High-Water Marks
Sensitivity Maps
Derivative-Based Global Sensitivity Measures (DGSM)

ABSTRACT

This contribution presents a novel approach for the calibration of distributed parameters in a 2D urban flood hydraulic model. It focuses on the challenging issue of inferring distributed friction parameters from multi-source heterogeneous spatio-temporal observations of their hydraulic signatures in the context of an urban flash flood in a complex street network. A variational data assimilation algorithm is used to infer high-dimensional multi-variate parameters (spatialized friction and inflow discharge time series) using multi-source observations. This method relies on a differentiable 2D shallow water hydraulic model which enables to generate high-resolution sensitivity maps of local gradients and Derivative-based Global Sensitivity Measures (DGSM), enabling to guide adequate definition of parameter spatialization for the data assimilation process. Assimilated data include real local limnigraphic measurements and high-water marks collected after a major flood event, as well as modeled flow velocity used in twin experiments setups. This study is the first to leverage high-water marks with a variational method for the calibration of distributed parameters in an urban flood model. The multi-source data is used to infer inflow hydrographs and distributed friction parameters in setups of varying complexity. In the main setup, the complex structure of the street network, along with the sensitivity maps and hydraulics expertise led to define a model configuration with 45 friction patches. A high-dimensional parameter vector composed of these friction values and an upstream inflow is inferred simultaneously by assimilating real limnigraphic data and high-water marks. This leads to an increase in model fit to observations and satisfying parameter estimates.

1. Introduction

In the context of global change, the potential increase in frequency and intensity (Masson-Delmotte et al. (2022)) of extreme rainfall events may lead to an increase in flood occurrences. Urbanization is linked to the sealing of natural soils, which may lead to increased flood impacts in densely populated areas (Ogden et al., 2011). Furthermore, the multiplicity of flow paths with complex geometries in urban areas makes the study of urban floods at High Resolution (HR) a challenge and a necessity Bulti and Abebe (2020). Understanding urban flows and improving our capability to predict urban floods is a key issue for the protection of populations, and prediction tools should rely on HR hydraulic models able to accurately model complex flows and to leverage heterogeneous data sources (Mignot and Dewals (2022)).

The hydrodynamic phenomena at play in urban floods are potentially rapidly varied in space and time. The interaction of relatively energetic flows with street networks and local geometries can trigger complex flood flows,

✉ leo.pujol@ird.fr (L. Pujol)
ORCID(s): 0000-0002-8903-1270 (L. Pujol)

43 which makes the modeling of urban floods particularly challenging. Local geometries can refer to culverts, street
44 intersections, obstacles such as cars or urban furniture which can all generate losses of mechanical flow energy. Urban
45 flood flows can be highly non-linear and model response can be sensitive to local controls, as studied through friction
46 sensitivity analysis in urban hydraulic models of urban floods in Chen et al. (2018) and through detailed hydraulic
47 signatures analysis of an experimental street network dataset in (Finaud-Guyot et al., 2018, 2019). This sensitivity is
48 not easily measurable or localizable on real cases (Mignot and Dewals, 2022). Modeling the influence of fine-scale
49 topography and complex geometries on flood flows can be performed with a 2D hydraulic modeling approach (see
50 e.g. model validations in (Arrault et al., 2016; Chen et al., 2018; Dellinger et al., in prep.) using experimental data
51 from (Finaud-Guyot et al., 2018, 2019), see also references in review of Mignot and Dewals (2022)). Still, building
52 and better constraining such models from heterogeneous data remains a challenge.

53 Indeed, building HR urban flood models requires HR data to describe fine spatial variations of topography and
54 hydraulic structures, as well as estimations of hydrological inflows and real flow data to estimate the unobservable
55 hydraulic friction which models flow momentum dissipation and is also often used to compensate modeling errors. A
56 key challenge that pertains to flow observation availability stems from the multi-scale aspect of flow variability and the
57 difficulty of adequately observing it, in part because of the localized, sudden and violent nature of most floods. Indeed,
58 observations of the local impacts of complex geometries on flow is difficult to acquire, while observations of the larger
59 scale impacts of friction effects may be more readily available. Therefore, it becomes necessary to adopt modeling
60 approaches of appropriate complexity that are capable of leveraging any available data, which requires methods for the
61 assimilation of heterogeneous, uncertain distributed observations of flow signals.

62 A growing wealth of information provided by multi-sensors measurements is exploitable to build and to better
63 constrain HR hydraulic models, as explored in recent works. To build a model, accurate topography – vital to HR
64 modeling – can be derived from remote-sensed data like HR LiDAR for urban models, see e.g. Haile and Rientjes
65 (2005). Soil occupation and building locations can be estimated from satellite imagery, see e.g. (Zhang et al., 2007;
66 Salvati et al., 2016; Li et al., 2019), although fine-scale variations remain difficult to identify. Finally, complex urban
67 geometries information can be derived from very HR aerial imagery, e.g. manhole cover locations in (Commandre
68 et al., 2017; Mattheuwsen and Vergauwen, 2020). To calibrate the resulting models, spatially sparse flow observations
69 (e.g. water depth time series from limnigraphs) can be combined with high-water marks (HWM), which are typically
70 either collected shortly after the flood or derived from pictures shared by local authorities and inhabitants. HWM
71 are generally more dense in space and can provide a useful complement to observations at static locations, thanks to
72 information on the spatial distribution of the water levels they carry. Indeed, the hydraulic model calibration issue is
73 difficult to tackle and multi-source distributed measurements are valuable.

74 The benefits of participative methods for data collection have already been identified by flood alert networks
75 (Douvinet et al., 2017) and HWM are sometimes used for validation e.g. in Hocini et al. (2021), for large rural-urban
76 floodplains modeled at relatively high resolution in steady state, and in Neal et al. (2009), for simplified urban flood
77 models. In Nguyen et al. (2022), satellite-based observations of water extents are used to calibrate 13 parameters
78 including longitudinally distributed friction in the minor bed of the Garonne river modeled with the full 2D SW model
79 Telemac2D (Galland et al., 1991). Validation is carried out against HWM and independent satellite data. A relatively
80 low spatialization of friction into 6 patches is defined and their estimation, which is a low dimensional inverse problem,
81 is tackled using with an EnKF-based approach. For relatively fast fluvial flood dynamics, satellite data may not be
82 available due to satellite sampling and water extent data may contain significant uncertainty preventing fine hydraulic
83 calibration. HWM were used in recent works for hydraulic model calibration in Dasgupta et al. (2022) who use crowd-
84 sourced, heterogeneously distributed HWM of a relatively fast fluvial flood for friction calibration with a sequential
85 algorithm in the non-inertial hydraulic model LISFLOOD-FP (Bates et al., 2013). In urban environments, HWM are
86 especially difficult to compare to model outputs for validation or calibration purposes due to locally complex dynamics.
87 To tackle this issue, Smith et al. (2021) proposes a framework to compare HWM to water depths from hyper-resolution
88 hydrological models for fluvial-urban floods, with ADHydro (Ogden et al., 2015) and WRF-Hydro (Gochis et al., 2018)
89 and mesh elements in the tens of meters. Nevertheless, the calibration of spatially distributed parameters in a full 2D
90 Shallow Water (SW) hydraulic model, enabled by sufficient amount of spatially distributed HWMs and water level
91 time series compared to flow variabilities, remains a difficult calibration problem that requires advanced optimization
92 approaches.

93 Calibrating spatially distributed effective friction, that is using friction effects for momentum dissipation to
94 compensate uncertainties of 2D SW modeling of complex urban flood flows, remains difficult due to the high potential
95 for spatial and structural equifinality when searching for such a parameter using sparse and uncertain observations of
96 complex signals. Since flow observations are generally sparse compared to the physical scales of interest, addressing
97 this challenging issue generally leads to solving difficult ill-posed inverse problems. The spatialization of friction of
98 a 2D hydraulic model has to be adjusted depending on the physical complexity of the real flow and on modeling
99 errors, but also on the availability and quality of calibration data, to enable sufficient freedom in model response for
100 approaching the data. Furthermore, this issue becomes even more challenging to address when other unknown or
101 uncertain quantities, such as temporal forcings at boundaries, must be estimated as well.

102 Such difficult inverse problems, aiming the estimation of large parameters of different nature, can be adequately
103 solved using Variational Data Assimilation (VDA) methods applied to hydraulic modeling which have proven their
104 capability to infer high-dimensional parameter vectors of such a linear dynamic flow model. Examples of VDA
105 applications to SW models are (Hostache et al., 2010; Monnier et al., 2016) on 2D rural floodplain flows, Pujol et al.

106 (2020) on large 1D model with multiple inflows, and Pujol et al. (2022) on multi-D floodplain and river network
107 model. Pujol et al. (2022) in particular exploits the informative richness of heterogeneous and uncertain observation
108 sets. In those studies, VDA approaches, based on differentiable hydraulic models, enable to tackle high-dimensional
109 inverse problems associated with increasing friction spatialization. As of yet, no VDA framework was studied for
110 the specific needs of urban floods, i.e. for the optimization of high-dimensional spatio-temporal parameter vectors
111 (uncertain friction and inflows for instance) in 2D hydraulic models with complex street networks, especially using
112 HWMs.

113 The sparsity of flow observations also encourages the leveraging of multi-source observations, which may be crucial
114 for putting hydraulic models in coherence with our best, yet still incomplete, observation of reality. This requires the use
115 of adequate observation operators, to allow a pertinent comparison of observed data to model states (e.g. as discussed
116 for hydrological models in Smith et al. (2021), for 1D modeling in Pujol et al. (2020) or for 2D hydraulic modeling
117 in (Hostache et al., 2010; Monnier et al., 2016; Pujol et al., 2022)). It also requires sufficient model controllability,
118 i.e. the ability to provide sufficient flexibility to the model response through freedom granted to its tunable parameters
119 to match multi-source distributed observations of rapidly varied hydraulic signals. Therefore, a 2D hydraulic model
120 with VDA capabilities (e.g. DassFlow2D with automatic adjoint derivation Monnier et al. (2016)) is well suited for
121 tackling the simultaneous estimation of large and multi-variate spatio-temporal parameters, such as spatially distributed
122 parameters, e.g. friction, and spatially distributed inflow time series. Furthermore, this property of the VDA method
123 is especially pertinent for urban model calibration, where potentially sharp spatial variations of model parameters
124 may be responsible for important flow variabilities. This creates a specific need in urban models for the inference of
125 high-dimensional spatial parameter fields. at are expected to be partial, heterogeneous and uncertain.

126 Simultaneously inferring parameters that have correlated influence on model response and observable signatures,
127 however, leads to equifinality issues (Larnier et al., 2021; Pujol et al., 2020). We can distinguish between structural
128 and spatial equifinality. Structural (resp. spatial) equifinality arises when two distinct parameters (resp. different spatial
129 patterns of a given parameter) can lead to similar observed (not fully) model responses within a range of meaningful
130 model parameterizations. Structural equifinality is expected, for example, when simultaneously estimating bathymetry
131 and friction parameters embedded in a friction term from water level observations (Garambois and Monnier, 2015;
132 Larnier et al., 2021). Spatial equifinality corresponds, for example, to a case of two friction parameters fields leading
133 to similar model fit of model response to the available information, e.g. in 1D (Garambois et al., 2020; Pujol et al.,
134 2020) and 2D Fabio et al. (2010) models. Equifinality is a key issue to address for urban flood model optimization,
135 but regularization strategies and constraints are required to enable meaningful estimation of the sought parameters.
136 The use of friction patches (Hostache et al., 2010; Monnier et al., 2016), consisting in spatial clustering of friction
137 parameters to provide a constraint in the forward model, enables to adjust model flexibility and controllability. Using

138 gradient-based sensitivity maps obtained with an adjoint of a 2D hydraulic model Monnier et al. (2016) to compute
139 Derivative-Based Sensitivity Measures (DGSM, Sobol' and Kucherenko (2009)) to guide the spatialization of model
140 parameters has seldom been done and is studied here.

141 This study presents the application of a VDA framework (DassFlow2D, Monnier et al. (2016)) for the inference of
142 multivariate spatio-temporal and potentially large parameter vectors by assimilation of multi-source and heterogeneous
143 observations into a 2D full SW model, tested here on a complex urban flash flood case. It focuses on the inference of a
144 boundary inflow hydrograph and spatially distributed friction coefficients performed by assimilation of heterogeneous
145 water depth observations, including HWM and water level time series, and of flow velocity observations. Furthermore,
146 it applies a gradient-based method for the generation of HR sensitivity maps, based on (Sobol' and Kucherenko, 2009;
147 Lamboni et al., 2013). Therefore, the contribution of the study is a demonstration of the potential of a VDA algorithm
148 and gradient-based sensitivity analysis to develop an understanding of the fine structure of spatialized parametric
149 sensitivities and the associated useful power for diagnostic and for recovering complex hydraulic parameters. Particular
150 attention is paid to definition of model degrees of freedom through the definition of friction spatialization, hence of
151 the parameters sought by VDA.

152 The article is organized as follows. In Section 2, the hydraulic model, the VDA algorithm and the method for
153 gradient-based sensitivity analysis are presented. In Section 3, the study area, the data for the considered flooding
154 event and the model building approach are detailed. In Section 4, a series of gradient-based analyses and inference
155 results are discussed, including the simultaneous calibration of distributed friction patches and inflow hydrograph.
156 The study is concluded in Section 5.

157 **2. Numerical tools and models**

158 This work uses an accurate 2D SW solver implemented in the DassFlow2D¹ hydraulic-hydrological modeling and
159 data assimilation platform. It consists of a Fortran kernel interfaced with Python. A numerical adjoint model, obtained
160 by source to source differentiation of the Fortran core performed with TAPENADE engine (Hascoet and Pascual, 2013),
161 enables access to gradient-based methods for sensitivity analysis and parameter inference. The code is open-source and
162 available through GitHub².

163 **2.1. 2D hydraulic model**

164 We consider a 2D spatial domain $\Omega \subset \mathbb{R}^2$ over which the numerical solver is applied and denote by $t \in]0, T]$
165 the physical time. T is the simulation time period length. The 2D SW equations in their conservative form write as
166 follows:

¹<https://www.math.univ-toulouse.fr/DassFlow/index.html>

²<https://github.com/DassHydro/dassflow2d>

$$\frac{\partial}{\partial t} \mathbf{U} + \frac{\partial}{\partial x} \mathbf{F}(\mathbf{U}) + \frac{\partial}{\partial y} \mathbf{G}(\mathbf{U}) = \mathbf{S}_g(\mathbf{U}) + \mathbf{S}_f(\mathbf{U})$$

$$\mathbf{U} = \begin{bmatrix} h \\ hu \\ hv \end{bmatrix}, \mathbf{F}(\mathbf{U}) = \begin{bmatrix} hu \\ hu^2 + \frac{gh^2}{2} \\ huv \end{bmatrix}, \mathbf{G}(\mathbf{U}) = \begin{bmatrix} hv \\ huv \\ hv^2 + \frac{gh^2}{2} \end{bmatrix}, \quad (1)$$

$$\mathbf{S}_g(\mathbf{U}) = \begin{bmatrix} 0 \\ -gh\nabla b \end{bmatrix}, \mathbf{S}_f(\mathbf{U}) = \begin{bmatrix} 0 \\ -g \frac{n^2 \|\mathbf{v}\|}{h^{1/3}} \mathbf{v} \end{bmatrix}$$

167 with the water depth h [m] and the depth-averaged velocity $\mathbf{v} = (u, v)^T$ [m/s] being the flow state variables. The
 168 flow model parameters are the gravity magnitude g [m/s²], the bed elevation b [m], and the Manning-Strickler friction
 169 coefficient n [s/m^{1/3}]. $\mathbf{F}(\mathbf{U})$ is the flux of the variable \mathbf{U} , $\mathbf{S}_g(\mathbf{U})$ is the gravitational source term, $\mathbf{S}_f(\mathbf{U})$ is the mass
 170 and friction source term. Adapted initial and boundary conditions are chosen (see (Monnier et al., 2016; DassFlow,
 171 2019)), namely imposed mass flux at upstream boundary and imposed water depth at downstream boundary.

172 A well-balanced Godunov finite volume scheme (Godunov and Bohachevsky, 1959) is used to solve Eq.(1). Either
 173 a classical first-order scheme with explicit Euler time stepping or a globally second-order Implicit-Explicit (IMEX)
 174 scheme with Runge-Kutta time stepping can be used along with a Harten-Lax-van Leer-Contact (HLLC) Riemann
 175 solver. This solver is an improvement on the Harten-Lax-van Leer-Contact (HLL) method with a three-wave velocity
 176 model for calculating flows (see Toro (2013) for more details).

177 2.2. Cost function for multi-source DA

178 Data assimilation aims to optimally combine model and data. It consists in minimizing the discrepancy between
 179 model and observations that is measured through a cost function. Let us define a set of heterogeneous observations Y^*
 180 and an observation operator \mathcal{H} that converts any component of Y^* into hydraulic model states variables projected into
 181 observation space $Y \in \Omega$. * denotes given values. Let us define θ a control vector of model parameters. It can contain
 182 any number of model parameters, including distributed friction and inflow time series as done in this work.

The objective function J is defined as the sum of two terms:

$$J(\theta) = J_{\text{obs}}(\theta) + \alpha J_{\text{reg}}(\theta) \quad (2)$$

183 where J_{obs} stands for the observation cost function measuring the discrepancy between model and flow observations,
 184 and J_{reg} is a regularization term weighted by a coefficient α .

The general form of the observation cost function writes:

$$J_{\text{obs}}(\boldsymbol{\theta}) = \left\| Y(\boldsymbol{\theta}, t) - \mathcal{H}(Y^*(t)) \right\|_{\mathcal{O}_Y}^2 \quad (3)$$

185 where \mathcal{O}_Y is a covariance matrix defining an euclidean weighted norm such that $\|z\|_{\mathcal{O}_Y}^2 = z^T \mathcal{O}_Y z$, with z a real valued
 186 vector.

187 Note that the cost function enables to account for multi-source observations and depends on the sought parameters
 188 $\boldsymbol{\theta}$ through the model response Y .

In this work, calibration relies on real and synthetic observations of water depth $h_{\text{obs}}(x, y, t)$ and synthetic observations of flow velocity $\mathbf{v}_{\text{obs}}(x, y, t)$ that are directly comparable to model states through $h(\boldsymbol{\theta}, x, y, t)$ and $\mathbf{v}(\boldsymbol{\theta}, x, y, t)$. For real HWM observations, peak time \hat{t}_p is unknown and must be estimated. Hence the general cost function considered hereafter writes as:

$$J_{\text{obs}}(\boldsymbol{\theta}) = a \left\| h(\boldsymbol{\theta}, t) - h_{\text{obs}}(t) \right\|_{\mathcal{O}_h}^2 + b \left\| h(\boldsymbol{\theta}, \hat{t}_p) - h_{\text{obs}}(\hat{t}_p) \right\|_{\mathcal{O}_{h_p}}^2 + c \left\| \mathbf{v}(\boldsymbol{\theta}, t) - \mathbf{v}_{\text{obs}}(t) \right\|_{\mathcal{O}_v}^2 \quad (4)$$

189 where a, b, c are weighting coefficients. The three terms account successively for:

- 190 1. the model misfit to water level time series at one or several gauges within the spatial domain, over part or the
 191 whole simulation duration, hence a sum in space and time.
- 192 2. the model misfit to high water marks at max flooding time \hat{t}_p , that has to be estimated if not known.
- 193 3. the model misfit to surface velocity observations - in this work we use observations of depth-averaged velocities,
 194 hence no observation operator needed.

195 The purpose of Eq.4 is to provide a single formula for the different cost functions simply used with equal and/or
 196 null weights in what follows. Moreover, in the absence of information on measurement errors, the covariance matrices
 197 of the observation error \mathcal{O}_h , \mathcal{O}_{h_p} and \mathcal{O}_v are simply set to the identity matrix.

198 2.3. Data assimilation problem

The data assimilation problem consists in minimizing the discrepancy between observations and model by adjusting its parameters. Considering the above defined cost function (Eq.(2) and Eq.(4)), the estimation of the parameter vector $\boldsymbol{\theta}$ of the 2D SW model (Eq.(1)) gives rise to an optimization problem that writes as follows:

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta}}{\text{argmin}} J(\boldsymbol{\theta}) \quad (5)$$

199 where $\hat{\theta}$ denotes the optimum parameter vector. This optimization problem is solved using a first order gradient-based
 200 algorithm, the classical L-BFGS quasi-Newton algorithm (Zhu et al., 1997). The gradient $\nabla_{\theta}J$ is computed with the
 201 help of the adjoint model, obtained by automatic differentiation using Tapenade (Hascoet and Pascual, 2013).

In this work, as affordable with the considered observations, the full control vector θ can contain spatially distributed friction coefficients n and inflow hydrographs Q_{in} such that:

$$\theta = (n(x, y), Q(t))^T, \forall [x, y] \in \Omega, t \in [0, T] \quad (6)$$

202 This multi-variate vector of spatio-temporal parameters of the 2D hydraulic model is optimized in order to reduce
 203 the misfit between simulated flows and heterogeneous observations of complex 2D urban flows. The optimization is
 204 started from a first guess θ^* on the sought parameters, $*$ denotes here the prior that is given as the flow observation.

205 Note that the inference capability depends on the informative content of observations and of their spatio-
 206 temporal sampling. The inference is particularly challenging in the case of parameters having correlated influence on
 207 observations. This is the case, for example, with spatially distributed friction fields, where distinct localised variations
 208 can trigger indistinguishable flow signatures, depending on the flow conditions; this relates to spatial equifinality. The
 209 simultaneous estimation of such a spatialized friction parameter and another parameter, such as a time-varying inflow
 210 hydrograph, makes the inverse problem even more difficult.

211 2.4. Gradient-based global sensitivity analysis

212 In the context of difficult inverse problems, analysis of the sensitivity of the model response to its parameters can
 213 provide useful guidance, especially if spatio-temporal sensitivity patterns are available. A strength of our differentiable
 214 numerical modelling approach is to enable the computation of accurate cost gradients $\nabla_{\theta}J$ with respect to spatio-
 215 temporal parameters (see Monnier et al. (2016)).

216 When dealing with heterogeneous data and structural and spatial equifinality problems, these local sensitivity maps
 217 are precious information for determining parameter patches as well as for examining global sensitivities over a plausible
 218 parameter space.

219 The estimation of global variance-based importance measures of model input parameters, called Sobol' indices
 220 Sobol' (2001), can be performed with Derivative-based Global Sensitivity Measures (DGSM) as proposed by Sobol'
 221 and Kucherenko (2009) (see also Lamboni et al. (2013)).

222 First and total order indices write Saltelli et al. (2008) $S_i = \frac{V_i}{V}$ and $S_{Ti} = 1 - \frac{V_{\sim i}}{V}$, where $V_i = V(E[J|\theta_i])$ is the
 223 variance caused by the input factor θ_i , and $V_{\sim i}$ is the variance of the expectation of J conditional on $\theta_{\sim i}$, i.e. all the
 224 variables except θ_i .

Assuming that $J(\theta_1, \dots, \theta_N)$ is square integrable over the parameter hypercube \mathcal{H}^N , following the Morris importance measure (Morris, 1991; Saltelli et al., 2008), the DGSM proposed by Sobol' and Kucherenko (2009) writes:

$$\mu_i = \int_{\mathcal{H}^N} \left(\frac{\partial J}{\partial \theta_i} \right)^2 dx \quad (7)$$

This gradient-based measure can be related to total order Sobol' indexes as shown in Sobol' and Kucherenko (2009) through the inequality $S_{Ti} V(J(\theta)) \leq \mu_i$. Then it can be extended to normal and uniform measures (Lamboni et al. (2013)), such that if input factors are independent and if factor θ_i follows a normal distribution of variance σ_i^2 then:

$$S_{Ti} \leq \frac{\mu_i \sigma_i^2}{V(J(\theta))} \quad (8)$$

225 The components of the gradient $\nabla_{\theta} J(\tilde{\theta}) = \left(\frac{\partial J(\tilde{\theta})}{\partial \theta_1}, \dots, \frac{\partial J(\tilde{\theta})}{\partial \theta_N} \right)$ at a given point $\tilde{\theta} \in \mathcal{H}_N$ can be computed accurately
 226 by solving the adjoint model of the forward numerical model presented in section above, even in high dimension which
 227 is hardly possible with finite difference approaches.

228 The computation of DGSM is made as in Chelil et al. (2022), where the global adjoint sensitivity analysis is applied
 229 to a spatially lumped hydrological model, considering a uniform sample of each member of θ as $\theta_i = (a_i - b_i)\epsilon_i + b_i \forall i =$
 230 $1..N$ with $\epsilon \in u(0, 1)$ and $[a_i, b_i]$ the expected range for the parameter θ_i . Then, for each sample $k = 1..K$ of the
 231 sampling, the forward 2D SW model is run to compute $J_k(\tilde{\theta})$ and the adjoint model is run to compute $\left(\frac{\partial J(\tilde{\theta})}{\partial \theta_i} \right)_k^2$ and
 232 finally get the expectation $E \left[\left(\frac{\partial J}{\partial \theta_i} \right)^2 \right]$ over the sample.

233 Gradient-based local sensitivity maps obtained by solving a numerical adjoint model are presented in Castaings
 234 et al. (2009) for a 2D hydrological model and in Monnier et al. (2016) for a 2D SW model. In this article, in order to
 235 study spatial variations in the sensitivity of a spatialized parameter, we present maps of cost function gradients with
 236 respect to fully distributed homogeneous friction coefficients. We then compute the expectation $E \left[\left(\frac{\partial J}{\partial \theta_i} \right)^2 \right]$ over a
 237 sample of homogeneous friction distribution within the expectable parameter space, i.e. within parameters bounds
 238 defined a priori. The goal is to inform the spatialization of the friction parameter to reach appropriate controllability,
 239 by sampling sensitivity over the parameter space that can be expected to be visited during the iterative deterministic
 240 assimilation process.

241 Appropriate controllability is intended as a sufficient spatialization of friction into spatial patches, i.e. giving
 242 freedom to model parameter, hence to modeled flow variability, such as enabling a better fit to the available observations
 243 while maintaining parameters identifiability. In this approach, the control spatialization is guided by analysis of
 244 hydrodynamics and data availability, which is originally complemented in this article by the HR sensitivity maps

245 obtained with DGSM. A parameter control vector is defined so that it can be inferred, which requires that simulated
246 quantities at observation locations are sensitive to control parameters.

247 3. Study area

248 The studied catchment is located in Abidjan, capital of the Ivory Coast, a rapidly growing megapole with a tropical
249 climate. It covers part of the Riviera-Palmeraie neighbourhood, which has suffered from recurrent flash flooding during
250 both the high and low rain seasons for over a decade. The area is centered around the channel of the Ministre street
251 that crosses the neighbourhood. Along the Ministre street, an existing asphalt road was washed away by the successive
252 floods. The materiel is packed dirt with regular obstacles such as rock piles, cars (see e.g. Fig.2(b)). Upstream from
253 the study area, the catchment presents two distinct urbanized zones, one of which features a dam just upstream from
254 the model boundary. Flow from both watersheds enters the study area through the Ministre street channel.

255 A particularly intense 4.5-hour-long flooding event that occurred in 19 June 2018 was documented through
256 limnigraphic measurements from a gauging station located in the Ministre street channel and the collection of HWM
257 throughout the study area (see Fig.3, left). The urban flooding was caused by an upstream flood hydrograph peaking at
258 around $57 \text{ m}^3/\text{s}$, according to hydrological model estimates. The impact on local hydraulics of this inflow is recorded
259 at the limnigraphic station, which carries important information on its temporal variations. Distributed information
260 on local dynamics and on the upstream flow is carried by HWM, with depths recorded outside of the channel often
261 reaching 1.5 m (see Fig.1).

262 HWM were collected the day after the event using a ruler and a GPS. Measurements are consistent overall in terms
263 of spatial variations of water surface elevation, oftentimes showing homogeneous variations along a street. Some
264 variations are less consistent with overall trends, but may be the result of local obstacles. Measurement uncertainty
265 with the ruler is expected to be around 5mm. Compounding errors are linked to i) placement the bottom of the ruler
266 on uneven ground, ii) generation of the LiDAR DEM and iii) projection of LiDAR data on the mesh grid, and difficult
267 to estimate. The data and modeling uncertainties will be classically compensated through friction calibration, with
268 various degrees of spatialization hence freedom.

269 In this work, taking into account spatio-temporal observations of flow depth, the goal is to estimate (1) an unknown
270 inflow hydrograph and (2) friction patterns of adequate spatialization in a 2D SW model. This hypothesis of 2D
271 hydraulic modeling with a single friction source term to represent dissipation of mechanical flow energy is widely
272 used and enables effective flow modeling of urban floods over complex geometries with local geometrical singularities
273 (e.g. Arrault et al. (2016), Chen et al. (2018)). The use of an optimized friction enables to effectively compensate
274 uncertainties of 2D modeling of complex and multiscale 3D flows over local geometries (see e.g. actual street view in
275 Fig.2(b)).

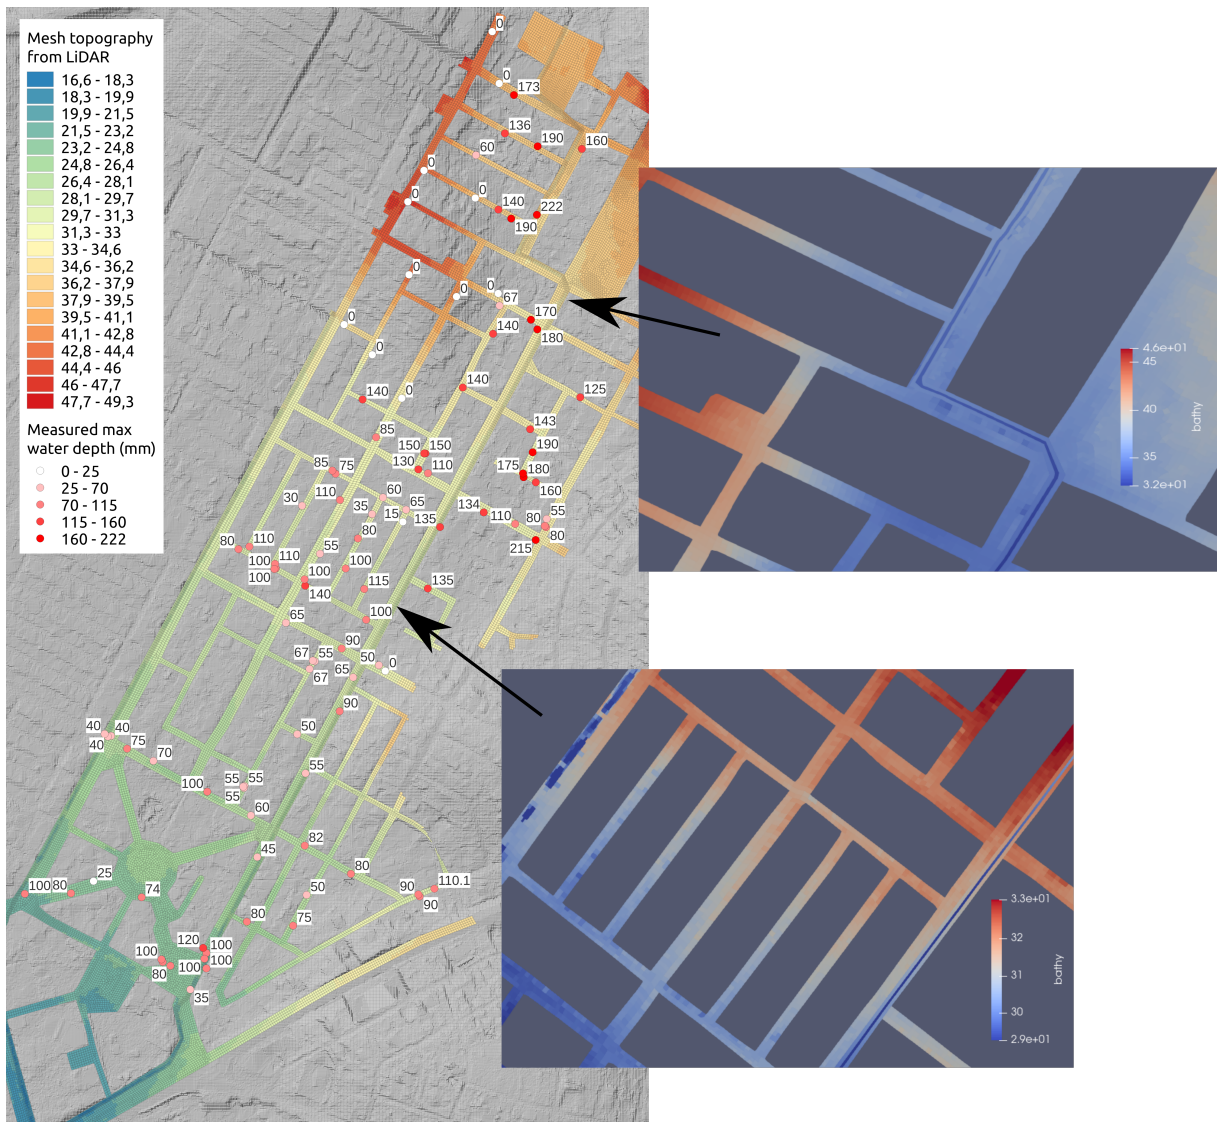

Figure 1: HWM locations with recorded water depth values in mm and model topography plotted on part of the mesh only for clarity. LiDAR DEM in background. HWM are overall spatially consistent with each other and LiDAR bathymetry. Observations of 0m depths are not used in assimilations. Zooms show homogeneous street slopes that are representative of the studied area. Top zoom focuses on the second double bend where overflow occur. Bottom zoom shows a street network of interest (studied in Section 4.1.2). The Ministre channel is visible in zooms and has a depth of 2m and a width of 2m (see Fig.2(a)).

276 Furthermore, the recent installation of a fixed camera at the gauging station should allow for the generation of
 277 surface velocity observation fields in the near future, through numerical velocimetry methods (using tools like e.g.
 278 ANDROMEDE (Cassan et al., 2024) or Fudaa-LSPIV (Jodeau et al., 2019)). The anticipated availability of this kind
 279 of observations motivates queries into the potential usefulness of surface velocity observations, especially for flooding
 280 events.

(b) Still from news footage on the 2018 flood: the Ministre street after the flood peak. Approximate location of channel edges in red.

Figure 2: Real views within the hydraulic domain

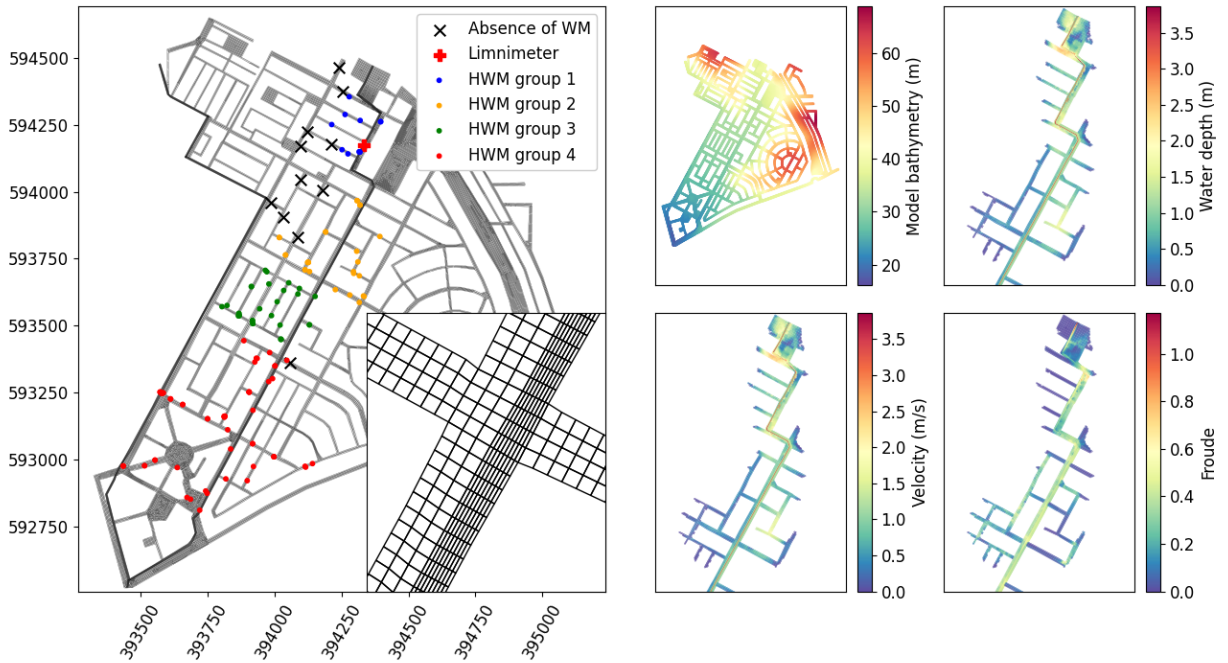

Figure 3: Model results and mesh with observation locations. Left: Full model mesh including zoom around an intersection with the Ministre street, where the mesh is refined around the channel. HWM locations for the flooding event are divided into 5 groups based on their distance from the upstream injection point and their distance from the channel. Modeled values of water depth, flow velocity and Froude are provided at peak flow for a hydrograph of max flow $57\text{m}^3/\text{s}$ and for a homogeneous friction of $n = 0.07 \text{ s/m}^{1/3}$. Average slope of the channel is 0.98%. Average slope of the straight part of the Ministre street is 0.84%.

281 3.1. Mesh building

282 The 2D unstructured mesh of the streets is composed of 52k quadrangular elements adapted to the sharp angles
 283 of the street network with crossroads and 2D flow patterns. Mesh resolution is designed to allow fast computation,
 284 especially useful in inverse modeling, and allow modeling the rapidly varied phenomena we expect around local

285 geometries. Buildings are assumed impermeable, which is reasonable since most lots around the Ministre street are
286 well delineated by high walls and building entryways are often blocked by smaller walls built in response to recurrent
287 flooding. Model topography is given by a 2.5m LiDAR DEM. Within the channel, homogeneous slopes were manually
288 set based on LiDAR topography analysis: 0.75% on the first 1500 m of channel and 1.05% on the remaining 900 m.

289 Most cells have an edge length of around 4m, i.e. from 2 to 4 cells per street width. Given the relative smoothness
290 of the topography and the homogeneity of street-scale slope in the model, this appears to be a reasonable trade-off
291 between resolution and computation time. The mesh was refined around the Ministre street channel to accurately
292 model the location and elevation of its bottom and its 2 meters-high side walls (see mesh zoom in Fig.3, the channel
293 has a width of 2m, or 2 fine cells). The time step is adaptive with a Courant-Friedrichs-Lewy (CFL) condition value
294 of 0.8, which results in time steps generally between 0.2 and 0.02 s.

295 **3.2. Direct model setup**

296 Based on field experience and interaction with local inhabitants, the flooding of the street network is largely due
297 to the Ministre street channel overflow that is inflowed by a single upstream hydrograph. This hydrograph is the only
298 considered inflow boundary condition for the 2D SW model resolution.

299 While other inflow locations are known in the downstream part of the model, forward simulations have shown that
300 these downstream inflows do not influence the hydrodynamic behaviour observed by HWM groups 1, 2 and 3 (see
301 Fig.3, left). They contribute to flood extent in the downstream part of the model only, due to the relatively high slope.
302 Since these inflows are not known a priori and their influence is not observed independently through time series (only
303 through a subset of HWM observations), they would be very difficult to estimate. This is why we choose not to account
304 for them and instead focus on the upstream inflow. This means that the hydraulic control exerted by the downstream
305 BC is not expected to match reality closely and it may be difficult to fit the model to observations in HWM group 4.

306 Other preliminary simulations showed that the contribution of rain over the urban hydraulic modeling domain to
307 the total volume is low. Homogeneous rain was modeled using rain intensity time series from the nearest pluviometer,
308 injected over the hydraulic domain as mass source term. A runoff coefficient of 1 is assumed. This setup corresponds
309 to what we expect to be the worse case of runoff generation in the area, hence it leads to an estimation of the maximum
310 expected contribution of runoff to the flood. At peak flow, the contribution of rain is under 11% of the water volume in
311 the model. This is why, in an effort to focus on channel overflow and complex flow distribution in the nearby streets,
312 the presented model does not account for rain within the hydraulic domain. It appears feasible to fit most HWM
313 observations by calibrating only the upstream inflow and distributed friction parameters.

314 4. Results and discussion

315 The aim of this section is to reconstruct an unknown upstream inflow hydrograph, while calibrating spatially
316 distributed friction of a 2D SW model by VDA of multi-source flow observations. The common focus of the following
317 numerical experiments is the analysis of the impact of the degrees of freedom given to a distributed friction parameter
318 on the assimilation results in a context of spatial equifinality. The method is applied to a single flood event with limited
319 but informative amount of data, hence validation on other events cannot be performed.

320 The presented cases are of varied complexity in terms of the informative content of the observations used. A
321 summary of considered parameter controls and observations is presented in Table 1.

322 A homogeneous friction value of $n = 0.07 \text{ s/m}^{1/3}$ was chosen as an initial estimate. It is a relatively high friction
323 in comparison to classical values used in hydraulics such as those in reference tables (e.g. Chow (1959)), especially for
324 the channel, which has smooth concrete bottom and sides, but it leads to fair fits overall (Fig.7, red). This homogeneous
325 friction distribution is used as a target value around which local gradients are sampled for sensitivity maps, in Section
326 4.1, and as a prior value in assimilation experiments, in Sections 4.2 and 4.3.

327 In Section 4.1, distributed friction is given a high degree of freedom, in the context of sparse (Section 4.1.1)
328 and dense (Section 4.1.2) observations. Spatial equifinality is discussed using gradient-based sensitivity metrics,
329 highlighting the complexity of the flow in the street network as seen through the assimilation process.

330 In Section 4.2, distributed friction is given a lesser degree of freedom with the intent to infer inflow hydrograph
331 and friction simultaneously. Real observations, spatially sparse with regard to the hydrodynamic phenomena at play,
332 but including a water level time series relevant to infer the time varied inflow, are assimilated.

333 In Section 4.3, distributed friction is given a high degree of freedom in a twin experiment setup, in the context of
334 sparse, local observations of localized phenomena. High friction areas are used to generate synthetic observations of
335 complex behaviours, then friction is inferred from these observations starting from a homogeneous prior.

336 For all experiments, the regularization weight is set to $\alpha = 0$. The only applied regularizing effect is achieved
337 through parameter spatialization in the direct model.

338 4.1. Gradient-based sensitivity maps: expectable optimization trends and hydraulic controls 339 spatialization

340 The local gradient of a cost function with regard to a set of chosen model parameters, $\nabla_{\theta} J(\tilde{\theta})$, can provide an
341 interesting insight into model sensitivity, locally at a given point $\tilde{\theta}$ in the parameter space \mathcal{H}^N . Furthermore, our
342 differentiable hydraulic model enables computation of accurate HR gradient maps for high-dimensional parameter
343 vectors by adjoint model resolution. As proposed in Section 2.4, the information conveyed by several local gradient
344 maps can be combined to compute, for a given sample of the parameter space, global sensitivity in the form of spatial

Section	Content	Parameter vector content (total elements)	Considered observations
4.1.1	Local gradient maps	Fully distributed friction (52118)	Synthetic, sparse HWM at peak flow
4.1.2	Global gradient map	Fully distributed friction in area of focus (1208)	Synthetic water depth time series at all cells of area of focus
4.2	Full model calibrations	Distributed friction (2, 15 or 45) and upstream hydrograph (20)	Real HWM and water depth time series at limnigraph
4.3	Localized high-friction calibration	Fully distributed friction (52118)	Synthetic water depth and flow velocity time series at chosen locations

Summary of experiment setups performed in Section 4

345 maps. This subsection presents (i) local gradient maps of distributed friction and (ii) a spatial map of global sensitivity
346 as defined in Eq.(8).

347 **4.1.1. Local friction sensitivity maps**

348 The local gradient maps are generated for a twin experiment. Observations of water depth are generated at the
349 locations of the actual HWM measurements using a reference model. This reference model features a homogeneous
350 friction of $n^* = 0.07 \text{ s/m}^{1/3}$ at all cells and a 3h symmetrical triangular upstream hydrograph of peak flow $30 \text{ m}^3/\text{s}$
351 as upstream BC. The distributed gradients of the cost with respect to friction are computed for each cell, for two prior
352 values of spatially homogeneous friction ($n = 0.065$ and $n = 0.075 \text{ s/m}^{1/3}$), as presented in Fig.4.

353 A positive (red in Fig.4) gradient value at a given cell indicates that the first iteration of our VDA method would
354 likely lead to a decrease in friction at that cell. A negative (blue in Fig.4) gradient would lead to an increase in friction.

355 An underestimation of the friction's first guess ($n = 0.065$, -7% from the reference n^*) leads to higher sensitivity
356 upstream (Fig.4a). Positive gradients are computed in Area 1, outside of the channel, while gradients are negative in
357 the channel, between two bends. An increase in friction in the channel in this area would exert a stronger hydraulic
358 control at or before the first bend, hence increasing the underestimated depths upstream. Downstream, other positive
359 gradients (Area 2) indicate that depth at observation points in the lateral streets is dependent on local friction, both in
360 and out of the channel. More spatially varied gradients are visible around the observations closest to the channel and
361 around the limnigraph (Area 3).

362 An overestimation of the friction's first guess ($n = 0.075$, +7% from the reference n^*) causes more outflows
363 toward the street adjacent to the channel, leading to a larger area of interest (Fig.4b). Positive gradient values on
364 most of the channel cells, especially downstream, indicate that the assimilation process should overall appropriately
365 lead to a reduction of friction. Several clusters of contrasted gradient values appear along the channel (e.g. Areas
366 1 and 2) and at street intersections (e.g. Area 3). This means that a local control impacting the flux distribution at
367 these important intersections can help reduce misfit to HWM observations, even when straying further from the lower

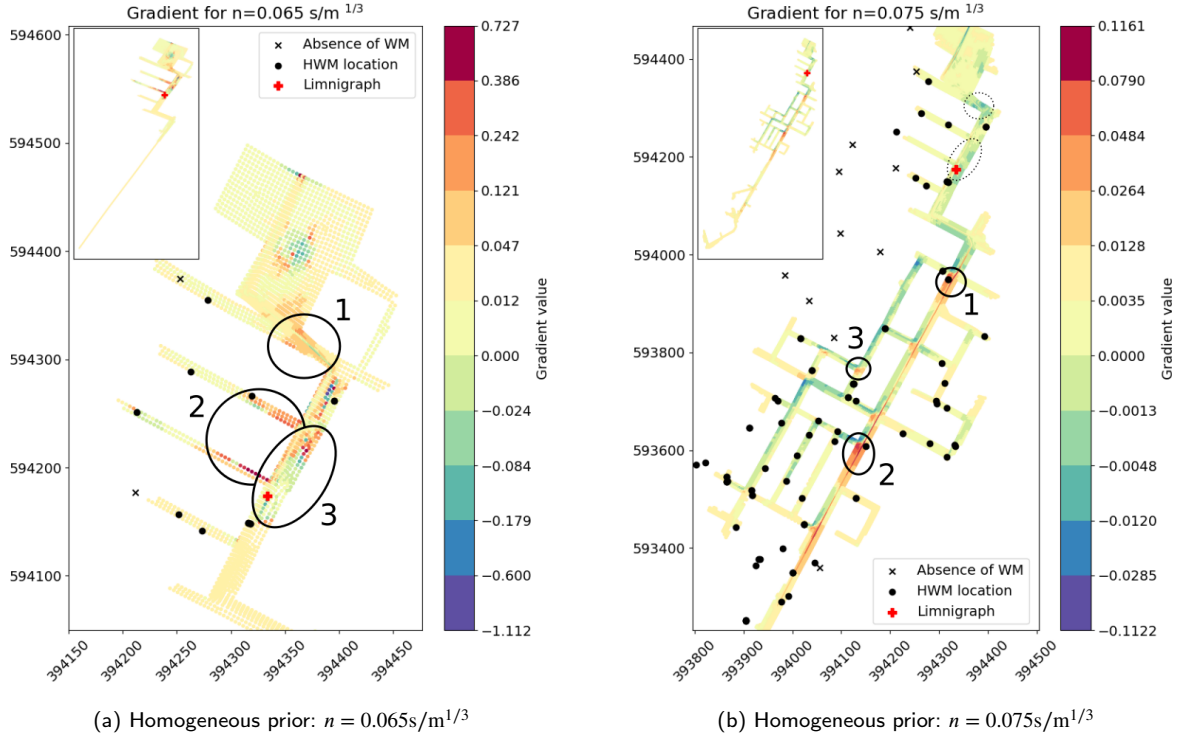

Figure 4: Maps of observation cost function sensitivity to friction parameter $\frac{\partial J(n)}{\partial n}$, locally in parameter space for $n = 0.065$ or $0.075 \text{ s/m}^{1/3}$. A positive (resp. negative) value means the assimilation process should decrease (resp. increase) the parameter to reduce cost. The reference friction $n^* = 0.07 \text{ s/m}^{1/3}$ is used to generate observations at HWM locations and cost function is computed with the water depth time series as $J(n) = \|h(n, t) - h_{\text{obs}}(n^*, t)\|_2^2$. Gradients are computed at all cells of Ω . Null values of gradient are not plotted. Left: gradient maps for $n = 0.065$. An underestimation of friction leads to a decreased flooded area, mostly limited to around the limnigraph. Right: gradient maps for $n = 0.075$. An overestimation of friction leads to an increased flooded area in the street network. The top-left miniatures present computed non-zero gradient values over the whole hydraulic domain.

reference homogeneous friction. Indeed, a reduction of the cost may be achieved "for wrong reasons" by rerouting water to areas where it has less impact on the cost functions, i.e. "hiding" water from the assimilation process in un-/less-observed or insensitive areas.

These gradient maps are those used in the iterative data assimilation process. The sign of the gradients indicates by definition the rate of variation of the functional J with respect to parameters, i.e. the descent trend in parameter space, so positive gradient means that reduction of the cost would be obtained by an decrease of this parameter locally in the hydraulic domain, and conversely. They show that parametric sensitivity in our street network is complex even with spatio-temporally dense observations from a homogeneous reference model and starting from homogeneous priors. The trajectories that they indicate provide some insight into the expectable optimization trends and inferred spatial patterns of parameters given high degrees of freedom. Still, they may not tell the whole story. Indeed, emerging hydraulic behaviors in subsequent parameter optimization iterations, such as a different channel overflow location or a different

379 flow repartition within the street network, may lead to different spatial distribution and relative weights of the gradient.
380 Hence the need to propose global sensitivity evaluations that sample a number of expectable hydraulic behaviours and
381 inform on its spatial distribution across all iterations, in order to adapt parameter spatialization.

382 4.1.2. *Global friction sensitivity maps*

383 A new setup is defined to study the global sensitivity of cost to distributed friction in a limited area of the hydraulic
384 domain: a subdivision of the flooded street network. The spatial domain is restricted to limit computation costs. Flows
385 reach the considered area from multiple directions, having seen potentially complex mixing upstream, hence inflows
386 to the considered area are highly dependent on friction as well as peak upstream inflow.

387 Observations of water depth are generated for each cell of the considered hydraulic subdomain of 1402 cells (see
388 Fig.5) throughout the simulated period, The reference model has a homogeneous friction of $0.07 \text{ s/m}^{1/3}$ and is inflowed
389 a 1.5h symmetrical triangular hydrograph of peak flow $54 \text{ m}^3/\text{s}$. Peak inflow is higher than in Section 4.1.1 to ensure
390 the area of interest is flooded for all below friction values.

391 A series of local gradient maps are generated for two separate triangular hydrographs and for 7 homogeneous
392 friction values. The peak flow values of these hydrographs are $Q_1 = 50$ and $Q_2 = 60 \text{ m}^3/\text{s}$. The friction is given
393 by a uniform sampling of the range of expectable values: $n_i = (a - b)\epsilon + a \forall i = 1..7$, with $a = 0.04$, $b = 0.1$ and
394 $\epsilon = 0.01$. Q_2 generally leads to earlier channel outflows than Q_1 and friction values also influence propagation times
395 in the streets and channel. This complexity is observed downstream, in a street network that receives inflow from both
396 local overflows and upstream urban areas.

397 Global gradient maps are generated for each inflow hydrograph (see Fig.5). Local gradients are available in Fig.
398 10 in the Appendix. They aim to identify sensitive areas across the range of friction that the assimilation may cover
399 during its iterative process.

400 The global maps further underline the role of localized friction in the control of flow at intersections in the street
401 network. Sensitivities are higher with an upstream peak inflow of $60 \text{ m}^3/\text{s}$ (Fig.5, right) which simply reflects that
402 this setup is further away from the target model than the $50 \text{ m}^3/\text{s}$ peak flow on, hence higher cost and gradient values.
403 Relative sensitivity values at hotspots vary but their location remains the close to the same. This can be explain by
404 the spatial variation of the observed misfit. With a $60\text{m}^3/\text{s}$ peak flow, higher sensitivity is computed to the east, i.e.
405 close to the overflowing drain and before this excess flow can be distributed in the street network, hence a higher
406 modeled water depth misfit. With a lower peak flow of $50\text{m}^3/\text{s}$, the misfit near the channel is lesser, hence a different
407 relative distribution of sensitivity and a relatively higher sensitivity far from the channel. Overall, both maps lead to
408 the identification of similar sensitivity patterns, regardless of the considered inflow. This seems to indicate that the

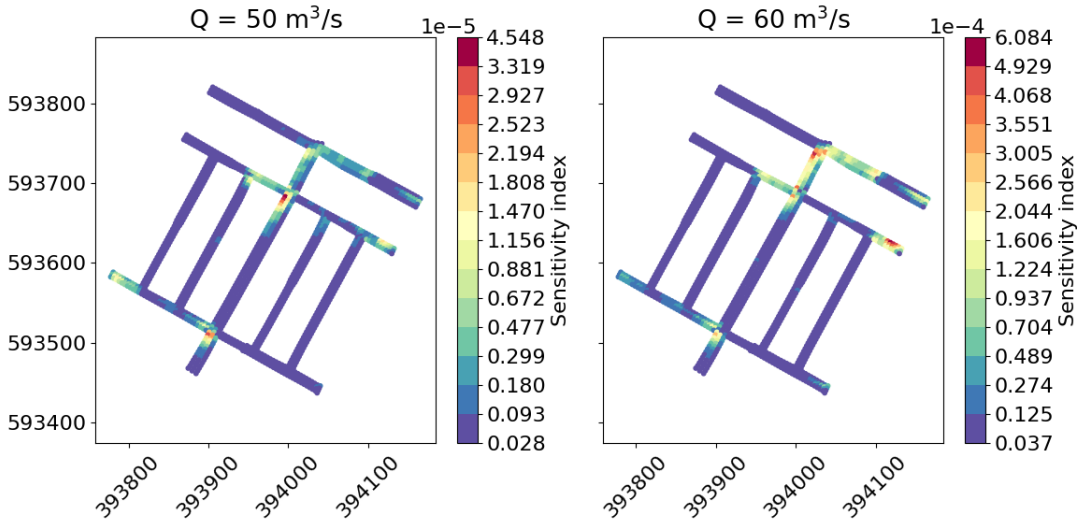

Figure 5: Global sensitivity maps of $E \left[\left(\frac{\partial J(\theta)}{\partial \theta_i} \right)^2 \right]$ for 7 samples of expected homogeneous friction (0.04, 0.05, 0.06, 0.07, 0.08, 0.09, 0.1 $\text{m/s}^{1/3}$) for two synthetic hydrographs with respective peak flows of 50 m^3/s (left) and 60 m^3/s (right). Local gradient maps of the parameter space samples are plotted in Appendix A.

409 simultaneous inference of a time-dependent inflow hydrograph and of distributed friction should not lead to a large
 410 difference in inferred friction patterns.

411 More generally, across the sampled parameter space, there is a risk for spatial equifinality in the context of sparse
 412 observations of complex phenomena. The above sensitivity maps provide insight on the spatial location of areas
 413 sensitive to the sought parameters, hence on where the assimilation method could lead to parameter corrections, which
 414 pertains to model controllability.

415 A fully distributed friction parameter would enable a higher controllability of model response, by enabling local
 416 corrections and the creation of variabilities in the simulated flow. Assuming that the reality is indeed varied, it may
 417 allow to better fit observations. Nevertheless, it is obvious that spatially dense observations are needed to constrain a
 418 spatialized parameter while avoiding spatial equifinality. Inversely, a uniform friction is easily identifiable from few
 419 observations, but it does not give enough controllability to fit spatialized observations like those available in our study
 420 area. The sensitivity maps help reach a sensible middle ground for the friction spatialization, with appropriate degrees
 421 of freedom, where spatial parameters patches are defined in coherence with available observations, sensitive areas and
 422 a priori knowledge of realistic parameter distribution.

423 **4.2. Model calibration from available data**

424 Building on sensitivity analysis, we devise a strategy where appropriate controls are defined in the form of friction
425 patches that enable model flexibility while avoiding spatial over-parameterization for the simultaneous inference of
426 friction and upstream inflow.

427 **4.2.1. Upstream inflow inference**

428 The observation most informative about the upstream discharge is the water depth time series obtained at the
429 limnigraph. It is located upstream (Fig.3) of most expected channel overflows.

430 In a first assimilation setup, we attempt to estimate the upstream inflow $Q_{in}(t)$ from available observations at the
431 limnigraph only. While peak flow estimates from hydrological modeling were available, the shape of the hydrograph
432 was not known. This is why we chose to infer this uncertain parameter as enabled by our assimilation framework,
433 showcasing the value of water level time series inside the hydraulic domain even without using a priori peak flow
434 knowledge from the hydrological model.

435 We set an homogeneous value of friction $n = 0.07 \text{ s/m}^{1/3}$ and we choose a constant discharge of $5 \text{ m}^3/\text{s}$ as a prior
436 value for $Q_{in}(t)$. This arbitrary constant low flow value does not create channel overflow and carries no information
437 on discharge amplitude or temporality, hence any such inferred variability will be extracted only from the limnigraphic
438 observation.

439 From this limited information and no a priori knowledge on hydrograph shape, a complex hydrograph shape is
440 inferred. Its peak flow is $44 \text{ m}^3/\text{s}$, quite close to the estimated $57 \text{ m}^3/\text{s}$ when considering the prior value of $5 \text{ m}^3/\text{s}$.
441 The hydrograph and its corresponding water surface elevation at the observation site are represented in Fig.6. In
442 what follows, the simultaneous inference of upstream hydrograph and friction fields is possible thanks to considering
443 spatially distributed HWMs in addition to the water level time series at one location. The current inferred hydrograph
444 serves as a prior for subsequent inference setups, where inferred peak inflows reach $58 \text{ m}^3/\text{s}$ with increased performance
445 at the limnigraph (see Fig.7, top right).

446 **4.2.2. Simultaneous inference of distributed friction and upstream inflow**

447 Leveraging both limnigraph and HWM data could allow the calibration of both inflows and distributed parameters.
448 However, as underlined in the previous sections, the distribution of spatial parameters should be coherent with both
449 observations and modeled hydraulic behaviours. In the following, we attempt to simultaneously infer the upstream
450 hydrograph, with a prior value set from a previous inference, and spatialized friction, with a prior homogeneous friction
451 of $n = 0.07 \text{ s/m}^{1/3}$, in setups of increasing complexity regarding the number of spatial patches. Performance of the
452 prior and calibrated models is presented at HWM and at the limnigraph in Fig.7.

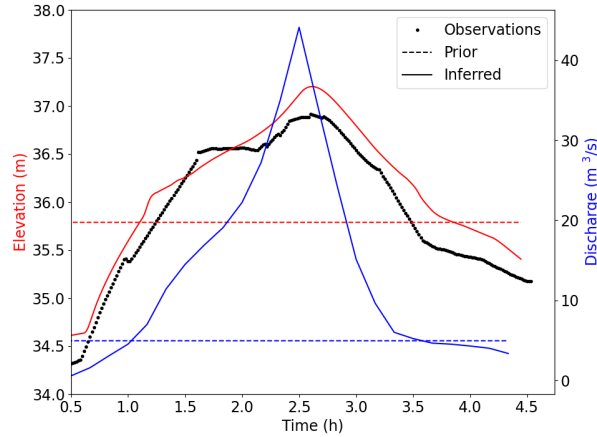

Figure 6: Inference of inflow time series from limnigraph observations starting from a flat prior ($5\text{m}^3/\text{s}$).

453 For HWM observations, the time of maximum depth \hat{t}_p is estimated for each HWM from a direct simulation using
 454 the prior values for inflows and friction. It is not updated during the assimilation process. Indeed, the emphasis is
 455 put on the VDA capacity to infer spatio-temporal parameters of a 2D SW model (friction and inflow discharge) from
 456 heterogeneous distributed observations (HWMs and water level time series), with simplified hypothesis regarding
 457 data uncertainties. Uncertainty on maximum water depth time is around 20min based on numerical experiments. It is
 458 controlled at first order by the inflow hydrograph and also by channel overflow location and timing, hence by friction
 459 effects.

- 460 • FrictionSet1 is the simplest setup, based on simple a priori knowledge only. We define two patches: the first
 461 containing all cells within the channel, and the second containing all other cells, i.e. street cells. This
- 462 • FrictionSet2 leaves some degrees of freedom to the model in the street network, but the patches are much larger
 463 than identified sensitivity hot-spots. We define 15 patches (see inference results in Fig.8, left). One patch contains
 464 cells within the channel, and the other patches contain subdivisions of the street cells where flooding is observed.
 465 This experiment A key assumption of this set is that the inference of friction requires more controllability outside
 466 of the channel than within.
- 467 • FrictionSet3 gives the model more flexibility within the channel, which could help change where overflows
 468 toward the street network occur. We define 45 patches (see inference results in Fig.8, right). In the street network,
 469 patches span either one large street or a group of smaller streets within the flooded area. Around the channel, in
 470 the Ministre street, one patch is defined between each intersection with another street.

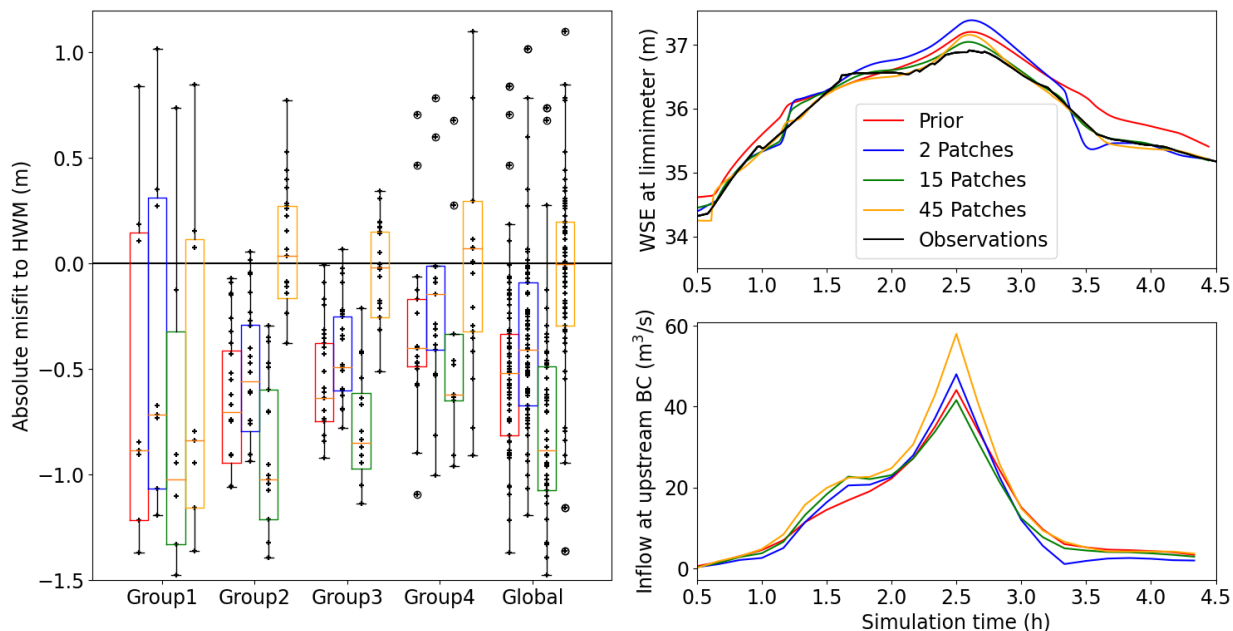

Figure 7: Model performance at HWM and at the limnigraph for FrictionSet 1, 2 and 3, after simultaneous calibration of upstream discharge and distributed friction coefficients, and for their common prior. Left: absolute misfit to observed water depth at HWM locations. Each individual misfit is plotted as a black cross, outliers are denoted by a black cross with a circle. HWM groups are defined in Fig.3. Top right: Simulated water surface elevation at the limnigraph. Bottom right: mass flux injected at the upstream boundary.

471 The simple FrictionSet1 affords very little controllability to the inverse problem. Calibration of the two patches
 472 leads to friction values of $0.059 \text{ s/m}^{1/3}$ in the channel and $0.045 \text{ s/m}^{1/3}$ in the streets. High friction in the channel
 473 helps cause overflows, but water depth in the street network are still underestimated. At around 3.5 hours, a sharp
 474 change in modeled water depth at the limnigraph (Fig.7, top right, in blue) reflects how a slight change in upstream
 475 inflow (which is around $5 \text{ m}^3/\text{s}$ at 3.5h) can impact resulting water depth, thus the quadratic cost function. It features
 476 a reasonable improvement of the overall fit to observations in all 4 HWM observation groups.

477 In FrictionSet2 however, the result of the calibration process is an overall degradation of the fit to HWM
 478 observations, while a improved] fit is obtained at the limnigraph (Fig.7, in green). Although FrictionSet2 leads to
 479 a lower cost function than the prior, misfit is reduced at the limnigraph but increased at HWMs. Remember that
 480 the absolute misfit plotted in Fig.7 is not the cost seen by the assimilation process. This result can be explained by
 481 a spatialization of friction ill-adapted to the phenomena that lead to street flooding. The model is given flexibility
 482 upstream, around the limnigraph, but not along the Ministre street, where local overflows are expected. This leads
 483 to a reduction of uncertainty only in the upstream part of the model, where the parameter spatialization allows such
 484 improvement, at the expense of the accurate modeling of downstream overflows. Overflows occur at both upstream
 485 double bends due to geometry. High friction at the second double bend, outside of the channel, exerts upstream control

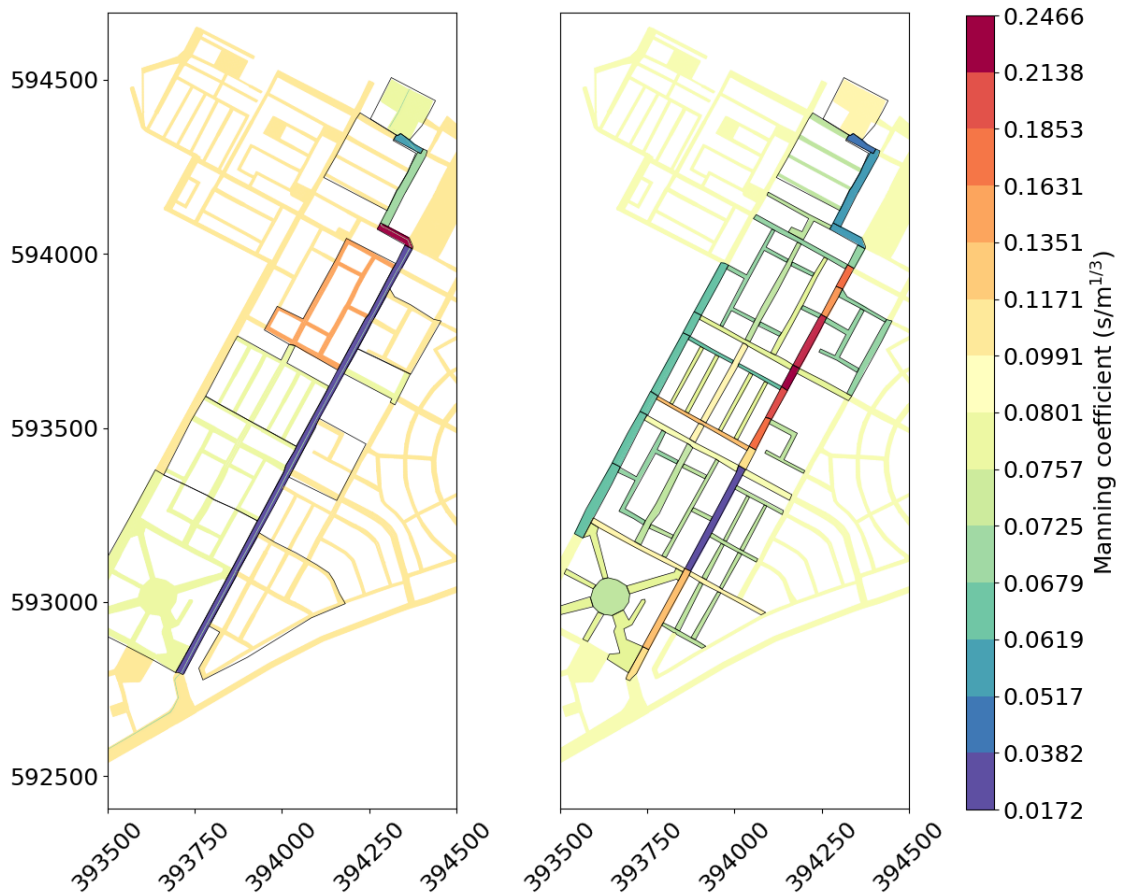

Figure 8: Calibrated Manning friction values for the FrictionSet2 and FrictionSet3 setups. Friction patches are represented as black polygons. The colormap is not linear, friction values are grouped based on a "natural breaks" classification. This enables showing the fine spatial contrasts, or lack thereof, of inferred frictions.

486 and helps fit HWM group 1 that are within range of the local hydraulic control. This setup, juxtaposed with the simpler
 487 FrictionSet1, serves to highlight the need for well-defined degrees of freedom.

488 FrictionSet3 provides more controllability and leads to greatly improved performance at HWM sites and at the
 489 limnigraph (Fig.7, in orange). On one hand, in most of the street network, friction values within a reasonable physical
 490 range of 0.06 to 0.09 are inferred. On the other hand, high friction values along the Ministre street allow the model
 491 to change the location and intensity of channel overflows. Median water depth misfits in HWM groups 2, 3 and 4 are
 492 close to 0, while misfits over HWM group 1 are close to that of FrictionSet1. Adequate degrees of freedom have led
 493 the assimilation process to an optimal solution that is a fair improvement over the prior value and features reasonable
 494 parameter ranges.

495 In FrictionSet 2 and 3, quite high (resp. low) friction values – $n > 0.1$ (resp. $n < 0.01$) – are inferred in patches along
 496 the Ministre street. They create local overflows toward the street network or instead facilitate the flow along the Ministre
 497 street. This enables controlling flow repartition and fitting flow observations by introducing an effective compensation

498 of modeling uncertainties of urban flood flows over local complex geometries. Excessive upstream overflows may be
499 compensated by low friction values further downstream.

500 In the end, FrictionSet3 has a good performance for a urban flow modeling with highly energetic flows and complex
501 flow repartition: the median misfit is close to 0m, 50% of stations have misfit between 0.19 and -0.29m and only 13 out
502 of 97 stations have a misfit greater than 0.5m. This is in line with other studies using HWM for validation. In Hocini
503 et al. (2021), misfit to HWM reaches 2m in a model of a river network, with 70% of misfit within the -0.9 to 0.7m
504 range. Neal et al. (2009) models a relatively slow river flood in an urban environment and features misfit to observed
505 water levels as high as 1.5m in an urban model, with most misfit within the -0.5 to 0.5m range. Finally, in Nguyen
506 et al. (2022), no statistical analysis is presented but the validation of the calibrated Garonne model against HWM yields
507 several misfits of more than 1m in absolute value.

508 Through 3 setups of increasing complexity, we showcased the capability of our VDA toolchain to infer high-
509 dimensional multi-variate control vectors from multi-source heterogeneous observations of hydraulic variables. The
510 studied urban flood has a relative lack of data compared to literature cases with very dense sensors networks and rainfall
511 radar for instance, but the available LiDAR topography plus a water depth time series and HWMs already provide very
512 interesting information as shown by our results. We underlined the usefulness of the method for cases with limited flow
513 observations and the necessity for adequate friction parameter spatialization, which is based on hydraulic knowledge
514 and sensitivity analysis.

515 **4.3. Assimilation of local controls from multi-source heterogeneous observations**

516 Regarding local singularities, this section takes a closer look at the capability of the assimilation process to infer
517 distributed parameters with localized influences on flow. It focuses on the inference of two strong local hydraulic
518 controls and the challenge of correctly attributing their spatial signatures from multi-source observations in a global
519 optimization setup in space and time (see cost function in Eq.(2)). The below inverse problem is purposefully over-
520 parameterized in order to both underline the capability of the assimilation process to handle high-dimensional controls
521 and showcase spatial equifinality at a finer scale.

522 A new synthetic reality was generated to include two small areas of high-friction ($n = 0.2 \text{ s/m}^{1/3}$) that exert
523 upstream hydraulic controls. The first area is located within the channel (Fig.9, middle, blue area) and increases
524 outflows from the channel towards the street network. The second is located at a street intersection where it influences
525 flow repartition (Fig.9, right, blue area). Aside from these 5 cells, the friction is set to $0.07 \text{ s/m}^{1/3}$ across the model.
526 The inflow is a symmetrical triangular hydrograph of peak flow $50 \text{ m}^3/\text{s}$.

527 The in-channel site is observed through a synthetic limnigraph upstream from the high-friction area. The crossroad
 528 site is observed through modeled velocities at 3 contiguous cells, where an outflow from the crossroad is expected (see
 529 Fig.9b). Both observed quantities are sensitive to the influence of the local high-friction patch.

530 The cost function is $j(\theta) = \frac{1}{3} \|\mathbf{v}(\theta, t) - \mathbf{v}_{\text{obs}}(t)\|^2 + \|h(\theta, t) - h_{\text{obs}}(t)\|^2$ and the control vector is the fully
 531 distributed friction parameters $\theta = (n_1, \dots, n_N)$, where N is the total number of cells. Component weights were set
 532 to obtain equal contributions of water depth observations and velocity observations at the first iteration. The prior
 533 value is an homogeneous friction of $0.07 \text{ s/m}^{1/3}$.

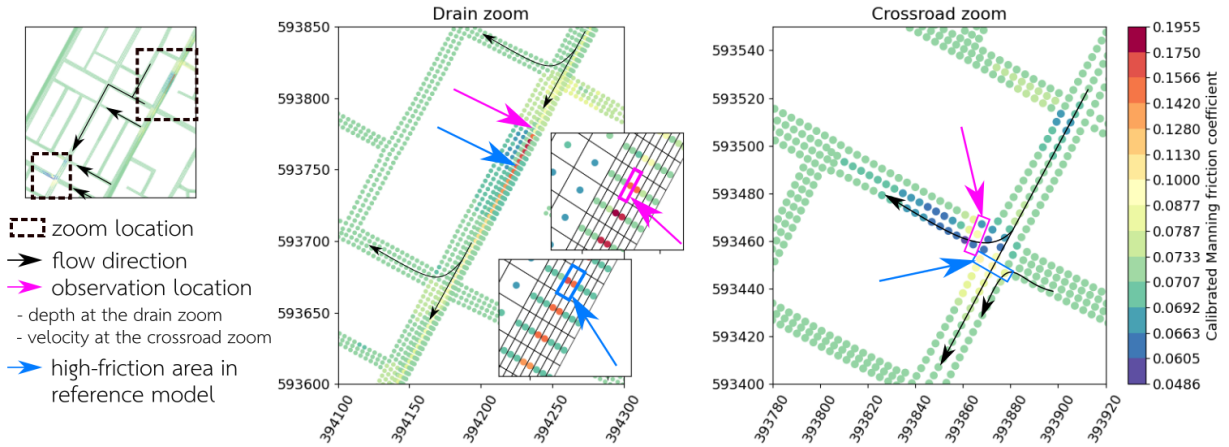

Figure 9: Inferred friction coefficients, starting from a homogeneous prior of $n = 0.07 \text{ s/m}^{1/3}$, from multi-source observations of a synthetic event. At the channel zoom, an observation of the water depth at a single point is used. At the crossroad zoom, observations of flow velocity at 3 cells are used. High-friction areas near the observations are present in the synthetic reality. Overflows occurring around the channel zoom can reach the crossroad zoom from the north-east. Other overflows from the channel reach the crossroad zoom from the east.

534 At each site, the inferred spatially distributed friction enables to match the synthetic observations of both types of
 535 state variables closely, which is expected in a high controllability twin experiment. However, the area where friction
 536 was modified is more spread out in space than the limited high-friction area of the target model.

537 Around the in-channel high-friction zone (Fig.9, middle), inferred friction is appropriately highest in the channel,
 538 with a max value close to $0.2 \text{ s/m}^{1/3}$. However, the longitudinal length of the zone in the channel is overestimated,
 539 from 2 in-channel cells in the target setup to around 20 in-channel cells in the inference result. Friction around the
 540 channel was incorrectly inferred to be lower than that of the target, further helping the channel overflow in a manner
 541 similar to that of the target model from the point of view of the single upstream observation point. Overall, the misfit
 542 to water depth observations was attributed, through the assimilation process, to a diffuse high-friction area rather than
 543 the very localized zone of the target model.

544 At the crossroad (Fig.9, right), high friction was attributed to the south-western street, around the location of the
 545 target friction patch. A channel of low friction seems to help guide runoff from the northern street to the western street,

546 reducing the need for high friction at the location of the target high-friction patch. Similarly to the other location, the
547 inferred distributed friction is reflective of the high degree of freedom given to the assimilation process through the
548 use of a HR parameter control vector.

549 Given the high degree of freedom given to the model, spatial equifinality was expected. Even when we provided
550 no a priori information on high-friction areas locations, we inferred reasonable friction distributions from limited
551 observations. Under the present modeling hypothesis and VDA algorithm setup, the inferred discharge hydrograph
552 and friction patterns are optimal solutions in the sense of the inverse problem solved with available spatio-temporal
553 flow observations.

554 This inference showcases the capacity of the VDA approach to solve high-dimensional inverse problems by
555 assimilating multi-source data of different types for an urban flood event. It shows that typical observations, i.e. depth
556 from a limnigraph installed in the channel and velocities that can be derived from optic imagery, of the hydraulic
557 controls exerted by localized friction can carry information relative to the location and amplitude of distributed
558 parameters. As for previous inference setups, it is necessary to reach the appropriate controllability to improve inference
559 results.

560 In an urban context, the calibration of high-friction areas, or other distributed parameters, could be improved
561 by i) the a priori localization of the complex geometries (e.g. through field surveys or satellite imagery analysis),
562 which would allow HR spatialization of parameters and thus appropriate fine scale model controllability and ii) the
563 deliberate collection of flow velocity observation over areas of interest, rather than its area of indirect influence, which
564 would improve identifiability. Such data collection could be carried out with sensors as common and as portable as a
565 smartphone.

566 **5. Conclusion**

567 This article presented a method for the calibration of multi-variate and large control vectors of a 2D hydraulic
568 model from multi-source heterogeneous observations in the context of urban flash floods in complex street networks.
569 A direct-inverse 2D hydraulic modeling toolchain that allows access to gradient-based methods (DassFlow2D Monnier
570 et al. (2016)), was applied in this work. This DA platform was used to study the sensitivity of model states to distributed
571 friction through the generation of gradient-based sensitivity measurement maps and to infer distributed friction and
572 inflow hydrographs from synthetic or real observations, including HWM.

573 From the obtained results, the following conclusions can be made:

- 574 • A gradient-based method for the generation of local and global sensitivity maps was implemented for a 2D SW
575 hydraulic model and applied to an urban flash flood. These sensitivity maps brought insights into the spatial
576 sensitivity of multi-source cost functions to a distributed friction parameter. They show fine scale sensitivity

577 pattern variations in the street network linked to complex urban flows. They were used, along with hydraulic
578 expertise and flow observations availability, to reach appropriate model controllability through parameter
579 spatialization.

- 580 • Spatialized friction parameters and upstream hydrograph time series were inferred simultaneously from real,
581 sparse and heterogeneously distributed observations of flow. When adequate degrees of freedom were granted
582 to the forward hydraulic model through the spatial pattern of distributed friction, misfits to the observed reality
583 were reduced through the assimilation process and the inferred parameters remained within reasonable ranges
584 given the complexity of the modeled hydraulic behaviours, without further constraints of the inverse problem.
585 Overall, the reduction of misfit to flow observations obtained by optimizing friction and/or hydrograph shows
586 the pertinence of the control setups and inverse algorithm.
- 587 • Notably, the upstream inflow hydrograph was inferred assuming no prior knowledge of its amplitude or
588 temporality, through the leveraging of a single water depth time series. The inferred peak discharge was consistent
589 with hydrological model estimates.
- 590 • Investigations into the capability of the assimilation method to locate and estimate localized high-friction
591 areas from multi-source observations including synthetic velocity fields were carried out. They highlighted the
592 potential use of such local observation fields for the calibration of distributed parameters in complex urban
593 networks. It was shown that local hydraulic signature caused by local loss of mechanical flow energy can carry
594 information on location and parameter value and be used to infer head loss law parameters.
- 595 • Finally, the assimilation of HWM along with multi-source limnigraphic observations was successfully carried
596 out for the first time in a variational framework in this paper and enabled the inference of meaningful parameter
597 patterns and values. Assimilation methods could be refined to account for observation and model uncertainty
598 for HWM, including estimations of local maximum depth times, but also for other types of observed quantities
599 acquired through different means.

600 The experiments presented herein address the issue of degrees of freedom and the framework offers useful
601 diagnostic power for spatial sensitivities structures and optimal combination of 2D hydraulic model and heterogeneous
602 data over complex cases. The presented VDA method was shown to be capable of ingesting multi-source heterogeneous
603 flow measurement in a complex urban flood case, and would enable to consider even more heterogeneous and rich
604 datasets. Having shown the value of HWMs along with water level time series for 2D shallow water urban flood model

605 calibration, the VDA method is transposable to other urban flood cases. This VDA method enables to infer high-
606 dimensional parameter vectors, which are multi-variate, such as uncertain spatialized friction and inflows as shown
607 here and would also enable to simultaneously infer uncertain bathymetry.

608 Further work should focus on the systematic identification of pertinent parameter distributions based on gradient-
609 based sensitivity metrics. The development of methods for the large-scale definition of parameter control vectors
610 would allow the resolution of inverse problems over greater hydraulic domains. In urban geometries, where HR
611 hydrodynamics and flow repartition may be explained by fine spatial variations in model parameters, the adequate
612 definition of high-dimensional large scale parameter controls could pave the way towards hydraulic model calibration
613 over full catchments. The capacity of the VDA method to infer high-dimensional parameter control vectors also opens
614 the way to inferring parameters of more complex flow models accounting for example for other friction/drag laws,
615 porosity, rainfall and infiltration. This would nevertheless require richer dataset but also to implement these new features
616 into the forward model in a differentiable manner as required by automatic adjoint model derivation. The demonstrated
617 capability of the VDA method to infer simultaneously spatial and temporal parameters depends on data availability and
618 could also be applied to a more complex shallow model with other source terms, such as accounting for local rainfall
619 on buildings and partially impervious surfaces, infiltration and mass exchanges with sewers and buildings. Accounting
620 for uncertainties on data and priors within the assimilation framework represents an important and interesting topic for
621 further research on other cases and also richer datasets.

622 **A. Appendix: Local gradient maps**

623 A synthetic reality is created. It has a homogeneous friction of $n = 0.07 \text{ s/m}^{1/3}$ and is inflowed by a 1.5h
624 symmetrical triangular hydrograph of peak flow $54 \text{ m}^3/\text{s}$. Water depth observation time series are generated at all
625 cells plotted in Fig.10.

626 The expectable parameter space is sampled for N homogeneous friction values over the whole model. For each
627 sample, a gradient-based sensitivity map is computed (Fig.10). The combination of these maps using the method
628 described in Section 2.4 gives a global sensitivity index over the range of values the VDA process is expected to
629 iterate.

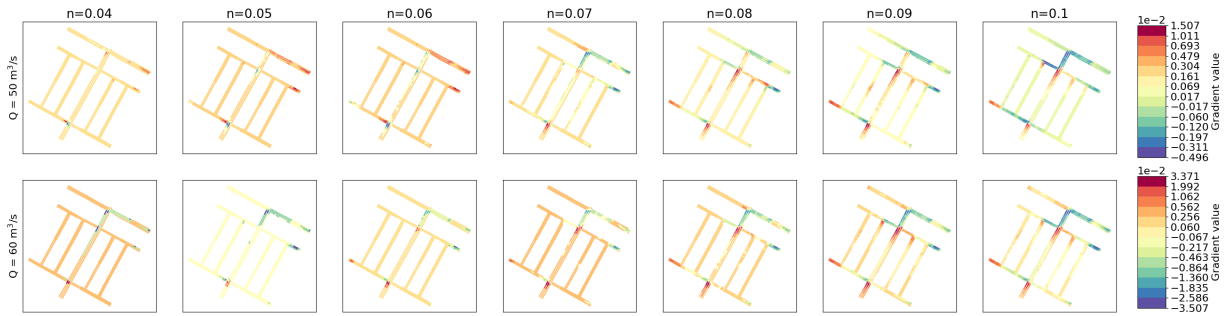

Figure 10: Local sensitivity maps used to build the global sensitivity maps in Fig.5. n (columns) is the homogeneous friction coefficient, Q (rows) is the peak flow of the 2-hour-long symmetrical triangular inflow hydrograph.
