniformity of the electric fields [18, 19], dropping to a minimum value at the pixel corners close to the
94 aforementioned deep planar junction. This is due to a weak lateral electric field compared to the potential difference
95 between the N-implant and the backside P-substrate. Figures 1.b and 1.c show two different approaches to increase
96 the lateral electric field at the pixel borders: the process modification #2 (figure 1.b) involves the creation of a gap
97 in the deep n-implant while the process modification #3 (figure 1.c), introduces an additional deeply buried p-type
98 implant (deep p-well) at the pixel border. These modifications in the CMOS process aim to ensure a better drive of
99 the charges towards the collection electrodes, reducing the drift path and the charge sharing. The first three rows
100 of table 1 reference the five IMIC configurations and their respective characteristics.

101

102 *2.2. Measurements*

103 All measurements were performed on single IMIC sensors in a light shielding and constant climate chamber. A
104 setup was built in order to perform measurements using a sealed radioactive source in the same conditions regardless
105 of the studied IMIC configuration. It was composed of a test PCB to which the single sensor was connected. A
106 source holder was then fixed on the PCB in order to set an invariant position of the source providing a uniform
107 irradiation of the sensors (figure 2) as all PCBs and source holders used were identical to the sub-milimeter. The
108 IMIC sensors were mechanically placed in the same position on each PCB. The source was placed in the same
109 position and could not move around or rotate as it was tightly fixed. Finally, the 3 mm active diameter of the
110 source considerably reduces the effect of any sub-milimetric variation in the set up positions. The temperature of
111 the setup was fixed to 38.5°C, as it is the maximum brain temperature expected for rats [20] when stimulated.

112 *2.2.1. Parameter settings*

113 The pixel front-end biasing currents and voltages are provided by 14 internal programmable DACs and are
114 common for all pixels in the array. Before operating the sensor, the correct range of biasing signals needed to be
115 determined. For that, post layout electrical simulations allowed to have nominal values for all parameters. These
116 values were set separately for each IMIC configuration and reverse bias as they affect the operating points of the
117 front end. The parameter that regulates the energy loss threshold [21], was fine tuned around the initial value
118 provided by simulations. The energy loss threshold, which will be referred to as "energy threshold" for simplicity,
119 is the energy that needs to be deposited in a pixel to trigger its activation with a probability of 50 %. The tuning
120 was done using injections of about 350 electrons into the pixels using the internal injection system, while varying
121 the parameter value, thus, the energy thresholds. This allowed, for a given configuration and reverse bias voltage,
122 to determine a range of achievable energy thresholds with which the sensor is able to correctly respond to such
123 injections. The range includes a minimum threshold for noise-free operation as well as a maximum threshold set

124 between 1 keV to 1.5 keV which corresponds to our goal in order to maximize the overall sensitivity as well as the
125 β^+/γ sensitivity ratio. A second phase consisted of a series of noise measurements without any radiation source in
126 this range of energy thresholds for background determination. As the energy threshold level has a big influence for
127 the pixel activation, it was the subject of a deep study. Therefore, the performances of each IMIC were compared
128 using several energy threshold values chosen within the range of achievable thresholds determined previously. This
129 allowed to study if this crucial parameter can be optimized to maximize the sensor's performance.

130 *2.2.2. Background*

131 The background noise was measured as the number of clusters activated during multiple hours of integration
132 without any source of radiation for each IMIC configuration. These measurements were performed using no reverse
133 bias (reverse bias of 0 V) and the lowest threshold achievable.

134 *2.2.3. Threshold*

135 In order to determine the average energy threshold value of the sensor, a variable amount of charges was injected
136 to the front-end of 10 % of the pixels [22], applying reverse bias voltages from 0 V to 2 V to the substrate. The
137 process was repeated 10 times for every pixel injected. The energy threshold E_{thr} was determined as the charge,
138 that induces a pixel activation with a probability of 50 % as from the s-curve on each pixel's activation probability
139 using a logistic regression method. In order to use a unit that is more indicative for the use of the probe, the
140 deposited charge is converted to absorbed energy, considering 3.67 eV are needed to create an electron-hole pair
141 in silicon at room temperature [23]. Additionally, the average individual pixel equivalent noise charge (ENC) was
142 determined for each IMIC, energy threshold and reverse bias.

143 *2.2.4. Performance measurements*

144 A short integration time of 1 ms was chosen to limit the number of events recorded in each frame in order to
145 minimize the pile-up probability.

146 Source measurements for a comparative study between different IMIC configurations were performed using a
147 sealed ^{204}Tl source (whose energy spectrum is close to ^{18}F positron one: β^- , maximum energy: 0.764 MeV) of
148 3 mm active diameter placed at a distance of 14.3 mm from the probe. The influence of both the threshold and
149 the reverse bias on the sensors' performance was studied since these two parameters are of great importance in
150 the MAPS technology. To assess these performances, particular attention was paid to two crucial metrics: the
151 sensitivity and the average cluster size. In this paper, the count rate (defined as the number of activated clusters)
152 is used as an observable that scales with the sensitivity.

153 **3. Results**

154 *3.1. Background*

155 Table 1 shows the result of the background measurements, in clusters per second, for all types of IMIC with
156 the lowest threshold setting available. All sensor configurations display a low background noise recording less than
157 10×10^{-3} cps.

158 3.2. Threshold

159 Figure 3 shows the mean activation probability as a function of the injected charge for IMIC-1a at 0 V. The chart
160 also displays the corresponding histogram of the individual pixel-threshold distribution. A Poissonian distribution is
161 noticeable with only a handful of pixels having a slightly higher energy threshold. Table 2 shows the threshold range
162 for each IMIC configuration. For all sensor configurations, the energy threshold is under 1.2 keV. The threshold
163 level gradually decreases when a higher reverse bias is applied for IMIC-1a. However, for all sensors with a modified
164 CMOS process, the increase of the reverse bias systematically induces an increase of the energy threshold level. The
165 standard deviation of the individual pixel-threshold histogram for each sensor varies for all IMIC configurations
166 from around 30 eV to 100 eV and is displayed in table 2.

167 Table 2 displays the average ENC for each IMIC and figure 4 shows it for IMIC-1a versus energy threshold.
168 For all sensors the ENC decreases as the energy threshold increases. No clear trend is observed when studying the
169 influence of the reverse bias on the ENC even though at low threshold, a 2 V reverse bias induces an increase of
170 around 12 % of the ENC.

171 3.3. Performance measurement

172 3.3.1. Energy threshold influence

173 Figure 5 shows the variation of the sensitivity and cluster size with the energy threshold for IMIC-1a at three
174 reverse biases. As shown by the fits, the sensitivity appears to decrease linearly with the threshold. A lower
175 threshold level has a slight and linear impact on the IMIC-1a sensor sensitivity inducing at best a 3.1 % increase in
176 sensitivity compared with the highest threshold value available. The same goes for IMIC-2b, IMIC-3a and 3b for
177 which a decrease in the threshold value permits an increase of the sensitivity by up to 5 %, 2 % and 2 %, respectively.
178 Finally, IMIC-2a appears to have a more stable sensitivity response across its range of energy threshold values with
179 an increase of less than 1 % at low threshold. Figure 6 shows indeed a very different impact of the threshold on
180 the sensitivity between IMIC-1a and IMIC-2a. Despite the noted gain in sensitivity, the performance of the sensors
181 in terms of cluster size are more altered by the decrease of the threshold. The average cluster size exponentially
182 increases as the threshold value gets lower with a drop of 19 % to 33 % for IMIC-1a, 13 % for IMIC-2a, 11 % to 14 %
183 for IMIC-2b, 8 % for IMIC-3a and 12 % to 15 % for IMIC-3b. The dependency of the cluster size on the energy
184 threshold is also illustrated in figure 6 showing the variation in the distribution of the cluster size at three energy
185 threshold levels for IMIC-1a and IMIC-2a. The increase of the threshold has indeed more impact for IMIC-1a as it
186 helps suppressing an important part of charges collected through diffusion whereas IMIC-2b mainly relies on charge
187 drift even at low threshold thanks to an optimized electric field.

188 3.3.2. Reverse bias influence

189 Variations in performances are shown in figure 5 for the standard IMIC configuration (IMIC-1a). The increase
190 of the reverse bias induces an increase in sensitivity. For instance, while a reverse bias of 1 V allows a marginal
191 gain compared to the 0 V bias (around 1 % on average across the threshold range), the gain in sensitivity at 2 V is

192 greater (4 % going from 1 V to 2 V). This increase in sensitivity is also followed by a decrease of 24 % in the average
193 cluster size. However, when studying other sensor configurations (Table 2), while the same behavior is observed
194 in terms of average cluster size reduction, no clear gain in sensitivity is induced by an increased reverse bias. For
195 IMIC-2b and IMIC-3b for instance, a slight drop in sensitivity of 4 % and 3 %, respectively is noted for the lowest
196 threshold configuration. For all IMIC configurations, an increase of the reverse bias provides better performances
197 in terms of cluster size (table 2), hence reducing the pile-up probability. At 2 V, the IMIC-1a shows a reduction
198 of 22 % compared to 0 V bias and 13 % to 1 V, respectively. Furthermore, the IMIC-2a displays a cluster size
199 reduction of 4 % on average using a 1 V reverse bias while the IMIC-2b allows a maximum cluster size decrease of
200 around 10 %. Finally, IMIC-3a allows to reduce the average cluster size by 13 % at best, and IMIC-3b enables a
201 9 % reduction.

202 3.3.3. IMIC sensor comparison

203 Table 2 shows the variations in sensitivity and cluster size for various energy thresholds and reverse bias values
204 for each IMIC configuration.

205 An increase in sensitivity up to 7 % is seen for sensors with modified CMOS process and a 25 μm epitaxial layer
206 (IMIC-2a and IMIC-3a) and up to 12 % for sensors with a 50 μm epitaxial layer (IMIC-2b and IMIC-3b) compared
207 to the IMIC-1a. Additionally, changes of the threshold value tend to have a greater impact on the sensitivity for
208 IMIC-1a compared to the others as shown by the color map in figure 6. The best performances in terms of average
209 cluster size are achieved with modified sensors having a 25 μm epitaxial layer (IMIC 2a and IMIC 3a) thanks to a
210 reduced drift path and an optimized charge collection. Figure 6 shows the distribution of the cluster size for IMIC-
211 1a and IMIC-2a, which induce respectively the largest and the smallest cluster sizes on average. A clear difference
212 is observed as IMIC-1a displays a wider distribution of cluster size while IMIC-2a provides a narrower one, with
213 a majority of clusters composed of one to two pixels. The increase of the energy threshold allows to significantly
214 reduce the cluster size for IMIC-1a and get closer to the performances achieved by IMIC-2a, which is less affected
215 by such a change. IMIC-2a and IMIC-3a allow for a reduction of 51 % to 64 % of the average cluster size, limiting
216 considerably the pile-up probability. Although sensors with a 50 μm epitaxial layer have smaller clusters on average
217 than IMIC-1a (reduction of 20 % to 28 % at best), they still show larger clusters compared to IMIC-2a and 3a due
218 to the longer path needed for the collection of the charges as they can be created deeper in the epitaxial layer, thus
219 facilitating charge sharing between pixels.

220 Finally, the minimal energy threshold achieved for each IMIC configuration seems to have a little impact on
221 the differences seen between sensors both in terms of sensitivity and cluster size as shown by table 2. IMIC-1a
222 has the lowest sensitivity of all sensors despite displaying the lower energy threshold regardless of the reverse bias.
223 On the other hand, IMIC-3b provides by far the highest sensitivity despite having among the highest minimal
224 energy threshold both at 0 V and 1 V. The results show that the impact of the minimal energy threshold on the
225 sensitivity is outweighed by other contributing factors such as the CMOS process or the epitaxial layer thickness.

226 The same observation can be made about the cluster size as IMIC-2b and IMIC-3b induce significantly larger clusters
227 compared to IMIC-2a and IMIC-3a respectively which have the same CMOS processes and similar thresholds but
228 thinner epitaxial layers.

229 4. Discussion

230 Given that in *in vivo* conditions, the signal is expected to be around few events per seconds in pharmacological
231 studies to approximately a hundred events per seconds in physiological studies [9], the background noise exhibited
232 by all the configurations of IMIC, being 3 to 5 orders of magnitude smaller, is considered to be acceptable.

233 The energy threshold study that was carried out confirms that the parameters set up for IMIC sensors are in
234 good agreement with a low energy threshold goal well below 1.5 keV per pixel. The ENC is higher than the one
235 measured in previous studies [17] though it is still one order of magnitude smaller than the thresholds actually
236 measured. The ENC decreases as the energy threshold increases. Furthermore, for IMIC-1a, results from source
237 measurements show that the higher the reverse bias, the better the performances, hence insuring a maximization
238 of the sensitivity and a limitation of the pile-up probability. On the other hand, no gain in sensitivity is noted for
239 increased reverse bias on sensors with a modified CMOS process. This can be due to an increase in the average
240 energy threshold when biasing these sensors with 1 V. This change in the average energy threshold value either
241 mitigates (IMIC 2a and 3a) and even outweighs (IMIC 2b and 3b) the gain provided by the better charge collection
242 at 1 V resulting in a stagnating or dropping sensitivity. This shows that the charge collection is the main factor of
243 improvement when the reverse bias is increased. Furthermore, as the charge collection is dominated by the charge
244 drift for sensors with a modified CMOS process, the increase of the reverse bias only marginally improves the charge
245 collection as it is already optimized. On the other hand, standard sensors greatly benefit from an increased reverse
246 bias as it limits the charge diffusion and favors the drift. Finally, previous studies have shown that the reverse bias
247 should be higher (up to 6 V) to provide bigger gains in sensitivity [24]. This is also confirmed by the notable gain
248 provided by the use of a 2 V reverse bias with the IMIC-1a. However, for reverse biases from 2 V to 6 V, it was not
249 possible to determine a range of suitable pixel parameters with the modified CMOS process IMIC sensors. This
250 issue is currently under study. Nevertheless, the increase of the reverse bias has a positive effect on the average
251 cluster size for all tested reverse-bias voltages, which is also shown in previous studies [25].

252 Results both in terms of sensitivity and average cluster size show improved performances with the modified
253 sensors compared to the standard IMIC-1a. Despite a unique sensor geometry, these results are in agreement with
254 previous studies [18, 24, 26] carried out on sensors used for high energy particle detection. The aforementioned
255 studies show similar gains with modified CMOS processes demonstrating significantly better performances than the
256 standard ones, especially at low reverse biases (0 V). These performances are caused by a fully depleted epitaxial
257 layer as well as a better charge collection based on charge drift and the limitation of slow diffusion. However, in
258 contrast to the cited studies, a slight difference in performances between sensors with the modified CMOS processes

259 #2 and #3 can be noted. Sensors with the modified CMOS process #2 (IMIC 2a and 2b) show indeed a lower
260 sensitivity and a slightly smaller cluster size on average compared to the modified CMOS process #3 (IMIC 3a and
261 3b) despite slightly lower energy thresholds. These comparative measurements show that choosing the best suited
262 IMIC configuration will depend on the expected *in vivo* conditions. For instance, if a low count rate is expected,
263 one should rather rely on 50 μm epitaxial layer sensors such as IMIC-2b and IMIC-3b as these will help maximizing
264 the sensitivity. This should particularly be the case in pharmacological studies [27]. As shown in a previous study,
265 having a 50 μm epitaxial layer will only marginally increase the proportion of gamma rays to the total sensitivity
266 by less than 3 % [9]. On the other hand, if the count rate is expected to be high, like in physiological studies for
267 instance, IMIC-2a and IMIC-3a appear to be better alternatives as they will notably limit the pile-up probability.
268 The same trade-off arises when trying to optimize the energy threshold as a low threshold will increase both the
269 sensitivity and the cluster size and, consequently, the pile-up probability.

270 **Conclusion**

271 A new version of IMIC, a monolithic active pixel sensor was produced in five different configurations. Mea-
272 surements performed with a sealed β^- radioactive source as well as charge injections have shown that such a
273 sensor is capable of recording a signal based on the detection of low energy charged particles. Optimization of
274 the aforementioned detection proved to be possible through a trade-off between increased sensitivity and limited
275 pile-up probability. Furthermore, the experimental validation carried out have also allowed to validate the gains in
276 performances induced by modifications in the CMOS process.

278 This project has received financial support from the CNRS through the MITI interdisciplinary programs.

Figure 1: Schematic cross section (not to scale) of three CMOS processes with a small collection electrode. a) Standard CMOS process, b) Modified CMOS process #2 with a gap in the deep n-implant, c) Modified CMOS process #3 with an additional deeply buried p-type implant (deep p-well). The arrows show the electric field lines around the gap/p-type implants. d) Single frame composed of 128×16 pixels clearly showing three different clusters resulting from the interaction of β^- particles from a ^{204}Tl source.

Figure 2: Pictures of the experimental setup for measurements with a sealed source. a) Test PCB mounted with the source holder and a ^{204}Tl source in place. b) Test PCB mounted with the source holder with no source in place showing the IMIC. c) Picture of the IMIC showing the pixel array and the bonding pads.

Figure 3: Blue line: Average pixel activation probability as a function of the injected charge for IMIC-1a associated with the 16th and 84th quantiles (light blue). Bars: individual pixel energy threshold distribution for all the 2048 pixels of the IMIC 1-a. Dotted red line: Average energy threshold of the IMIC-1a for the given set of parameters.

Figure 4: Average ENC as a function of the energy threshold for IMIC-1a at 3 reverse biases. Uncertainty bars are the propagated uncertainties on absolute value of charge injection.

Figure 5: Left: Sensitivity as a function of the energy threshold for IMIC-1a at 3 reverse biases. Uncertainty bars showing the standard deviation assuming a Poissonian distribution. Lines show a linear fit corresponding to the data. Right: Average cluster size as a function of the energy threshold for IMIC-1a at 3 reverse biases (in logarithmic scale). Uncertainty bars show the standard deviation on the mean. Lines show the exponential fits corresponding to the data.

Figure 6: Violin plot showing the distribution of the cluster size at three energy thresholds for IMIC-1a (left semi-violins) and IMIC-2a (right semi-violins). For each distribution (semi-violins), the lower and the upper short dashed lines represent the first and third quartile respectively and the long dashed line in between represents the median. For the IMIC-2a, (right semi-violins) the first quartile is so low that it is actually confounded with the edge of the distribution. The color palette shows the variation of the sensitivity for these threshold values.

IMIC Configuration	1a	2a	2b	3a	3b
CMOS process	Standard	Gap (#2)	Gap (#2)	Deep p-well (#3)	Deep p-well (#3)
Epitaxial layer thickness (μm)	25	25	50	25	50
Background ($\times 10^{-3}$ cps)	1.09 ± 0.10	1.70 ± 0.47	4.30 ± 0.66	2.10 ± 0.46	7.50 ± 0.87

Table 1: Detailed characteristics and background noise count rate in counts (clusters) per second per sensor for each IMIC configurations.

IMIC Config.	Reverse bias	Energy threshold range (eV)	Energy threshold std dev. (eV)	Average ENC (e^-)	Mean count rate (cps)	Average cluster size (pixels)
1a	0 V	$853 \pm 6 - 373 \pm 3$	82 - 36	19 - 24	159.5 - 164.5	4.5 - 6.7
	1 V	$804 \pm 7 - 370 \pm 3$	97 - 36	20 - 23	161.4 - 165.9	4.5 - 6.1
	2 V	$696 \pm 7 - 382 \pm 3$	96 - 36	21 - 25	168.0 - 170.9	4.2 - 5.2
2a	0 V	$849 \pm 7 - 397 \pm 3$	101 - 45	18 - 25	168.2 - 168.9	2.2 - 2.4
	1 V	$1037 \pm 5 - 514 \pm 4$	70 - 52	15 - 22	168.7 - 168.5	2.1 - 2.4
2b	0 V	$960 \pm 5 - 531 \pm 4$	74 - 51	16 - 21	170.5 - 174.1	4.2 - 4.93
	1 V	$1176 \pm 4 - 665 \pm 6$	59 - 79	20 - 32	164.1 - 171.6	3.9 - 4.4
3a	0 V	$1077 \pm 4 - 670 \pm 6$	57 - 90	16 - 33	170.8 - 174.1	2.3 - 2.5
	1 V	$1212 \pm 4 - 1167 \pm 4$	57 - 62	15 - 15	172.4 - 175.0	2.2 - 2.2
3b	0 V	$1028 \pm 5 - 546 \pm 5$	76 - 68	16 - 23	178.4 - 178.6	4.6 - 5.4
	1 V	$1226 \pm 6 - 856 \pm 7$	85 - 103	20 - 21	172.3 - 174.9	4.3 - 4.9

Table 2: Table of the performances in terms of sensitivity and cluster size using a ^{204}Tl sealed source as a function of the threshold and reverse bias used for all the IMIC configurations. The sensitivity and cluster size values presented correspond to the lowest and highest values of the achievable energy thresholds.
