## Abstract

Despite of its central importance in the chemistry of aromatic compounds and fuels derived from biomass, only few experimental studies about on phenol combustion can be found in literature. In this paper, unique measurements of the adiabatic laminar burning velocities of phenol are presented, together with the first experimental study of the oxidation of this molecule in a jet-stirred reactor. The burning velocities were measured with a flat-flame burner using the heat-flux method for a fresh gas temperature of 398 K and equivalence ratios from 0.7 to 1.35. In the reactor experiments, the oxidation of a stoichiometric mixture of phenol highly diluted in helium was investigated at temperatures between 600 and 1100 K at near-atmospheric pressure. The mole fraction of the reactants, as well as 32 products, mainly carbon monoxide, carbon dioxide, methane, acetylene ethylene, acrolein, cyclopentadiene, benzene, naphthalene and dibenzofuran, were recorded.

Based on previous literature work, a new detailed kinetic model is developed based on several published sub-mechanisms and updated considering rate constants taken from recent literature studies or calculated at the CBS-QB3 or G4 level of theory. This model leads to a significantly improved prediction of the phenol burning velocities compared to literature models, as well as a reasonable prediction of most species mole fractions during phenol oxidation in the jet-stirred reactor. Sensitivity analyses as well as flow rate analyses are discussed to explain the obtained model improvements.

*Keywords:* Phenol; Laminar burning velocity; Jet-stirred reactor; Detailed kinetic model.

### 1) Novelty and Significance Statement

The novelty of this research consists in the first measurements of the laminar burning velocity of phenol, a solid fuel and the smallest oxygenated molecule including a phenyl ring, which is of central importance in the chemistry of aromatic compounds. It also reports the first experimental study of phenol oxidation in a jet-stirred reactor including the quantification of 32 products and the development of a new model able to satisfactorily reproduce this new data, better than existing literature models.

### 2) Author Contributions

- ND: Performed LBV measurements, Developed the kinetic model, Performed kinetic analyses, Wrote the paper;
- IM: Performed JSR measurements, Analyzed data, Reviewed the paper;
- OH: Supervision, Set-up experiments, Analyzed data, Reviewed the paper;
- HHC: Performed theoretical calculations, Reviewed the paper;
- FBL: Supervision, Analyzed data, Wrote the paper.

### 3) Authors' Preference and Justification for Mode of Presentation at the Symposium

The authors prefer **OPP** presentation at the Symposium, for the following reasons:

- Work on a reactant of pivotal importance in the combustion chemistry of aromatic compounds, thus of wide interest.
- Unique measurements of the laminar burning velocity of phenol.
- First experimental study of phenol oxidation in a jet-stirred reactor, including the quantification of 32 products.
- Rate constant revision based on literature and theoretical calculations with wide discussion possibilities,
- Development of a new model leading to significantly improved predictions compared to literature ones.

## 1 Introduction

Phenol is a species of central importance in all detailed kinetic mechanisms proposed to model the oxidation of monoaromatic compounds [1,2] as it is a key intermediate both involved in the PAH formation and in the formation of smaller species. Indeed, the CO elimination reactions either directly from phenol, or through its resonance-stabilized phenoxy radical, are prominent ring contractions that convert an aromatic six-membered ring species into a five-membered ring product.

Phenol is the smallest aromatic molecule found in notable amounts in bio-oils obtained by the fast pyrolysis of biomass [3,4]. It is also produced during the catalytic lignin solvolysis, a promising process to transform lignin, usually a waste of bioethanol production, into valuable biofuels [5]. **Erreur ! Source du renvoi introuvable.** This process is the target of the EHL CATHOL European project (<https://ehlcathol.eu/>).

Despite its above-mentioned importance, there is only a very limited number of experimental studies available on phenol pyrolysis and combustion, certainly due to the fact that it is solid at room temperature. Two of them were performed using shock-tubes by He et al. [6] and Horn et al. [7] allowing to derive rate constants of, respectively, the H abstractions by H-atoms and OH radicals and the CO-elimination from phenol. Three flow reactors studies are known [8–10], among which two focused on pyrolysis [8,10], while the work by Brezinsky et al. [9] in 1998 investigated phenol oxidation around 1170 K, at atmospheric pressure over a range of equivalence ratios, 0.64–1.73. A total of 9 products were quantified by gas chromatography, namely, methane, carbon monoxide, acetylene, carbon dioxide, C<sub>3</sub> unsaturated hydrocarbons, cyclopentadiene, 1,3-butadiene, benzene, and naphthalene.

Since the work of Alzueta et al. [1] in 2000 on benzene followed by the study of Bounaceur et al. [11] on toluene, phenol is a key species found in all the detailed kinetic models dealing with the oxidation of aromatic compounds, e.g. [4,12–14]. In 2020, Pratali Maffei et al. [15] revisited the rate constants of the main reactions for phenol pyrolysis based on theoretical calculations. These new values were used in the CRECK model to satisfactorily simulate the experimental data available for phenol pyrolysis [7,9,10].

To our best knowledge, phenol oxidation has not been studied in a reactor since the work by Brezinsky et al. [9]. Furthermore, no experimental flame data for phenol is available in literature. The first purpose of the current paper is therefore to present the first measurements of laminar burning velocities (LBV) for phenol, as well as the first product quantifications during its oxidation in a jet-stirred reactor. Its second objective is to update an existing detailed kinetic model for aromatic compounds [2,16] using recent

theoretical calculations in order to improve the predictions of the newly obtained experimental data.

## 2. Experimental methods and results

This section starts by describing the setups used in LRGP-Nancy to measure LBVs with a laminar flat flame burner and to quantify products during fuel oxidation in a heated JSR. A special focus will be on adaptations made to handle phenol, a solid reactant at room temperature ( $T_{\text{melting}} = 314$  K), and with low volatility ( $T_{\text{boiling}} = 455$  K) [5]. It is followed by a description on the obtained experimental results.

### 2.1 Experimental methods

The methods used in flame and in JSR, as well as needed adaptations are described below:

#### 2.1.1. Flame measurements

The measurements of LBV were performed under atmospheric pressure based on the heat-flux method [17] using a flat flame burner, a set-up already utilized for measuring LBV of a wide range of organic reactants, among which are anisole and guaiacol [16]. The adiabaticity of the flame is indicated by the flat shape of the temperature profile across the burner plate verified by eight thermocouples. At these conditions, the velocity of the flame is equal to the velocity of the gases.

#### 2.1.2. JSR measurements

The JSR consists of a 92 cm<sup>3</sup> fused silica sphere including four injection nozzles located at the center of the sphere to provide turbulent jets for an efficient mixing. Details can be found in previous publications, e.g. including the recent ones reporting on arenes [2] and guaiacol oxidation [16]. The gas mixture leaving the JSR, maintained at a pressure of 1.067 bar (residence time 2s), was analyzed by three gas chromatographs (GCs). The first GC is used for the quantification of oxygen. It was equipped with a Carbosphere packed column and a thermal conductivity detector. The second GC was fitted with a Q-Bond capillary column and a flame ionization detector (FID), preceded by a methanizer. It served for the quantification of CO, CO<sub>2</sub> and organic compounds containing from two carbon atoms, such as acetylene or ethylene, up to compounds with 6 carbon atoms, such as benzene. A third GC, which was equipped with a HP-5 capillary column and both a mass spectrometer and a FID detector, was used for the quantification of the heaviest compounds (C<sub>6+</sub>). The identification of reaction products was performed using a GC equipped with both types of capillary columns and coupled to a mass spectrometer and an FID (CG-MS-FID).

### 2.1.3. Phenol specific adaptations

In both set-ups, the flow rates of oxygen and carrier gas ( $N_2$  for LBV, He in JSR) are regulated by mass flow controllers. The liquid fuel flow rate is monitored using a Cori-Flow mass flow controller, which is fed by a pressurized stainless-steel fuel tank and connected to an evaporation chamber also alimented by the carrier gas. After mixing with oxygen, the gaseous mixture is transferred by a heated line ( $T = 398$  K) to the plenum chamber preceding the burner or to the preheating zone of the JSR. The relative uncertainty of the flow rates is  $\pm 0.5\%$ . Phenol was provided by Merck with a purity above 99%; oxygen (purity  $\geq 99.999\%$ ), helium (purity  $\geq 99.999\%$ ), and nitrogen (purity: 99.995%) were provided by Messer France.

The use of solid phenol required the following main modifications to the feeding system. The fuel container was kept in a hot water bath until it was used to fill the fuel tank. The tank and all the lines transferring liquid to the evaporator were wrapped by electric heating to ensure a constant temperature of 353 K, i.e. above phenol melting point.

The second modification concerns the analyses of the reacted gases. At the outlet of the JSR, instead of analyzing the heavy molecules ( $>C_6$ ) after on-line transfer to the GC as in [2], those were cryogenically trapped. The content of the trap was then dissolved in acetone and injected with an auto-sampler into the GC-MS-FID.

## 2.2 Experimental results

All the obtained experimental data are provided in an Excel spreadsheet in Supplementary Materials (SM). In all figures of this section, symbols represent experimental results and lines simulations using COLIBRI v3 model (see next section).

### 2.2.1. Flame results

The LBV measurements are displayed in Figure 1. The range of equivalence ratios ( $\Phi$ ), from 0.7 to 1.35, is limited by flame stability. For these ratios, the flame shape was flat in lean mixtures and there was neither liquid condensation at the walls nor cellular instabilities in rich mixtures. The uncertainties indicated in Figure 1 are calculated for each individual experiment and take into account the uncertainties of devices: those of the flow controllers, of the used K-type thermocouples in the plate and of the T-type thermocouple monitoring the chamber temperature, as well as minor sources of uncertainties such as distortion and edge effects. The small variations of the chamber temperature and the adiabatic condition consideration both lead to uncertainties attributed to the user; they are also considered. More details about the experimental uncertainties are given in SM.

The obtained LBV profile shows a maximum burning velocity ( $LBV_{max}$ ) of 59.2 cm/s at around  $\Phi$

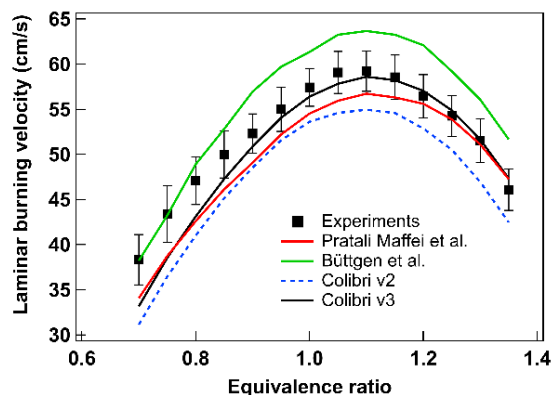

Fig. 1. Phenol LBV for fresh gases at 398 K. Simulations using literature models (Colibri v2 [16], Büttgen et al. [14], Pratali Maffei et al. [15]) are added.

$\Phi = 1.1$ , and a slightly steeper decline towards higher  $\Phi$  than towards lower  $\Phi$ . The data show that the burning velocity of phenol is slightly higher than that of toluene ( $LBV_{max} = 56.0$  cm/s [18], measured with the same setup under the same conditions) and almost equal to that of anisole ( $LBV_{max} = 60.0$  cm/s [16]).

### 2.2.2. JSR results

The mole fractions of both reactants at the outlet of the JSR are presented in Figure 2. The uncertainty of the  $O_2$  mole fraction is around  $\pm 5\%$ , in contrast to that of phenol, which is  $\pm 10\%$ . Figure 2 indicates that phenol consumption starts at the chosen conditions around 900 K and complete consumption is reached above 1050 K. A similar reactivity profile is observed for oxygen; however, it is not yet completely

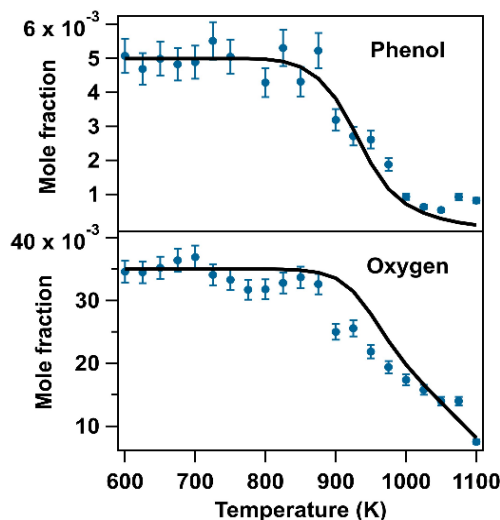

Fig. 2. JSR mole fractions of phenol and  $O_2$ .

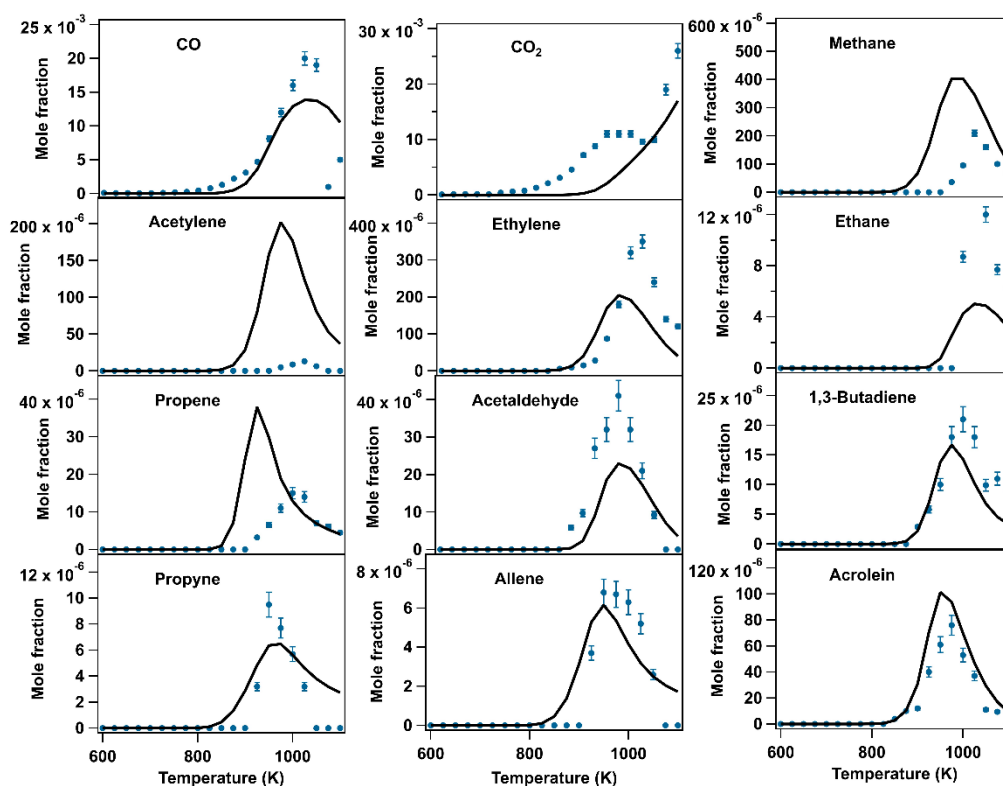

Fig.3. Mole fraction profiles of C<sub>1</sub>-C<sub>4</sub> products quantified during the JSR oxidation of phenol.

1 consumed even at the highest temperatures. One  
 2 possible reason for this – oscillations – is discussed  
 3 later.

4  
 5 In this study, 32 products were identified and  
 6 quantified and, in addition, traces of 2-butene, cumene  
 7 and phenyloxirane, were detected.

8 The quantified products can be grouped into four  
 9 categories: (1) Five C<sub>1</sub>-C<sub>4</sub> oxygenated species: CO,  
 10 CO<sub>2</sub>, acetaldehyde (CH<sub>3</sub>CHO), acrolein  
 11 (CH<sub>2</sub>CHCHO), and furan, (2) 13 C<sub>1</sub>-C<sub>5</sub> hydrocarbons:  
 12 methane (CH<sub>4</sub>), acetylene (C<sub>2</sub>H<sub>2</sub>), ethylene (C<sub>2</sub>H<sub>4</sub>),  
 13 ethane (C<sub>2</sub>H<sub>6</sub>), propene (C<sub>3</sub>H<sub>6</sub>), allene (a-C<sub>3</sub>H<sub>4</sub>),  
 14 propyne (p-C<sub>3</sub>H<sub>4</sub>), 1-butene (1-C<sub>4</sub>H<sub>8</sub>), 1,3-butadiene  
 15 (1,3-C<sub>4</sub>H<sub>6</sub>), 1,2-butadiene (1,2-C<sub>4</sub>H<sub>6</sub>), 2-butene  
 16 (2-C<sub>4</sub>H<sub>8</sub>), 1,3-cyclopentadiene, cyclopentene, and  
 17 1,3-cyclohexadiene, (3) 6 aromatic hydrocarbons:  
 18 benzene, toluene, styrene, ethylbenzene, indene,  
 19 3-methyl-1H-indene, and naphthalene, (4) 8  
 20 oxygenated aromatics: benzaldehyde, o-cresol,  
 21 methylbenzaldehyde, 1-indanone, dibenzofuran, a  
 22 C<sub>12</sub>H<sub>8</sub>O<sub>2</sub> species, 2,5'-biphenyldiol and  
 23 2,2':5',2''-diepoxy-p-terphenyl. The formulas, and the  
 24 possible names and structures of the cyclic  
 25 compounds are given in Table S1 in SM. The C<sub>12</sub>H<sub>8</sub>O<sub>2</sub>  
 26 might most probably be 2-phenoxyphenol, but the  
 27 formation of 3-hydroxydibenzofuran and dibenzo-  
 28 1,4-dioxin cannot be discarded.

29 Concerning the C<sub>12</sub>H<sub>10</sub>O<sub>2</sub> species, we assume that  
 30 they were formed through phenoxy radical  
 31 recombination. 2,5'-biphenyldiol provided the best  
 32 match with the mass spectrum of the NIST08 library.  
 33 The relative stability of possible structures will be  
 34 discussed in the text.

35 Calibrations were performed by injecting  
 36 standards for C<sub>1</sub>-C<sub>2</sub> species, with a maximum relative  
 37 error in mole fractions around ±5%. Otherwise, the  
 38 effective carbon number method was used with an  
 39 uncertainty of 10%, possibly higher for products  
 40 analyzed off-line, e.g., 20 % for C<sub>12</sub>-C<sub>18</sub> species.

41 Figures 3 and 4 present the experimental mole  
 42 fractions of the most significant products quantified  
 43 during the JSR oxidation of phenol; more products are  
 44 shown in Figure S2 in SM.

45 The two products found in the largest amounts are  
 46 CO and CO<sub>2</sub>. However, as already noticed in [2,16],  
 47 the mole fractions of CO<sub>2</sub> is overestimated, likely  
 48 because of an artifact during the sampling or the  
 49 analysis, partly explaining the large positive  
 50 deviations around +30% in the carbon balance  
 51 displayed in Table S2 in SM. As in [2], this does not  
 52 affect the formation of the other products.

53 Another factor explaining the observed deviation in  
 54 the carbon balance is the phenomenon of oscillations  
 55 (a transient evolution of species mole fractions with  
 56 time), also reported in our previous work [2,16],

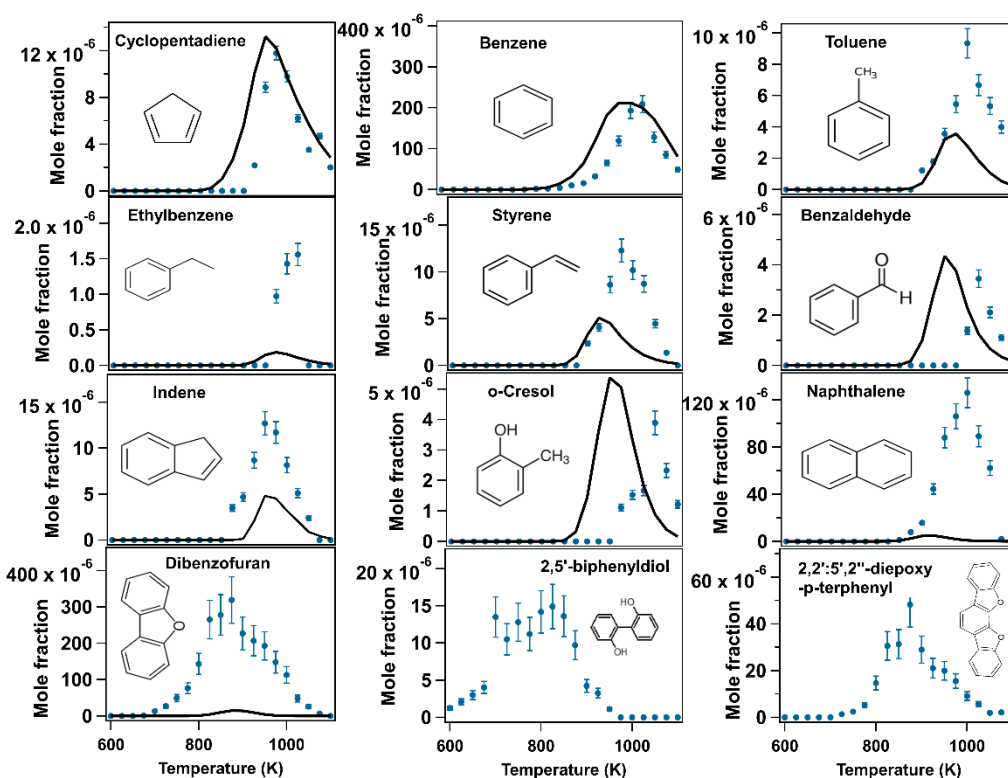

Fig. 4. Mole fraction profiles of the main C<sub>5</sub>-C<sub>12</sub> products quantified during the JSR oxidation of phenol.

1 which occurs from 1050 K and explains the strange  
 2 evolution of phenol and CO mole fractions at and  
 3 above this temperature.

4 Besides CO and CO<sub>2</sub>, other products found in  
 5 significant concentrations, e.g., with a maximum mole  
 6 fraction above 100 ppm, are methane, dibenzofuran,  
 7 ethylene, benzene, and naphthalene. While notable  
 8 phenol consumption is observed from 900 K, some  
 9 products with non-negligible yields are already  
 10 detected starting at 700 K. As it is shown by the  
 11 selectivity analysis displayed in Figure S1 in SM, the  
 12 aromatic compounds with the largest selectivity at  
 13 700 K are 4-hydroxydibenzofuran and dibenzofuran.  
 14 Except for CO, naphthalene has the largest selectivity  
 15 at 900 K at the start of phenol conversion.

### 17 3. Detailed kinetic modeling

18  
 19 Figures 1 and S3-S5 show a comparison between the  
 20 present experimental LBV and JSR mole fractions  
 21 and simulation using literature models considering  
 22 phenol: COLIBRI v2 [16], the model of Büttgen et al.  
 23 [14], that of Yuan et al. for anisole [19], and that of  
 24 Pratali Maffei et al. [15]. All the simulations displayed  
 25 in the paper and its SM were performed using  
 26 CHEMKIN-Pro software [20] with GRAD and  
 27 CURV parameters equal to 0.1 for LBV calculations.  
 28 While most JSR mole fraction are reasonably well  
 29 predicted by literature models, especially by

30 COLIBRI v2 [16], this is not the case for the LBV data  
 31 for which significant deviations are observed. More  
 32 specifically, simulations using COLIBRI v2 and  
 33 Pratali Maffei et al. [15] model underestimate the  
 34 measured maximum LBV by about 4 cm/s and 3 cm/s  
 35 respectively. In contrast, the model of Büttgen et al.  
 36 [14] overestimates the maximum experimental LBV  
 37 by 5 cm/s. Numerical convergence with a refined grid  
 38 has not been successfully reached with Yuan et al.  
 39 model [19], which presents a high stiffness. The  
 40 deviations of LBV predictions between different  
 41 models is mainly due to the C<sub>5</sub>H<sub>x</sub>O submechanism,  
 42 notably composed of reaction of cyclopentadienone,  
 43 cyclopentadienol and their derived radicals. As shown  
 44 by the sensitivity analysis in Fig. 5e, these reactions  
 45 have a strong influence on the LBV. Many reactions  
 46 of the COLIBRI model are lacking in the Büttgen and  
 47 the CRECK ones. Additionally, some species are not  
 48 considered in the CRECK model. The rate constants  
 49 of inhibiting reactions are also far lower in Büttgen  
 50 model compared to those of COLIBRI. Notably, Fig.  
 51 S20 in Supplementary Material compares the  
 52 termination reaction of cyclopentadienyl-ol radicals  
 53 with H-atoms yielding cyclopentadienol found in  
 54 COLIBRI and in the model of Büttgen. The rate  
 55 constant of Büttgen model is two and one orders of  
 56 magnitude lower at 1000 K and 1400 K, respectively.  
 57 The inhibiting effect of the C<sub>5</sub>H<sub>x</sub>O submechanism is  
 58 globally less present in the Büttgen model.

1 The unsatisfactory LBV simulation results call for  
 2 an updated and extended kinetic model. Such a model,  
 3 named COLIBRI v3, is developed in this study. It  
 4 contains 477 species and 3007 reactions and is  
 5 provided in SM along with its thermochemical data  
 6 and transport data.

### 7 3.1. Development of a new model

9  
 10 The COLIBRI v3 model is an offspring of the  
 11 COLIBRI v2 model, which allows a satisfactory  
 12 simulation of the combustion of guaiacol, anisole,  
 13 xylene isomers and toluene [2,16]. In addition to few  
 14 in-house reactions added in order to explain the  
 15 formation of minor products, this previous model is  
 16 mainly built as a merge of 6 literature models in order  
 17 to combine their accuracy, but keeping good  
 18 convergence performances: (1) the Galway reaction  
 19 base [21], (2) the toluene model of Yuan et al. [12], in  
 20 which phenol reactions are considered, (3) the xylene  
 21 model of Kukkadapu et al. [13], (4,5) the anisole  
 22 models of Büttgen et al. [14] and Wagnon et al. [22],  
 23 and (6) the guaiacol model of Nowakowska et al. [23].

24 Figures S3 to S5 show that simulations using the  
 25 COLIBRI v2 model best reproduce the mole fraction  
 26 of phenol, CO, ethylene, acetaldehyde, and acrolein,  
 27 but, significant deviations are observed for  
 28 compounds, such a cyclopentadiene or 1,3-butadiene.  
 29 Latter products are better predicted by the models of  
 30 Büttgen et al. [14] and Pratali Maffei et al. [15].

31 An initial flow rate analysis showed that the  
 32 formation of cyclopentadiene is due to the reaction,  
 33  $\text{OH} + \text{C}_6\text{H}_5\text{OH} = \text{OH} + \text{CO} + \text{C}_5\text{H}_6$ , which was not  
 34 considered neither by Büttgen et al. [14] and Pratali  
 35 Maffei et al. [15], nor in Yuan's updated model for  
 36 anisole [19]. This reaction, for which no sound  
 37 justification was given by Yuan et al. [12], was  
 38 therefore removed in COLIBRI v3.

39 Many theoretical studies have focused on the  
 40 H-abstractions from phenol, its unimolecular  
 41 decomposition, that of phenoxy radical, and other  
 42 reactions involved in the first steps of phenol thermal  
 43 decomposition. In oxidation, the start of phenol  
 44 reactivity and products formation as well as the LBV  
 45 are especially sensitive to the rate constants of the  
 46 H--abstractions by OH and of the CO elimination  
 47 from phenoxy radical yielding  $\text{C}_5\text{H}_5$  radical and CO.  
 48 The rate constants of these three reactions, found in  
 49 literature in existing models [14–16,19] or  
 50 theoretically calculated [15,24–27], are compared in  
 51 Figure S6 where deviations of about a factor 10 are  
 52 observed, whatever the reaction.

53 In COLIBRI v3, isomers of hydroxyphenyl,  
 54 hydroxyphenoxy and catechol are differentiated. All  
 55 kinetic calculations by Pratali Maffei et al. [15] are  
 56 incorporated; they concern the reactions relevant to  
 57 phenol pyrolysis, including the H-abstractions by H  
 58 atoms. Other H-abstractions from phenol are updated  
 59 with the data by Wang et al. [24].

60 Additionally, rate expressions related to  
 61 hydroxyphenyl radicals were calculated at the G4

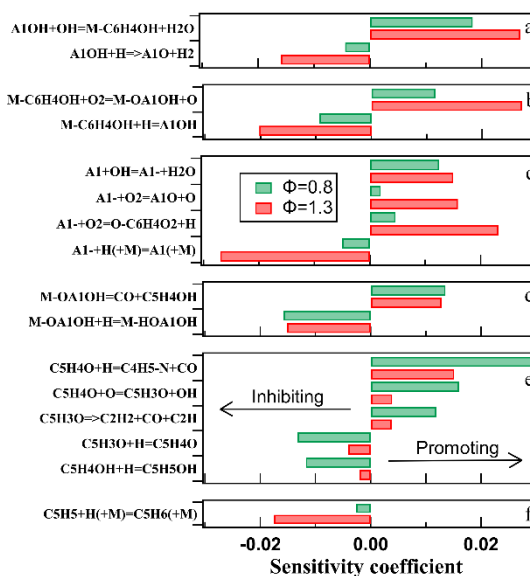

Fig.5. Sensitivity analysis for the most sensitive reactions involving  $\text{C}_5+$  reactions for the LBV at  $\phi = 0.8$  and  $1.3$ . The reactions concern (a) phenol consumption, (b) hydroxyphenyl radicals, (c) benzene and phenyl radicals, (d) hydroxyphenoxy radicals, (e) the  $\text{C}_5\text{H}_x\text{O}$  submechanism, (f) cyclopentadienyl radicals. The species names are those used in the COLIBRI v3 model.

62 level of theory [28] as part of this study. They concern  
 63 CO and water eliminations, isomerizations between  
 64 phenoxy and hydroxyphenyl radical isomers as well  
 65 as the oxygen addition to ortho-hydroxyphenyl  
 66 leading to ortho-benzoquinone and the OH radical.  
 67 Calculation details can be found in SM.

68 Quantum mechanical calculations were also used  
 69 to qualitatively explore feasible pathways to  
 70 experimentally detected  $\text{C}_{12}$ - $\text{C}_{18}$  products in the low  
 71 temperature range. While the initial dimerization  
 72 products of phenoxy radicals are only modestly stable  
 73 with respect to redissociation (see Table S3), the  
 74 ortho-ortho dimer may rearrange through a low  
 75 barrier transition state to the significantly more stable  
 76 isomer 2,5'-biphenyldiol (see Figure S7), which is the  
 77 only  $\text{C}_{12}\text{H}_{10}\text{O}_2$  isomer identified experimentally (see  
 78 Table S1) in the lower temperature range. H  
 79 abstraction from 2,5'-biphenyldiol followed by  
 80 intramolecular addition and release of OH would then  
 81 lead to the observed dibenzofuran. Figure S8 shows  
 82 that this sequence has only modest barriers. Similarly,  
 83 if the intramolecular addition occurs to the aryl-C-H  
 84 site followed by H-atom elimination,  
 85 3-hydroxydibenzofuran is formed, which is one of the  
 86 proposed species for the  $\text{C}_{12}\text{H}_8\text{O}_2$  product (see Figure  
 87 S9). An extension of this chemistry naturally leads to  
 88 a single  $\text{C}_{18}\text{H}_{10}\text{O}_2$  isomer, in agreement with the  
 89 experimental data (see Figure S10). Initial tests using  
 90 approximated rate expressions for these reactions

Fig.6. Flux analysis of phenol oxidation in JSR at 935 K corresponding to half of the fuel consumption. Only ortho-hydroxyphenyl, hydroxyphenoxy and catechol are drawn and represent the three ortho, meta and para isomers. The thickness of arrows is proportional to the flow.

1 showed an improvement of the predicted  
 2 2,5'-biphenyldiol yield, however its formation started  
 3 at higher temperatures than seen experimentally. This  
 4 indicates that more work is needed to address the low  
 5 temperature reactivity seen in phenol oxidation.  
 6 Table S4 lists all the updated reactions with rate  
 7 constants given at 1 atm; the full pressure dependence  
 8 can be found in the COLIBRI v3 mechanism file  
 9 given in SM. Because of the sensitivity of results to  
 10 the thermodynamic properties of the fuel and its first  
 11 intermediates, the thermodynamic data of phenol,  
 12 phenoxy and hydroxyphenyl are updated in this study,  
 13 thanks to their calculation at the G4 level of theory.  
 14 Validations against literature data are shown in SM.

### 15 3.2 Comparison between simulated and 16 experimental results

17  
 18  
 19 As far as LBV are concerned, as it is shown in  
 20 Figure 1, the updates in the COLIBRI v3 model  
 21 significantly improve the predictions over a wide  
 22 range of investigated equivalence ratios. Numerical  
 23 values are close to the experimental ones and within  
 24 the uncertainties, except for the lowest equivalence  
 25 ratios for which the LBV is slightly underestimated.  
 26 Concerning JSR mole fractions, as it is shown in  
 27 Figures 2 to 4, the agreement with COLIBRI v3 is  
 28 similar to that with COLIBRI v2 for both reactants  
 29 and main products such as CO, ethylene, acrolein,  
 30 acetaldehyde, benzene, benzaldehyde and is  
 31 significantly better for 1,3-butadiene and  
 32 cyclopentadiene. Acetylene is a minor product, which  
 33 is overestimated by one order of magnitude by  
 34 COLIBRI model as well as by the other models of the

35 literature (see Fig. S4). Despite being among major  
 36 oxidation products, methane is overestimated by a  
 37 factor of two by the COLIBRI model while numerical  
 38 predictions of literature models are worse, as shown  
 39 in Fig. S4. Obvious problems exist with the large  
 40 underprediction of several C<sub>10+</sub> species such as  
 41 naphthalene and dibenzofuran. Some detected  
 42 molecular weight growth species are not even  
 43 included in the model.

### 44 3.3 Kinetic analyses

45 Kinetic analyses were performed both in flame and  
 46 in JSR.

#### 47 3.3.1. Flame kinetic analysis

48  
 49  
 50 The particularity of phenol in flame is that it is  
 51 consumed through many different pathways as shown  
 52 in Figure S12. H-abstractions leading to  
 53 hydroxyphenyl radicals are the main decomposition  
 54 pathways and highly promote the flame propagation.  
 55 They are among the most sensitive reactions on the  
 56 LBV as shown in the sensitivity analysis in Figure 5a.  
 57 Reacting with O<sub>2</sub>, hydroxyphenyl radical is involved  
 58 in two pathways, one forming benzoquinone and OH,  
 59 only for the ortho isomer, and the highly promoting  
 60 branching reaction in competition with the inhibiting  
 61 termination reaction with H-atoms in Figure 5b. The  
 62 H-abstractions from the hydroxy group of phenol  
 63 appear as an inhibiting pathway as it forms the  
 64 resonantly stabilized phenoxy radical (see Figure 5a).  
 65 Another important pathway is the ipso-addition of  
 66 H-atoms to the hydroxy group forming benzene  
 67 and

1 because it mainly leads to phenyl, the key role of  
2 which is highlighted in Figure 5c notably because of  
3 its involvement both in the promoting branching  
4 reaction,  $\text{phenyl} + \text{O}_2 \rightarrow \text{phenoxy} + \text{O}$ , and in the  
5 inhibiting termination with H-atoms. The flux  
6 analysis in Figure S12 highlights one last  
7 consumption pathway of phenol: the ipso-addition of  
8 O-atoms to the aromatic ring. Because of its  
9 resonantly stabilized behavior, hydroxyphenoxy  
10 radical is at the heart of a strong competition between  
11 the inhibiting termination reaction with H-atoms  
12 forming catechol and the promoting CO elimination  
13 leading to hydroxycyclopentadienyl. Due to this  
14 competition, these reactions have a strong impact on  
15 LBV (see Figure 5d). In addition, in Figure 5e, the  
16 sensitivity analysis highlights a very sensitive  
17 submechanism composed of  $\text{C}_5\text{H}_x\text{O}$  species:  
18 cyclopentadienone ( $\text{C}_5\text{H}_4\text{O}$ ), cyclopentadienol  
19 ( $\text{C}_5\text{H}_5\text{OH}$ ) and its radicals ( $\text{C}_5\text{H}_4\text{OH}$  and  $\text{C}_5\text{H}_5\text{O}_2$ ).  
20 The only way to exit this loop submechanism is the  
21 decomposition of cyclopentadienone into smaller  
22 linear species or into  $\text{C}_5\text{H}_3\text{O}$  through H-abstractions.  
23 Therefore, these reactions, as well as the  
24 decomposition of  $\text{C}_5\text{H}_3\text{O}$  into smaller species,  
25 promote flame propagation. The terminations of  
26  $\text{C}_5\text{H}_3\text{O}$  and  $\text{C}_5\text{H}_4\text{OH}$  with H-atoms respectively form  
27 back cyclopentadienone and produce  
28 cyclopentadienol in the inhibitory loop  
29 submechanism and strongly slow down the LBV.  
30 Interestingly, the CO elimination on hydroxyphenoxy  
31 radicals forming  $\text{C}_5\text{H}_4\text{OH}$  promotes the flame  
32 propagation even if it leads to the  $\text{C}_5$  inhibiting  
33 submechanism. Cyclopentadiene and  
34 cyclopentadienyl radical are mainly produced from  
35 phenoxy and hydroxyphenyl radicals and constitutes  
36 another way to form  $\text{C}_5$  species.

37 The most significant influence of the equivalence  
38 ratio in phenol flame is the inhibition of the  $\text{C}_5\text{H}_x\text{O}$   
39 loop submechanism under rich condition coupled to a  
40 higher proportion of  $\text{C}_5\text{H}_4\text{O}$  and  $\text{C}_5\text{H}_3\text{O}$  decomposing  
41 into smaller linear species. Consequently, these  
42 reactions in figure 5e are not sensitive in rich mixture  
43 and most of other key reactions in figure 5 are even  
44 more sensitive.

### 45 3.3.2. JSR kinetic analysis

46  
47  
48 The flow analysis of the first pathways in phenol  
49 oxidation at 935 K is presented in Figure 6. The main  
50 decomposition pathways of phenol are the H-  
51 abstractions leading to phenoxy radicals;  
52  $\text{phenol} + \text{HO}_2 \rightarrow \text{phenoxy} + \text{H}_2\text{O}_2$  consumes 29% of the  
53 fuel and is the most sensitive reaction for the phenol  
54 mole fraction as shows Figure S13a. Phenoxy radicals  
55 mainly lead to cyclopentadienyl by CO elimination  
56 and re-form phenol by termination with H-atoms.  
57 Phenoxy radicals are also involved in additions and  
58 terminations typical of this temperature range [2,16]  
59 leading to benzodioxole, benzofuran and  
60 dibenzofuran, which were detected experimentally.

61 Phenoxy radicals are also formed through minor  
62 pathways coming from the formation of benzene by  
63 ipso-addition with H-atoms on the hydroxy group of  
64 phenol. The second main way to decompose phenol  
65 are the H-abstractions on the aromatic ring. The  
66 hydroxyphenyl radicals mainly react with  $\text{O}_2$  through  
67 branching reactions leading to hydroxyphenoxy  
68 radicals, also directly formed from phenol. The Figure  
69 S13b-c highlights that phenoxy-like radicals are at the  
70 heart of a competition between inhibiting termination  
71 reactions with H-atoms and  $\text{HO}_2$ , and alternative  
72 promoting pathways, notably CO eliminations. Other  
73 sensitive reactions concern the fuel consumption and  
74  $\text{H}_2\text{O}_2 \rightarrow 2\text{OH}$  multiplying OH radicals. Finally, the  
75 flow analysis contains numerous cyclopentadienone  
76 pathways (not experimentally detected, but leading to  
77 quantified  $\text{C}_2$  products), with  $\text{C}_5\text{H}_4\text{OH}$  and ortho-  
78 benzoquinone as intermediates, as in flame.

## 79 4. Conclusion

80  
81  
82 This paper presents the first detailed kinetic model  
83 for phenol oxidation validated on new experimental  
84 data, both LBV measurements and products  
85 quantification in a JSR. After revising the phenol  
86 related rate constants using recent literature data and  
87 theoretical calculations, a global satisfactory  
88 agreement can be obtained between measured and  
89 simulated data. However, some species like acetylene,  
90 methane and  $\text{C}_{12\leq}$  compounds are still poorly  
91 estimated, what calls for future works on phenol  
92 kinetic in order to perfectly understand its combustion  
93 behaviour. Finally, the key role of phenoxy-like and  
94 phenyl radicals, as well as of the  $\text{C}_5\text{H}_x\text{O}$   
95 submechanism, is highlighted in kinetic analyses in  
96 both JSR and flame.

### 97 Declaration of competing interest

98  
99  
100 The authors declare that they have no known  
101 competing financial interests or personal relationships  
102 that could have appeared to influence the work  
103 reported in this paper.

### 104 Acknowledgements

105
