13 Abstract

14 Recent years have seen the development of multiple *in silico* lung models, notably with the aim of
15 improving patient care for pulmonary diseases. These models vary in complexity, and typically only
16 consider the implementation of pleural pressure, a depression that keeps the lungs inflated. Gravity,
17 often considered negligible compared to pleural pressure, has been largely overlooked, also due to
18 the complexity of formulating physiological boundary conditions to counterbalance it. However,
19 gravity is known to affect pulmonary functions, such as ventilation. In this study, we incorporated
20 gravity into a recent lung poromechanical model. To do so, in addition to the gravitational body
21 force, we proposed novel boundary conditions consisting in a heterogeneous pleural pressure field
22 constrained to counterbalance gravity to reach global equilibrium of applied forces. We assessed
23 the impact of gravity on the global and local behavior of the model, including the pressure-volume
24 response and porosity field. Our findings reveal that gravity, despite being small, influences lung
25 response. Specifically, the inclusion of gravity in our model led to the emergence of heterogeneities
26 in deformation and stress distribution, compatible with *in vivo* imaging data. This could provide
27 valuable insights for predicting the progression of certain pulmonary diseases by correlating areas
28 subjected to higher deformation and stresses with disease evolution patterns.

29 Keywords

30 Pulmonary mechanics; Gravity; Modeling; Constrained optimization; Finite element method.

31 1 Introduction

32 Idiopathic Pulmonary Fibrosis (IPF) is an interstitial lung disease, characterized by increased
33 difficulty for patients to breath [Swigris et al. 2005]. Although a rare disease, its impact has grown
34 over the last few decades, becoming an important health burden [Nalysnyk et al. 2012; Hutchinson
35 et al. 2015], especially as no cure is known as of today [Spagnolo et al. 2018; Wells 2018]. As
36 an idiopathic disease, the mechanisms behind the appearance and evolution of IPF still remain
37 unclear. However, the existence of a mechanical vicious circle that could explain the evolution
38 of IPF has been hypothesized [Liu et al. 2010; Hinz et al. 2016; Wu et al. 2020]. This disease is
39 indeed characterized by a stiffening of localized areas of the interstitial tissue of the lungs, i.e., the
40 appearance of fibrosed tissue [Plantier et al. 2018; Wijsenbeek et al. 2020], which induces larger
41 —non-physiological— stresses during breathing, and could in turn injure the healthy tissue, leading

1 to collagen deposits during repairing processes [McKleroy et al. 2013]. These collagen deposits are
2 abnormally high in IPF and stiffen the tissues, leading to higher stresses, and so on. Although tissue
3 stiffening in IPF is irreversible, recent breakthroughs in treatments have significantly increased
4 patient life expectancy, making early diagnosis a key issue in patient care [Cottin et al. 2022]. A
5 better understanding of the disease and its progression could also help clinicians targeting the most
6 efficient treatment and improve patient care.

7 *In silico* models are increasingly used to tackle these issues. They have indeed gained consider-
8 able interest in recent years in the medical field and have become valuable tools for doctors, as
9 they are proved to be extremely useful to help with diagnosis and prognosis, and for improving
10 patient care [Himanshu 2019; Carniel et al. 2020]. To handle issues related to diagnosis, prognosis
11 or treatment, models should be patient-dependent [Vy et al. 2016; Gindre et al. 2016], as the
12 behavior of biological tissues or organ geometries, for example, differ highly from an individual to
13 another. Questions related to the accuracy and complexity of these models is therefore essential.
14 In particular, for medical applications, a high level of accuracy is generally required, e.g., to predict
15 with a good level of confidence the evolution of a disease. This is for example the case in cardiac
16 modeling. A wide variety of models, integrating clinical data, have been developed to tackle vari-
17 ous medical issues [Smith et al. 2011; Chabiniok, Wang, et al. 2016]. Personalized models allow to
18 investigate, for example, various pathologies [Genet, L. C. Lee, Baillargeon, et al. 2016] or surgical
19 procedures [L. C. Lee et al. 2014]. Similarly, a model of the lungs [Patte, Genet, et al. 2022],
20 integrating clinical data [Genet, Patte, Fetita, et al. 2020; Patte, Brillet, et al. 2022; Laville et al.
21 2023], has recently been developed to improve the diagnosis, classification and prognosis of IPF.

22
23 A wide variety of lung models, each investigating various constitutive frameworks, loading and
24 scales, can be found in the literature [Neelakantan et al. 2022]. The framework chosen to represent
25 the deformation of the lungs depends greatly on the level of accuracy wanted. Linear elastic
26 behaviors have been widely used to describe the deformation of the parenchyma [Fuerst et al.
27 2014; Werner et al. 2009], which can be an acceptable approximation within the scope of some
28 studies. More complex frameworks, such as the one proposed by [Tawhai et al. 2009] allow to take
29 into account the non-linear behavior of the lungs. Heterogeneity of tissue porosity in the lung has
30 been investigated at the microscopic level [Álvarez-Barrientos et al. 2021; Manoochehrtayebi et al.
31 2023], who studied the microstructure of the lungs, most macroscale models of the literature but
32 largely overlooked at the macroscopic level. We therefore chose to work within a poromechanical
33 framework [Chapelle et al. 2014; Patte, Genet, et al. 2022], which allows us to include at all points
34 the contributions of both the solid and the fluid, and hence the material heterogeneity resulting
35 from the heterogeneous porosity field.

36 Different timescales have been investigated for the development of lung models. If dynamic models
37 have been formulated [Kyriakou et al. 2011], we however chose to develop a quasi-static model of
38 the lungs. Our model is indeed based on clinical data, which consists solely in two CT-scans for
39 each patient—one at end-exhalation and one at end-inhalation. Dynamic data, for example from
40 MRI [Boucneau et al. 2020] being unavailable for our study, our model focuses on representing a
41 quasi-static breathing cycle, i.e., the deformation of the lungs from the end-exhalation configuration
42 to the end-inhalation configuration.

43 Different techniques have also been proposed to pilot the deformation of the lungs from end-
44 exhalation to end-inhalation, such as imposing a displacement field, obtained by image correlation,
45 on the boundary of the lungs [Zhang et al. 2004; Berger et al. 2016] or on the parietal membrane,
46 when a frictionless contact between the surface of the lungs and the parietal membrane is imple-
47 mented [Tawhai et al. 2009]. These approaches, implemented as Dirichlet boundary conditions, do
48 not take the pleural pressure, a negative (compared to the reference atmospheric pressure) pressure
49 responsible for inflation of the lungs, in consideration. The pleural pressure being of particular
50 interest in this study, since we could potentially derive biomarkers from it in future work, we
51 chose to drive our deformation with this pleural pressure, following the example of [Baudet et al.
52 2003; Zhang et al. 2004; Han et al. 2017]. The distribution of the pleural pressure is discussed
53 in this article. Its magnitude, however, will be determined to match the displacement field from
54 end-exhalation to end-inhalation extracted from CT-scans when handling clinical cases.

1 Gravity has almost systematically been either neglected [Patte, Genet, et al. 2022], or only partially
2 included [Patte 2020], in *in silico* lung models, probably for two main reasons. The first reason is
3 that the impact of gravity is often considered to be negligible regarding other forces acting on the
4 lungs, e.g., the pleural pressure. The second reason would be that is not always straightforward
5 to take gravity into account, since it requires the formulation of additional boundary conditions
6 that can balance gravity to satisfy the global equilibrium. Notably, [Seyfi Noferest et al. 2018] has
7 proposed a model that includes gravity, but the boundary conditions —i.e., fixing the lungs at the
8 helium— seem non-applicable for our problem. It would indeed require to identify precisely the
9 location of those points in CT-scans, and these boundary conditions do not take into account the
10 impact of the surroundings of the lungs on their deformation.

11 However, even though complex to implement, gravity does have an impact on lung response.
12 There is indeed a pleural pressure gradient in the lungs, more negative at the apex than at the
13 base [Barrau et al. 2022]. Lungs also behave differently in the prone and the supine position [Kallet
14 2015]. While it was initially assumed that gravity was responsible for differences in ventilation and
15 blood flow between the prone and supine positions [Kaneko et al. 1966], more recent articles,
16 such as [Galvin et al. 2007], have emphasized that the impact of gravity on these phenomena is
17 in reality marginal. However, gravity is identified as one of the main factors causing the differ-
18 ences of pulmonary pressures and lung densities between the prone and supine positions [Tawhai
19 et al. 2009; Kumaresan et al. 2018]. In addition, studies have shown that gravity induces not
20 only local phenomena in the lungs [West and Matthews 1972; Hurtado et al. 2017], but also af-
21 fects the global behavior of the lungs, e.g., its compliance [Ganesan et al. 1995]. In light of these
22 phenomena, we therefore decided to take gravity into account in our model to improve its accuracy.
23

24 Integrating gravity into lung models therefore represents an important challenge, which we address
25 in this article by formulating novel physiological boundary conditions including effectively grav-
26 ity. For illustration purpose, the novel boundary conditions are described in the context of our
27 poromechanical lung model [Patte, Genet, et al. 2022], though they could be applied to any lung
28 model. Briefly, in [Patte, Genet, et al. 2022], the lung deformation was driven by the motion (pre-
29 scribed arbitrarily in [Patte, Genet, et al. 2022] or extracted from clinical images in [Patte, Brillet,
30 et al. 2022; Laville et al. 2023]) of the thoracic cage (modeled as a surface in frictionless bilateral
31 contact with the lung volume). Previous efforts to integrate gravity in the model have been docu-
32 mented in [Patte 2020]; however, these attempts proved incomplete, notably because gravity was
33 successfully implemented only for the loading problem (i.e., the computation of the end-inhalation
34 configuration from the unloaded configuration), and not for the unloading problem (i.e., the com-
35 putation of the unloaded configuration from the end-exhalation configuration). Compared to these
36 earlier models, the boundary conditions introduced in this paper do not require contact definition
37 nor additional geometries such as the rib cage; moreover, gravity is present at both loading and
38 unloading computation steps. Basically, they rely on the incorporation of an additional term in
39 the pleural pressure distribution, defined through a minimization problem enforcing the balance of
40 gravity to satisfy the global equilibrium of the lung.

41 The paper is organized as follows. In the Methods Section 2, we briefly recall [Patte, Genet,
42 et al. 2022]’s lung poromechanics framework (Section 2.1) and then introduce our new boundary
43 conditions (Section 2.2). Next, in the Results Section 3, we propose several analysis of the model,
44 including the impact of gravity on the computed pleural pressure distribution (Section 3.1) and the
45 model response (Section 3.2), as well as a comparison of our new model response to experimental
46 data (Section 3.3) and our previous model response (Section 3.4). These, results, as well as the
47 relevance and accuracy of our proposed boundary conditions, are thoroughly discussed in the
48 Discussion Section 4.

2 Methods

2.1 Recall of our lungs poromechanical modeling framework

As mentioned in the Introduction, the novel boundary conditions we introduce in this paper could be applied to any lung model, but are described here in the context of our lung poromechanical model, which is described in details in [Patte, Genet, et al. 2022], and is briefly recalled in this Section.

2.1.1 General hypotheses

As reminded in the Introduction, our model is quasi-static and computes the end-inhalation configuration from the end-exhalation configuration. At end-exhalation, lungs are already loaded, notably by the pleural pressure, a negative pressure keeping them inflated. (Note that in this paper, pressure is always relative to the atmospheric, i.e., a “negative” pressure corresponds to a sub-atmospheric pressure.) Computing the end-inhalation configuration from the end-exhalation configuration is therefore not straightforward. It requires two steps. The first step consists in computing the unloaded configuration from the end-exhalation configuration. In the scope of this work, we will call this problem the unloading problem. The second step consists in computing the end-inhalation configuration from the unloaded configuration. We will call this problem the loading problem. These problems are illustrated in Figure 1.

Figure 1: Description of the computation of a full breathing cycle with our finite-element model.

2.1.2 Poromechanical framework

To compute the end-inhalation configuration from the end-exhalation configuration, we chose to work within a poromechanical framework, which is consistent with experimental data and allows to integrate the porosity field extracted from the CT-scans. In this work, we consider that at each point of our domain, the matter is split into a solid phase, in our case the blood and the tissues, and a fluid phase, the air, that interact with each other. To describe the behavior of the different phases, classical kinematical and mechanical operators, as well as operators specific to poromechanics, are used. The notation used in this paper is detailed hereafter. Quantities with the subscript “e” refer to quantities defined in the end-exhalation configuration, whilst quantities with the subscript “i” refer to quantities defined in the end-inhalation configuration. Similarly, the volumes and surfaces written in capital letters represent quantities in the unloaded configuration,

1 whilst lowercase letters refer to quantities in loaded configurations. The operators and quantities
2 introduced are also described in Figure 1.

3 **Kinematics operators for the loading problem.** The function $\underline{\chi}$, representing the mapping
4 of a material point at a position \underline{X} in the unloaded configuration Ω to a position \underline{x} in the deformed
5 configuration ω , can be written as

$$\underline{\chi} : \underline{X} \rightarrow \underline{\chi}(\underline{X}) = \underline{x}(\underline{X}). \quad (1)$$

6 The displacement field from the unloaded to the deformed configuration is then simply defined by
7 the difference between the two position vectors

$$\underline{U}(\underline{X}) := \underline{x}(\underline{X}) - \underline{X}. \quad (2)$$

8 The deformation gradient tensor can be derived from the mapping function, and is defined as

$$\underline{\underline{F}} := \underline{\underline{\nabla}} \underline{\chi} = \underline{\underline{1}} + \underline{\underline{\nabla}} \underline{U}. \quad (3)$$

9 The volume change of the mixture is in turn defined from the deformation gradient tensor:

$$J := \det(\underline{\underline{F}}). \quad (4)$$

10 In order to fully describe our problem, two additional operators need to be introduced: the right
11 Cauchy tensor can be defined from the deformation gradient tensor:

$$\underline{\underline{C}} := {}^t \underline{\underline{F}} \cdot \underline{\underline{F}}, \quad (5)$$

12 from which the Green-Lagrange strain tensor is in turn defined:

$$\underline{\underline{E}} := \frac{1}{2}(\underline{\underline{C}} - \underline{\underline{1}}). \quad (6)$$

13 **Kinematics operators for the unloading problem** The operators described so far can be
14 used for the loading problem, i.e., for computing a deformed configuration from an unloaded
15 configuration. These operators are classical but cannot be directly used for the unloading problem,
16 for which the unloaded configuration is unknown. Let us here describe multiple quantities that
17 will allow us to properly define the unloading problem.

18 The displacement field from the deformed configuration to the unloaded configuration, written \underline{u} ,
19 can be expressed as

$$\underline{u}(\underline{x}) := \underline{X}(\underline{x}) - \underline{x}, \quad (7)$$

20 where the position vector \underline{X} in the unloaded configuration is defined through the inverse mapping
21 function

$$\underline{\chi}^{-1} : \underline{x} \rightarrow \underline{\chi}^{-1}(\underline{x}) = \underline{X}(\underline{x}). \quad (8)$$

22 The deformation gradient tensor from the deformed configuration to the unloaded configuration
23 can also be derived, in the same way as before, from the mapping function:

$$\underline{\underline{f}} := \underline{\underline{\nabla}} \underline{\chi}^{-1}, \quad (9)$$

24 from which the volume change can in turn be defined:

$$j := \det(\underline{\underline{f}}) = \frac{1}{J \circ \underline{\chi}^{-1}}. \quad (10)$$

25 We also define the infinitesimal strain tensor with its usual definition

$$\underline{\underline{\epsilon}} := \frac{1}{2}(\underline{\underline{\nabla}} \underline{u} + {}^t \underline{\underline{\nabla}} \underline{u}). \quad (11)$$

1 **Poromechanics operators.** As a reminder, at each point of our domain, a fluid and a solid
 2 phase interact. Their proportions are defined through the volume fraction of fluid, Φ_f , and the
 3 volume fraction of solid, Φ_s . In this article, operators with the subscript "f" refer to quantities
 4 related to the fluid phase and operators with the subscript "s" refer to quantities related to the
 5 solid phase. Φ_f and Φ_s are defined as

$$\begin{cases} \Phi_f := \frac{|d\omega_f|}{|d\Omega|} \\ \Phi_s := \frac{|d\omega_s|}{|d\Omega|} \end{cases}, \quad (12)$$

6 where $d\Omega$ corresponds to an infinitesimal volume of matter of the reference volume Ω and $d\omega_f$
 7 and $d\omega_s$ represent an infinitesimal volume of the fluid and solid phase respectively in the deformed
 8 configuration (see Figure 1). It is here possible to notice that the Jacobian, defined in Equation (4)
 9 can be written as the sum of Φ_s and Φ_f :

$$J = \frac{|d\omega|}{|d\Omega|} = \frac{|d\omega_f|}{|d\Omega|} + \frac{|d\omega_s|}{|d\Omega|} = \Phi_f + \Phi_s. \quad (13)$$

10 Other constituent volume fractions can be defined, such as

$$\begin{cases} \Phi_{f0} := \frac{|d\Omega_{f0}|}{|d\Omega|} \\ \Phi_{s0} := \frac{|d\Omega_{s0}|}{|d\Omega|} \end{cases}, \quad \begin{cases} \phi_f := \frac{|d\omega_f|}{|d\omega|} \\ \phi_s := \frac{|d\omega_s|}{|d\omega|} \end{cases} \quad \text{and} \quad \begin{cases} \phi_{f0} := \frac{|d\Omega_{f0}|}{|d\omega|} \\ \phi_{s0} := \frac{|d\Omega_{s0}|}{|d\omega|} \end{cases}, \quad (14)$$

11 where $d\omega$ corresponds to an infinitesimal volume of matter of the deformed volume ω . Φ_{s0} and Φ_{f0}
 12 represent the reference volume fraction, while ϕ_s and ϕ_f represent the deformed volume fraction,
 13 and ϕ_{s0} and ϕ_{f0} represent the reference volume fraction of solid and fluid respectively, pushed
 14 forward onto the deformed configuration. In this article, we will refer to ϕ_f as the deformed (or
 15 loaded) porosity and Φ_{f0} as the reference (or unloaded) porosity. ϕ_s and Φ_{s0} will be referred to as
 16 the deformed (or loaded) and reference (or unloaded) solid volume fractions, respectively.

17 2.1.3 Equilibrium equations

18 **Unloading problem.** In the deformed configuration, the internal and external forces must be
 19 at equilibrium. This can be expressed in weak form as the balance of the virtual work of internal
 20 and external forces:

$$W_{\text{int}}(\underline{\mathbf{u}}; \underline{\mathbf{u}}^*) = W_{\text{ext}}(\underline{\mathbf{u}}; \underline{\mathbf{u}}^*) \quad \forall \underline{\mathbf{u}}^*, \quad (15)$$

21 where W_{int} is the so-called virtual work of internal forces:

$$W_{\text{int}}(\underline{\mathbf{u}}; \underline{\mathbf{u}}^*) := \int_{\omega} \underline{\underline{\sigma}}(\underline{\mathbf{u}}) : \underline{\underline{\epsilon}}(\underline{\mathbf{u}}^*) \, d\omega. \quad (16)$$

22 Here, $\underline{\mathbf{u}}$ is the displacement field from the deformed configuration ω to the reference configuration
 23 Ω (see Figure 1), $\underline{\underline{\sigma}}$ corresponds to the Cauchy stress associated to $\underline{\mathbf{u}}$ and p_f (see next Section on
 24 constitutive framework), $\underline{\mathbf{u}}^*$ is to so-called virtual displacements, $\underline{\underline{\epsilon}}(\underline{\mathbf{u}}^*)$ corresponds to infinitesimal
 25 strain tensor associated to $\underline{\mathbf{u}}^*$, and W_{ext} is the so-called virtual work of external forces. The Cauchy
 26 stress $\underline{\underline{\sigma}}$ is linked to the second Piola-Kirchhoff stress tensor $\underline{\underline{\Sigma}}$ through the relation

$$\underline{\underline{\sigma}}(\underline{\mathbf{u}}) = j(\underline{\mathbf{u}}) \underline{\underline{\mathbf{f}}}^{-1}(\underline{\mathbf{u}}) (\underline{\underline{\Sigma}}(\underline{\mathbf{u}}) \circ \underline{\underline{\chi}}^{-1}) \overset{t}{\underline{\underline{\mathbf{f}}}}^{-1}(\underline{\mathbf{u}}). \quad (17)$$

27 As a reminder, j corresponds here to the Jacobian describing the volume change from the deformed
 28 configuration to the unloaded configuration, and not the traditional Jacobian, which characterizes
 29 the volume change from the unloaded configuration to the deformed configuration.

1 **Loading problem.** Equation (15) is sufficient to describe the unloading problem, since the
2 deformed configuration is known. However, the loading problem corresponds to a classical hyper-
3 elastic problem, where only the reference configuration is known, and the deformed configuration
4 has to be determined. Following the standard Lagrangian approach, the equilibrium equation is
5 pulled back onto the reference configuration:

$$W_{\text{int}}(\underline{\mathbf{U}}; \underline{\mathbf{U}}^*) = W_{\text{ext}}(\underline{\mathbf{U}}; \underline{\mathbf{U}}^*) \quad \forall \underline{\mathbf{U}}^*, \quad (18)$$

6 where

$$W_{\text{int}}(\underline{\mathbf{U}}; \underline{\mathbf{U}}^*) := \int_{\Omega} \underline{\underline{\Sigma}}(\underline{\mathbf{U}}) : d\underline{\mathbf{U}} \underline{\underline{\mathbf{E}}} \cdot \underline{\mathbf{U}}^* d\Omega. \quad (19)$$

7 Here, $\underline{\mathbf{U}}$ is the displacement field from the reference configuration Ω to the deformed configuration
8 ω (see Figure 1), $\underline{\underline{\Sigma}}$ is the second Piola-Kirchhoff stress tensor, and $d\underline{\mathbf{U}} \underline{\underline{\mathbf{E}}} \cdot \underline{\mathbf{U}}^*$ is the first differential
9 of the Green-Lagrange strain tensor.

10 2.1.4 Constitutive laws

11 **Constitutive framework.** According to the second principle of thermodynamics, the second
12 Piola-Kirchhoff stress tensor is equal to the derivative of the Helmholtz free energy of the system
13 Ψ with respect to the Green-Lagrange strain tensor $\underline{\underline{\mathbf{E}}}$. Classically, the free energy Ψ is additively
14 split into solid Ψ_s and fluid Ψ_f contributions [Coussy 2004; Chapelle et al. 2014]. We thus have

$$\underline{\underline{\Sigma}} = \frac{\partial \Psi}{\partial \underline{\underline{\mathbf{E}}}} = \underline{\underline{\Sigma}}_s - p_f \underline{\underline{\mathbf{J}}} \underline{\underline{\mathbf{C}}}^{-1} \quad \text{with} \quad \underline{\underline{\Sigma}}_s := \frac{\partial \Psi_s}{\partial \underline{\underline{\mathbf{E}}}}, \quad (20)$$

15 where $\underline{\underline{\Sigma}}_s$ is the so-called solid stress, and p_f is the internal fluid pressure field. Internal mixture
16 equilibrium, i.e., between the solid and fluid, leads to the following additional equilibrium equation:

$$p_f = - \frac{\partial \Psi_s}{\partial \Phi_s}. \quad (21)$$

17 **Energy potentials.** Following [Coussy 2004; Chapelle et al. 2014], we write the solid free energy
18 as the sum of two potentials, Ψ_{skel} and Ψ_{bulk} , respectively associated to the deformation and to the
19 pressure, to which a third potential, Ψ_{por} , notably ensuring positive porosity values, is added [Patte
20 2020]:

$$\Psi_s = \Psi_{\text{skel}} + \Psi_{\text{bulk}} + \Psi_{\text{por}}. \quad (22)$$

21 The choice for the expression of Ψ_{skel} and Ψ_{bulk} is based on [Patte, Genet, et al. 2022]. Thus, the
22 potential associated to the solid deformation, Ψ_{skel} , is expressed with an exponential term, a usual
23 choice for soft tissues [Demiray 1972; Caruel et al. 2014; Genet, Chuan Lee, et al. 2015]:

$$\Psi_{\text{skel}} = \alpha (e^{\delta(J^2 - 1 - 2 \ln J)} - 1) + \beta_1 (I_1 - 3 - 2 \ln(J)) + \beta_2 (I_2 - 3 - 4 \ln J). \quad (23)$$

24 And the potential describing the response of the lungs to pressure, Ψ_{bulk} , is expressed as

$$\Psi_{\text{bulk}} = \kappa \left(\left(\frac{\Phi_s}{\Phi_{s0}} \right)^2 - 1 - 2 \ln \left(\frac{\Phi_s}{\Phi_{s0}} \right) \right). \quad (24)$$

25 In these expressions, I_1 is the first invariant of $\underline{\underline{\mathbf{C}}}$, and α , β_1 , β_2 , δ , and κ are material constants.

26 A third potential needs to be added to ensure positive porosities [Coussy 2004; Chapelle et al. 2014],
27 which is especially important, in the context of lung modeling, for the unloading problem [Patte,
28 Genet, et al. 2022]. This potential should notably tend to $+\infty$ when the porosity (loaded or
29 unloaded) tends to 0, representing the energy barrier require to fully collapse pores, thus preventing
30 the model to reach negative porosities. Note that there is no need to do anything special to
31 ensure that porosities remain below 1, as in this regime the solid deformation becomes very large,

1 which already represents an energy barrier thanks to the skeleton energy potential. Nevertheless,
 2 following [Patte, Genet, et al. 2022], we propose to express the pore energy as:

$$\Psi_{\text{por}} = \eta \begin{cases} +\infty & \text{if } \Phi_f < 0 \text{ or } \Phi_{f0} < 0 \\ (\Phi_{f0}/\Phi_f - 1)^2 & \text{if } \Phi_f < \Phi_{f0} \\ (\Phi_f/\Phi_{f0} - 1)^2 & \text{if } \Phi_{f0} < \Phi_f \end{cases}, \quad (25)$$

3 where η is a material constant.

4 **2.1.5 Weak formulation of the loading and unloading problems**

5 **Unloading problem.** Combining all previous definitions and hypotheses, the unloading prob-
 6 lem can be written as a coupled system of partial differential equations written on the deformed
 7 configuration, which is known in this case. Its weak formulation is:

$$(\underline{\mathbf{u}}, \phi_{s0}) \quad | \quad \begin{cases} \int_{\omega} \underline{\underline{\sigma}}_s : \underline{\underline{\epsilon}}(\underline{\mathbf{u}}^*) \, d\omega - \int_{\omega} p_f \operatorname{tr}(\underline{\underline{\epsilon}}(\underline{\mathbf{u}}^*)) \, d\omega = W_{\text{ext}}(\underline{\mathbf{u}}; \underline{\mathbf{u}}^*) \quad \forall \underline{\mathbf{u}}^* \\ \int_{\omega} (p_f + \frac{\partial \Psi_s}{\partial \Phi_s}) \phi_{s0}^* \, d\omega = 0 \quad \forall \phi_{s0}^* \end{cases}. \quad (26)$$

8 Let us point out that Equation (21) is local; however, it is written here in weak form for consistency
 9 in notations and to have a formulation as close as possible to our numerical implementation.

10 **Loading problem.** The loading problem is obtained by pulling back these equations onto the
 11 reference configuration, which is known in this case:

$$(\underline{\mathbf{U}}, \Phi_s) \quad | \quad \begin{cases} \int_{\Omega} \underline{\underline{\Sigma}}_s : d\underline{\underline{\mathbf{U}}} \underline{\underline{\mathbf{E}}} \cdot \underline{\mathbf{U}}^* \, d\Omega - \int_{\Omega} p_f J \underline{\underline{\mathbf{C}}}^{-1} : d\underline{\underline{\mathbf{U}}} \underline{\underline{\mathbf{E}}} \cdot \underline{\mathbf{U}}^* \, d\Omega = W_{\text{ext}}(\underline{\mathbf{U}}; \underline{\mathbf{U}}^*) \quad \forall \underline{\mathbf{U}}^* \\ \int_{\Omega} (p_f + \frac{\partial \Psi_s}{\partial \Phi_s}) \Phi_s^* \, d\Omega = 0 \quad \forall \Phi_s^* \end{cases}. \quad (27)$$

12 **2.2 Introducing gravity and a balancing pleural pressure**

13 In the previous Section, we described all operators and potentials used for the virtual work of
 14 internal forces. The virtual work of external forces is now described in this Section, which focuses
 15 on the formulation of our novel boundary conditions.

16 **2.2.1 General expression of the virtual work of external forces**

17 We consider two main forces applied onto the lungs. The first force is the pleural pressure, a
 18 negative pressure due to a depression in the pleural cavity. The pleural pressure keeps the lungs
 19 inflated, and becomes more negative during inhalation. The second considered force is gravity,
 20 often neglected but that we chose to take into account to improve the physiological relevance of
 21 our model. The virtual work of external forces, W_{ext} , can therefore be written as:

$$W_{\text{ext}} = \int_{\omega} \rho \phi_s \underline{\mathbf{g}} \underline{\mathbf{u}}^* \, d\omega + \int_{\gamma} -p_{\text{pl}} \underline{\mathbf{n}} \underline{\mathbf{u}}^* \, d\gamma \quad (28)$$

22 where $\gamma := \partial\omega$ is the external surface of the domain in the deformed configuration ω , $\underline{\mathbf{n}}$ is the
 23 surface normal in the deformed configuration, p_{pl} is the pleural pressure field, $\underline{\mathbf{g}}$ is the acceleration
 24 of gravity, and ρ is the density of the solid phase. The density considered is only the density of the
 25 solid phase since the density of the fluid phase, i.e., the density of the air, is much smaller than the
 26 density of the solid phase, i.e., the density of the blood and the tissues. The impact of the weight
 27 of the fluid is hence neglected.

2.2.2 Definition of the balancing pleural pressure field

Integrating gravity in our model requires the formulation of a counterbalancing loading to ensure global equilibrium of applied forces. Considering the explicit modeling of the fixations of the lungs to its surroundings could be considered in a first approach. This approach would, however, be far too complex to implement. Because of the physiological complexity of the surroundings of organs, their fixations are indeed often dismissed in biomechanics [Chabiniok, Moireau, et al. 2012; Genet, L. C. Lee, Nguyen, et al. 2014]. Solutions, such as using linear springs [Moireau et al. 2012; Pfaller et al. 2020], have been proposed in the literature. Choosing a proper value for the stiffness of the springs is, however, always difficult.

Physiologically, gravity is balanced in the lungs by the pleural pressure gradient and by the reaction forces of the surroundings of the lungs. It therefore seemed reasonable to hypothesize that these reaction forces —some distributed, some localized, e.g., reaction at the hilum, friction against the visceral pleura, etc.— could be approximated as a heterogeneous pressure field on the external surface of the lungs. We therefore chose to formulate a pressure that could balance gravity as a boundary condition. To have a boundary condition as physiological as possible, we chose to constrain this boundary pressure to be as regular as possible, i.e., to have a surface gradient as close as possible to the physiological pressure gradient already existing in the lungs.

In order to balance gravity, the boundary pressure field should also verify the forces and momentum equilibrium. In addition, the magnitude of the boundary pressure field, i.e., its surface average value, should match the one of the reference pleural pressure field. The problem can therefore be written as a minimization problem:

$$p_{\text{pl}} = \underset{\left\{ p \text{ such that } \begin{cases} \int_{\omega} \rho \phi_s \underline{g} \, d\omega - \int_{\gamma} p \underline{n} \, d\gamma = \underline{0} \\ \int_{\gamma} \underline{\tilde{x}} \times p \underline{n} \, d\gamma = \underline{0} \\ \int_{\gamma} (p - \tilde{p}_{\text{pl}}) \, d\gamma = \underline{0} \end{cases} \right.}{\text{argmin}} \left\{ \frac{1}{2} \int_{\gamma} (\nabla_s p - \nabla_s \tilde{p}_{\text{pl}})^2 \, d\gamma \right\} \quad (29)$$

where \tilde{p}_{pl} represents a reference pleural pressure field and $\underline{\tilde{x}} := \begin{pmatrix} \tilde{x} \\ \tilde{y} \\ \tilde{z} \end{pmatrix}$ corresponds to the center of mass of the structure.

2.2.3 Expression of the reference pleural pressure field

Simple model. In previous approaches, we implemented the pleural pressure as a constant [Patte, Genet, et al. 2022]. However, the pleural pressure of the lungs is known to be heterogeneous, notably because of gravity [Barrau et al. 2022]. Moreover, [Glaister et al. 1975] observed that the lung compliance decreased as the acceleration of gravity applied increased. There therefore seems to be a direct relationship between gravity and the response of the lungs. In a first approach, we propose a simple model with only a linear gradient in the direction of application of gravity, which we denote by z :

$$\tilde{p}_{\text{pl}} = \tilde{p}_0 + K(z - \tilde{z}), \quad (30)$$

where \tilde{p}_0 and K are constants. The linear vertical gradient corresponding to the hydrostatic pressure distribution within the pleural fluid, we chose $K = \rho_{\text{pl}} g$, with ρ_{pl} the density of the pleural liquid and g the acceleration of gravity. Thus, this model has basically one degree of freedom, \tilde{p}_0 , which controls the magnitude of the reference pleural pressure.

Introducing perturbations for ventral and thoracic respirations. However, people can breathe in very different manners, for instance using diaphragmatic vs. costal respirations, which cannot be described with the above simple model. In principle one could use a complex reference pleural pressure field, obtained by modeling the lung surrounding, or from images, but here only aim at characterizing the impact of reference pleural pressure field spatial variations onto the lung response. Hence, we propose to modify the expression of the pleural pressure presented previously by adding a term along the thoracic axis, which we denote by y :

$$\tilde{p}_{\text{pl}} = \tilde{p}_0 + K(z - \tilde{z}) - H(y - \tilde{y})^2, \quad (31)$$

1 where H is a parameter. If H is positive, Equation (31) represents “diaphragmatic” breathing,
 2 while it represents “costal” breathing if H is negative. Note that y and z can be aligned in some
 3 cases, e.g., in the upright position.

4 These expressions are only preliminary propositions to take the different types of breathing into
 5 account. We are well aware that the formulations we propose here are insufficient to describe the
 6 real physiological behavior of the lungs; again, they were only proposed to study the impact of
 7 different types of breathing on the response of the lungs, and further investigations of better forms
 8 of pleural pressure accounting for costal and diaphragmatic breathing will be investigated in future
 9 work. Given the obvious limitations of the formulations we propose in this work, we will refer to
 10 the expression accounting —preliminarily— for the costal breathing as ventral breathing and for
 11 the diaphragmatic breathing as thoracic breathing. In the rest of the study, if there is no mention
 12 of the type of breathing, \tilde{p}_{pl} is considered to be of the form of the simple breathing, i.e., with
 13 $H = 0$.

14 2.2.4 Weak formulation of the full loading and unloading problems

15 **Unloading problem.** To solve the constrained minimization problem (29), the Lagrange mul-
 16 tipliers method was used. To write the Lagrangian function associated to our problem, three
 17 additional global variables $\underline{\lambda}$, $\underline{\mu}$ and δ are introduced, which are additional unknowns. The La-
 18 grangian function can be written as:

$$\mathcal{L}(\mathbf{p}, \underline{\lambda}, \underline{\mu}, \delta) = \frac{1}{2} \int_{\gamma} (\nabla_s \mathbf{p} - \nabla_s \tilde{p}_{pl})^2 d\gamma + \underline{\lambda} \cdot \left(\int_{\omega} \rho \phi_s \underline{g} d\omega - \int_{\gamma} \mathbf{p} \underline{n} d\gamma \right) + \underline{\mu} \cdot \int_{\gamma} (\underline{x} - \tilde{\underline{x}}) \times \mathbf{p} \underline{n} d\gamma + \delta \int_{\gamma} (\mathbf{p} - \tilde{p}_{pl}) d\gamma. \quad (32)$$

19 The stationary points can be found by deriving Equation (32) with respect to \mathbf{p} , $\underline{\lambda}$, $\underline{\mu}$ and δ , which
 20 allows to rewrite Equation (29) as a system of partial differential equations:

$$(\mathbf{p}, \underline{\lambda}, \underline{\mu}, \delta) \mid \begin{cases} \int_{\gamma} (\nabla_s \mathbf{p} - \nabla_s \tilde{p}_{pl}) \cdot \nabla_s \mathbf{p}^* d\gamma - \underline{\lambda} \cdot \int_{\gamma} \mathbf{p}^* \underline{n} d\gamma \\ \qquad \qquad \qquad + \underline{\mu} \cdot \int_{\gamma} (\underline{x} - \tilde{\underline{x}}) \times \mathbf{p}^* \underline{n} d\gamma + \delta \int_{\gamma} \mathbf{p}^* d\gamma = 0 \quad \forall \mathbf{p}^* \\ \int_{\omega} \rho \phi_s \underline{g} d\omega - \int_{\gamma} \mathbf{p} \underline{n} d\gamma = 0 \\ \int_{\gamma} (\underline{x} - \tilde{\underline{x}}) \times \mathbf{p} \underline{n} d\gamma = 0 \\ \int_{\gamma} (\mathbf{p} - \tilde{p}_{pl}) d\gamma = 0 \end{cases} . \quad (33)$$

1 Equation (33) can then be injected into Equation (26). The full unloading problem can therefore
 2 be expressed with the following weak formulation:

$$(\underline{u}, \phi_{s0}, \mathbf{p}, \underline{\lambda}, \underline{\mu}, \delta) \quad | \quad \left\{ \begin{array}{l} \int_{\omega} \underline{\sigma}_s : \underline{\epsilon}(\underline{u}^*) \, d\omega - \int_{\omega} \mathbf{p}_f \operatorname{tr}(\underline{\epsilon}(\underline{u}^*)) \, d\omega \\ \qquad \qquad \qquad = \int_{\omega} \rho \phi_{s0} \underline{g} \cdot \underline{u}^* \, d\omega - \int_{\gamma} \mathbf{p} \underline{n} \cdot \underline{u}^* \, d\gamma \quad \forall \underline{u}^* \\ \int_{\omega} (\mathbf{p}_f + \frac{\partial \Psi}{\partial \Phi_s}) \phi_{s0}^* \, d\omega = 0 \quad \forall \phi_{s0}^* \\ \int_{\gamma} (\nabla_s \mathbf{p} - \nabla_s \tilde{\mathbf{p}}_{pl}) \cdot \nabla_s \mathbf{p}^* \, d\gamma - \underline{\lambda} \cdot \int_{\gamma} \mathbf{p}^* \underline{n} \, d\gamma \\ \qquad \qquad \qquad + \underline{\mu} \cdot \int_{\gamma} (\underline{x} - \tilde{\underline{x}}) \times \mathbf{p}^* \underline{n} \, d\gamma + \delta \int_{\gamma} \mathbf{p}^* \, d\gamma = 0 \quad \forall \mathbf{p}^* \\ \int_{\omega} \rho \phi_{s0} \underline{g} \cdot \underline{\lambda}^* \, d\omega - \int_{\gamma} \mathbf{p} \underline{n} \cdot \underline{\lambda}^* \, d\gamma = 0 \quad \forall \underline{\lambda}^* \\ \int_{\gamma} (\underline{x} - \tilde{\underline{x}}) \times \mathbf{p} \underline{n} \cdot \underline{\mu}^* \, d\gamma = 0 \quad \forall \underline{\mu}^* \\ \int_{\gamma} (\mathbf{p} - \tilde{\mathbf{p}}_{pl}) \delta^* \, d\gamma = 0 \quad \forall \delta^* \end{array} \right. \quad (34)$$

3 As discussed in Section 2.1.5, all equations are written in weak form, for consistency and closeness
 4 to the numerical implementation. Note that in this system, only the first two equations were
 5 already present in the model of [Patte, Genet, et al. 2022]; our novel boundary conditions lead to
 6 the formulation of the four following equations.

7 **Loading problem.** Problem (34) can be used as is for the unloading problem. However, the
 8 deformed configuration being unknown in the loading problem, it needs to be pulled back onto the
 9 reference configuration. These transformations are classical and lead to the following system:

$$(\underline{U}, \Phi_f, \mathbf{p}, \underline{\lambda}, \underline{\mu}, \delta, \tilde{\underline{x}}) \quad | \quad \left\{ \begin{array}{l} \int_{\Omega} \underline{\Sigma}_s : \mathbf{d} \underline{U} \underline{E} \cdot \underline{U}^* \, d\Omega - \int_{\Omega} \mathbf{p}_f \mathbf{J} \underline{C}^{-1} : \mathbf{d} \underline{U} \underline{E} \cdot \underline{U}^* \, d\Omega \\ \qquad \qquad \qquad = \int_{\Omega} \rho \Phi_{s0} \underline{g} \cdot \underline{U}^* \, d\Omega - \int_{\Gamma} \mathbf{p} \mathbf{J} \underline{F}^{-T} \cdot \underline{N} \cdot \underline{U}^* \, d\Gamma \quad \forall \underline{U}^* \\ \int_{\Omega} (\mathbf{p}_f + \frac{\partial \Psi}{\partial \Phi_s}) \Phi_f^* \, d\Omega = 0 \quad \forall \Phi_f^* \\ \int_{\Gamma} \underline{F}^{-T} \cdot (\nabla_s \mathbf{p} - \nabla_s \tilde{\mathbf{p}}_{pl}) \cdot \underline{F}^{-T} \cdot \nabla_s \mathbf{p}^* \mathbf{J} \|\underline{F}^{-T} \underline{N}\| \, d\Gamma - \underline{\lambda} \cdot \int_{\Gamma} \mathbf{J} \underline{F}^{-T} \underline{N} \mathbf{p}^* \, d\Gamma \\ \qquad \qquad \qquad - \underline{\mu} \cdot \int_{\Gamma} (\underline{X} + \underline{U} - \tilde{\underline{x}}) \times \mathbf{J} \underline{F}^{-T} \underline{N} \mathbf{p}^* \, d\Gamma + \delta \int_{\Gamma} \mathbf{J} \|\underline{F}^{-T} \underline{N}\| \mathbf{p}^* \, d\Gamma = 0 \quad \forall \mathbf{p}^* \\ \int_{\Omega} \rho \Phi_{s0} \underline{g} \cdot \underline{\lambda}^* \, d\Omega - \int_{\Gamma} \mathbf{p} \mathbf{J} \underline{F}^{-T} \underline{N} \cdot \underline{\lambda}^* \, d\Gamma = 0 \quad \forall \underline{\lambda}^* \\ \int_{\Gamma} (\underline{X} + \underline{U} - \tilde{\underline{x}}) \times \mathbf{p} \mathbf{J} \underline{F}^{-T} \underline{N} \cdot \underline{\mu}^* \, d\Gamma = 0 \quad \forall \underline{\mu}^* \\ \int_{\Gamma} (\mathbf{p} - \tilde{\mathbf{p}}_{pl}) \mathbf{J} \|\underline{F}^{-T} \underline{N}\| \delta^* \, d\Gamma = 0 \quad \forall \delta^* \\ \int_{\Omega} (\frac{\Phi_{s0}}{\Phi_{s0}} (\underline{X} + \underline{U}) - \frac{\tilde{\underline{x}}}{V_0}) \tilde{\underline{x}}^* \, d\Omega = 0 \quad \forall \tilde{\underline{x}}^* \end{array} \right. \quad (35)$$

10 where $\Gamma := \partial\Omega$ represents the external surface of the lungs in the reference configuration, \underline{N}
 11 represents the external normal in the reference configuration, $V_0 := |\Omega|$ represents the volume in
 12 the reference configuration and $\bar{\Phi}_{s0} := \frac{1}{|\Omega|} \int_{\Omega} \Phi_{s0} \, d\Omega$ represents the mean value of the solid volume
 13 fraction field in the reference configuration. Note that in this system, only the first two equations
 14 were already present in the model of [Patte, Genet, et al. 2022]; our novel boundary conditions
 15 lead to the formulation of the five following equations.

1 Let us point out that improving the physiological relevancy of our model by taking gravity into
 2 account induces greater computation times –computation times approximately multiplied by 6–
 3 compared to the case without gravity, i.e., the case where the loading consists in solely a homoge-
 4 neous pleural pressure. However, the formulation of our new boundary conditions decrease greatly
 5 the computation times –computation times approximately divided by 6– compared to the former
 6 boundary conditions of the model, i.e., the case where boundary conditions consisted of a friction-
 7 less contact between the lungs and the rib cage. Our new boundary conditions indeed transform
 8 our original problem of two field variables (displacement and porosity) to a problem dependent
 9 on three field variables (the pleural pressure field that is defined on the lung surface) and three
 10 (for the unloading problem) or four (for the loading problem) global variables. This additional
 11 equations are, however, relatively straightforward to implement in modern finite element libraries.

12 Problems (34) and (35) have been implemented in an open-source finite element code [Genet, Patte,
 13 Manoochehrtayebi, et al. 2024] based on the FEniCS library [Logg et al. 2012; Alnæs et al. 2015],
 14 and is currently freely available online at https://github.com/mgenet/dolfin_mech.

15 2.3 Problem setting for model response analysis

16 **Geometry, mesh and porosity.** In the scope of this study, we investigated the influence of
 17 gravity on our model response. To do so, we used a generic model of the right lung at end-
 18 exhalation¹, corresponding to a generic patient lying in the supine position. The lung was meshed
 19 using 32416 tetrahedral elements. The geometry and mesh remain consistent with the model
 20 presented in [Patte, Genet, et al. 2022].

21 **Loading process and porosity.** It is important to note that no generic porosity field is avail-
 22 able alongside this mesh. Thus, the actual end-exhalation and end-inhalation configurations were
 23 computed from this generic end-exhalation mesh using the following process. First, an arbitrary
 24 uniformly distributed porosity bounded by 0.6 and 0.8 was assumed in the generic end-exhalation
 25 mesh. The range [0.6, 0.8] was chosen based on (i) typical porosity values at end-inhalation –
 26 ranging from 0.7 to 0.9 in [DeGroot et al. 2018], and around 0.7 in [Yang et al. 2020]–, and (ii) the
 27 work of [Y. K. Lee et al. 2008] where densities for patients at end-exhalation appear to be approxi-
 28 mately 1.2 times smaller than for patients at end-inhalation. The associated unloaded configuration
 29 was then computed by solving Problem (34), leading to an unphysiological porosity gradient when
 30 gravity is present in the model, despite that fact that it should correspond to a state of zero-gravity
 31 pneumothorax. To address this issue, the computed unloaded porosity was replaced by an imposed
 32 uniformly distributed porosity on the obtained unloaded mesh, bounded by 0.4 and 0.6. The range
 33 [0.4, 0.6] was chosen based on (i) the typical porosity values at end-inhalation described before,
 34 and (ii) the work of [Smit et al. 2004] where densities for patients with pneumothorax appear to
 35 be approximately 1.4 times smaller than for healthy patients. Finally, the actual end-exhalation
 36 and end-inhalation configurations were computed by solving Problem (35), leading to physiological
 37 porosity gradients when gravity is present in the model. Note that more complex and physiological
 38 porosity distributions, for instance taking into account tissue scale heterogeneities induced by the
 39 airway tree, could be straightforwardly incorporated in the model, should such data be available.

40 **Loading constants.** For both problems, the only loads considered in the scope of this model are
 41 gravity and pleural pressure. When we consider that there is no gravity, the constant g appearing in
 42 Problems (34) and (35) is set to 0, and the reference pleural pressure \tilde{p}_{pl} is a constant. Conversely,
 43 when we take gravity into account, the constant g appearing in Problems (34) and (35) is chosen
 44 to be equal to its typical value, i.e., 9.81 m/s^2 , and the reference pleural pressure \tilde{p}_{pl} depends
 45 linearly on z (see Section 2.2.3). At end-exhalation, the mean value of the pleural pressure is
 46 around -0.5 kPa [Kallet 2015; Tawhai et al. 2009]. During normal breathing, this pressure can
 47 reach between -0.8 kPa and -1.5 kPa at end-inhalation [Mentzer et al. 2018; Patte 2020]. However,
 48 medical images are rarely acquired during normal breathing. End-inhalation images are indeed
 49 often acquired at full inspiration capacity, which corresponds to a pleural pressure that can reach
 50 -2 kPa [Patte 2020] or even -3 kPa [San Bok et al. 2018]. We therefore chose to define the mean

¹<https://www.zygotec.com>

1 value of our pleural pressure at -0.5 kPa at end-exhalation and -2 kPa or -3 kPa at end-inhalation,
2 depending on the cases, cf. Tables 1 and 2.

3 **Material constants.** Our model involves many material constants, chosen to fit experimental
4 data. Two sets of material values are used in this study. The first set of values, detailed in Table 1
5 is chosen to fit data from [Patte 2020], while the second set, detailed in Table 2, is chosen to fit
6 data from [Hurtado et al. 2017].

7 **Analyses.** This article focuses on studying the impact of gravity on our model response, in
8 the context of our novel boundary conditions. We first studied the pleural pressure distribution,
9 with and without gravity. We then studied the impact of gravity on the global behavior of the
10 lungs, through the investigation of the pressure-volume response, as well as its impact on the local
11 behavior of the lungs, with the investigation of porosity distribution, with and without gravity. We
12 focused in particular in highlighting the heterogeneities induced by gravity on the lungs, by studying
13 the strain and stress distribution in the lungs. We notably validated our model by comparing
14 the local deformation of the lungs with the data of [Hurtado et al. 2017]. We also conducted a
15 comparison with our previous model to highlight the interest of the method implemented in this
16 article. The results of all these studies are detailed in the following section.

Name	Symbol	Unit	Value
Skeleton energy parameters	α	[kPa]	[0.016, 0.16, 1.6]
	δ	[-]	0.5
	β_1	[kPa]	0.4
	β_2	[kPa]	0.2
Bulk energy parameter	κ	[kPa]	100
Pore energy parameter	η	[-]	10^{-5}
End-exhalation pleural pressure	$p_{pl,e}$	[kPa]	-0.5
End-inhalation pleural pressure	$p_{pl,i}$	[kPa]	-2.0

Table 1: Parameters used for the breathing calculations when computing the Jacobian depending on the end-inhalation pleural pressure value and when comparing our results with the results of [Patte 2020]. The parameters presented here are similar to the parameters used in [Patte, Genet, et al. 2022].

Name	Symbol	Unit	Value
Skeleton energy parameters	α	[kPa]	0.16
	δ	[-]	0.5
	β_1	[kPa]	0.8
	β_2	[kPa]	0.2
Bulk energy parameter	κ	[kPa]	100
Pore energy parameter	η	[-]	10^{-5}
End-exhalation pleural pressure	$p_{pl,e}$	[kPa]	-0.5
End-inhalation pleural pressure	$p_{pl,i}$	[kPa]	-3.0

Table 2: Parameters used for porosity calculations and for comparison with [Hurtado et al. 2017]. The parameters are based on [Patte, Genet, et al. 2022], but adapted to fit data from [Hurtado et al. 2017].

3 Results

We provide the code to reproduce the results of this paper under the form of jupyter notebooks [Peyraut et al. 2024]: static versions are given in the appendix of the paper while interactive versions are currently available online at <https://apeyraud.gitlabpages.inria.fr/gravity-modeling-paper-demos>.

3.1 Computed pleural pressure distribution

The computed pleural pressure fields are presented in Figure 2. In this figure, the value of the pressure (in kPa) on the surface of the right lung is presented at end-exhalation and at end-inhalation, for the case with and the case without gravity. The patient lying in supine position, gravity is oriented from the ventral region (denoted "V" in the figure) to the dorsal region (denoted "D" in the figure). These results show that when gravity is not taken into account, the pleural pressure is homogeneous, and equal to -0.5 kPa at end-exhalation and -3 kPa at end-inhalation, which corresponds to the values specified in our model. When gravity is taken into account, the pleural pressure takes the form of a gradient, ranging from -0.1 kPa in the dorsal region to -1 kPa in the ventral region at end-exhalation and from -2.6 kPa in the dorsal region to -3.5 kPa in the ventral region at end-inhalation. It is this gradient that balances the gravitational volume force, allowing to reach a global equilibrium.

Figure 2: Pleural pressure distribution with and without gravity, at end-exhalation and end-inhalation. In our model, without gravity, the pleural pressure applied onto the lung is homogeneous. Conversely, when gravity is taken into account, a pleural pressure gradient appears, with a higher value in the ventral region than in the dorsal region.

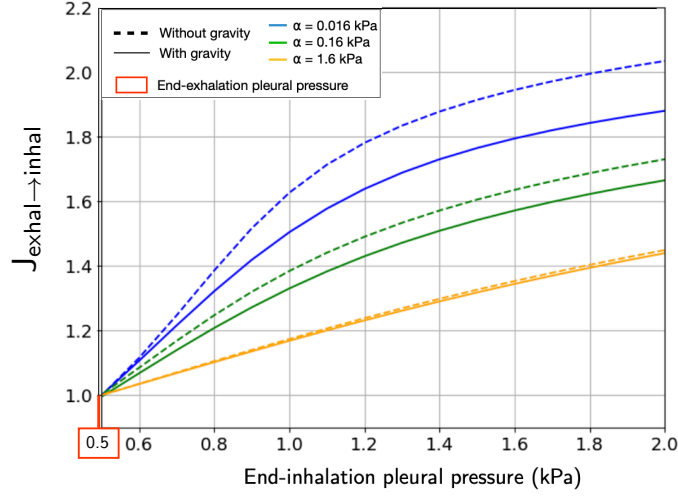

3.2 Model response

3.2.1 Global pressure-volume response

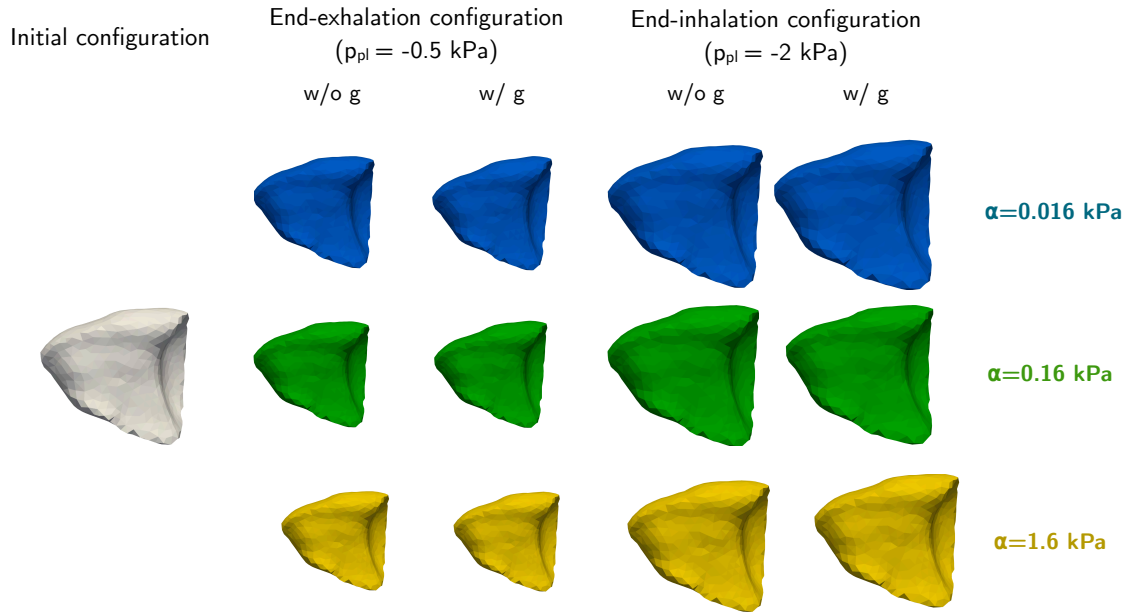

We expect gravity to have an impact on both global and local responses of the lungs. In order to study its impact on the global response of the lungs, we chose to study the pressure-deformation response of the right lung. The change in the global pressure-deformation response of the lungs, as a function of the absolute value of the end-inhalation pleural pressure, is presented in Figure 3(a).

This figure presents the changes of volume for various values of pleural pressure at end-inhalation. The dotted lines represent the pressure-Jacobian response without gravity while the plain lines represent the pressure-Jacobian response with gravity. The Jacobian plotted in Figure 3 corresponds to the volume change from end-exhalation to end-inhalation. The study was conducted for three different values of stiffnesses, within physiological range. The curves in blue represent the response for a stiffness $\alpha = 0.016$ kPa, the curves in green represent the response for a stiffness $\alpha = 0.16$ kPa and the curves in yellow represent the response for a stiffness $\alpha = 1.6$ kPa. The values of the other parameters used in this calculation are specified in Table 1.

The pleural pressure at end-exhalation is considered to be of -0.5 kPa in the problem. For a pleural pressure at end-inhalation of -0.5 kPa, i.e., a similar loading at end-exhalation and at end-inhalation, the Jacobian is, as expected, of 1. When the end-inhalation pleural pressure is different from the end-exhalation pleural pressure, the value of the Jacobian is different with and

(a)

(b)

Figure 3: (a) Pressure-deformation response of the lungs for various values of stiffnesses, with and without gravity. The stiffer the tissues, the less compliant the lung. When gravity is not taken into account, the lung is more compliant. (b) Illustrations of the right lung in the cases with and without gravity for the three values of stiffnesses, and for the three configurations. The end-inhalation configuration is chosen for a pleural pressure of 2 kPa. The initial configuration (generic end-exhalation mesh) is the same for all cases.

1 without gravity. The maximum difference between the case with and the case without gravity for
 2 a stiffness of 1.6 kPa is indeed of 0.6%, while it is of 3% for a stiffness of 0.16 kPa and of 8%
 3 for a stiffness of 0.016 kPa. Globally, for each value of stiffness studied, the volume change from
 4 end-exhalation to end-inhalation is higher when gravity is taken into account.

5 Figure 3(b) illustrates the shape of the lungs for all cases. The initial generic end-exhalation con-
 6 figuration is the same for all cases. At "true" end-exhalation (i.e., the end-exhalation configuration
 7 computed with the porosity changes), gravity changes slightly the shape of the right lung in com-
 8 parison to the case without gravity. This change is more noticeable for lower values of stiffnesses.
 9 Similarly, the shape of the right lung at end-inhalation is slightly different between the case with
 10 and the case without gravity. This change is more noticeable for lower values of stiffnesses, but
 11 barely noticeable for a stiffness of 1.6 kPa, and far less noticeable than for the end-exhalation
 12 configuration.

13 3.2.2 Porosity distribution

14 We now study the impact of gravity on various local quantities of interest of the model. First, we
 15 study the impact of gravity on the porosity, which has an influence on the macroscopic behavior
 16 of the lung tissues. The model parametrization chosen for this computation is detailed in Table 1.

17 Figure 4 presents the porosity maps and distributions of the right lung in the unloaded state, and
 18 the end-exhalation and end-inhalation states with and without gravity. The initial distribution, in
 19 the unloaded state is plotted in green for both graphs. Its values range from 0.4 to 0.6, resulting
 20 from the uniform law used to define the initial porosity field.

21 At both end-exhalation and end-inhalation, the bars in blue represent the porosity distribution
 22 without gravity and the bars in orange represent the porosity distribution with gravity. At end-
 23 exhalation, the distributions are centered around $\phi_{fe} = 0.7$ when gravity is taken into account in
 24 the model and around $\phi_{fe} = 0.66$ when gravity is not taken into account, which is close to the
 25 mean of the generic porosity imposed in the initial generic end-exhalation configuration. A notable
 26 difference is visible between the cases with and without gravity: in the case without gravity, the
 27 distribution remains uniform, ranging from approximately 0.58 to 0.75; on the other hand, in
 28 the case with gravity, the form of the distribution is different from the initial distribution. The
 29 distribution is much wider, with porosity values ranging from 0.42 to 0.82; it is also closer to a
 30 Gaussian than to a uniform distribution. This results from the porosity gradient visible in the
 31 end-exhalation porosity map of Figure 4, top center image.

32 At end-inhalation the distributions with and without gravity are very similar. The distribution
 33 seems to remain uniform in both cases, with values ranging from approximately 0.75 to 0.85. This
 34 corresponds to the near-homogeneous porosity distribution visible in the end-inhalation porosity
 35 map of Figure 4, top right image.

36 3.2.3 Strain distribution

37 To study the impact of gravity on regional deformations, we chose to plot the sagittal map of
 38 the three invariants of the right stretch tensor $\underline{\underline{U}}$. The right stretch tensor is defined through the
 39 classical polar decomposition of $\underline{\underline{F}}$ in a product of two tensors:

$$\underline{\underline{F}} = \underline{\underline{R}} \cdot \underline{\underline{U}}, \quad (36)$$

40 where $\underline{\underline{R}}$ is an orthogonal rotation matrix and $\underline{\underline{U}}$ is the right stretch tensor. Let us call I_{1U} , I_{2U}
 41 and J_U the three invariants of the right stretch tensor:

$$I_{1U} := \frac{1}{3} \text{tr}(\underline{\underline{U}}), \quad I_{2U} := \frac{1}{6} (\text{tr}(\underline{\underline{U}})^2 - \text{tr}(\underline{\underline{U}}^2)), \quad J_U := \det(\underline{\underline{U}}). \quad (37)$$

42 I_{1U} is a measure of the length deformation, I_{2U} is a measure of the surface deformation and J_U is
 43 a measure of the volume change.

44 To have a complete idea of the deformation of the lungs under gravity, we also chose to study
 45 the distribution of the deviatoric strain, which is an indicator of the distortion of the tissue. The

Figure 4: Top row: Prescribed porosity map in the unloaded state (left); Computed porosity maps in the end-exhalation (center) and end-inhalation (right) states, with gravity. Bottom row: Corresponding porosity distributions in unloaded state & end-exhalation (left) and unloading & end-inhalation (right), with (red) and without (blue) gravity. At end-exhalation, the distribution is wider with gravity than without gravity. At end-inhalation, the cases with and without gravity are very similar.

1 deviatoric strain $\underline{\underline{E}}_{\text{dev}}$ is classically defined as

$$\underline{\underline{E}}_{\text{dev}} := \sqrt{\frac{3}{2} \underline{\underline{E}}_{\text{dev}} : \underline{\underline{E}}_{\text{dev}}} \quad \text{with} \quad \underline{\underline{E}}_{\text{dev}} := \frac{1}{2} (\underline{\underline{J}}^{-\frac{2}{3}} \underline{\underline{C}} - \underline{\underline{1}}). \quad (38)$$

2 Figure 5 presents sagittal views of the distributions of I_{1U} , I_{2U} , J_U and $\underline{\underline{E}}_{\text{dev}}$. I_{1U} , I_{2U} and J_U
3 display the same behavior. The parametrization chosen for this calculation is detailed in Table 2.
4 When there is no gravity, they are constant throughout the lungs and express an increase of each
5 dimension—length, surface and volume—. But when there is gravity, they become heterogeneous:
6 both length, surface and volume change increase more in the dorsal region than in the ventral
7 region. As for the deviatoric strain, when there is no gravity, it is null as the deformation of
8 the lung is purely volumetric. However, when there is gravity, the deviatoric strain is highly
9 heterogeneous, with higher values localized at the base of the lung.

10 3.2.4 Stress distribution

11 To study the impact of gravity on regional stresses, we study the distributions of hydrostatic and
12 deviatoric stresses. The hydrostatic stress is classically defined as

$$\underline{\underline{\sigma}}_{\text{hydro}} := \sqrt{\frac{1}{3} \underline{\underline{\sigma}}_{\text{hydro}} : \underline{\underline{\sigma}}_{\text{hydro}}} \quad \text{with} \quad \underline{\underline{\sigma}}_{\text{hydro}} := \frac{1}{3} \text{tr}(\underline{\underline{\sigma}}) \underline{\underline{1}}, \quad (39)$$

13 and the deviatoric stress as

$$\underline{\underline{\sigma}}_{\text{dev}} := \sqrt{\frac{3}{2} \underline{\underline{\sigma}}_{\text{dev}} : \underline{\underline{\sigma}}_{\text{dev}}} \quad \text{with} \quad \underline{\underline{\sigma}}_{\text{dev}} := \underline{\underline{\sigma}} - \underline{\underline{\sigma}}_{\text{hydro}}. \quad (40)$$

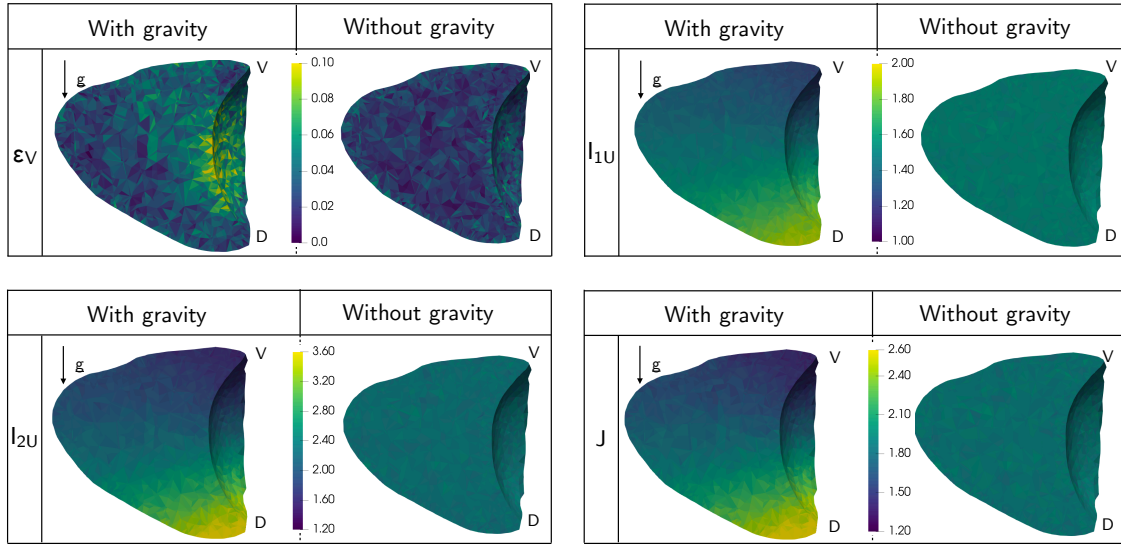

Figure 5: Sagittal maps of the deviatoric strain (top left, quantifying shear deformation), the first (top right, quantifying length change), second (bottom left, quantifying surface change) and third (bottom right, quantifying volume change) invariants of the right stretch tensor, with and without gravity. Without gravity, all quantities are homogeneous. With gravity, the length, surface and volume changes are larger in the dorsal area, while the deviatoric strain is localized at the base of the lungs.

- 1 Figure 6 presents sagittal views of the distributions of σ_{hydro} and σ_{dev} . The parametrization chosen
- 2 for this calculation is detailed in Table 2. When there is no gravity in the model, the hydrostatic
- 3 and deviatoric stresses are distributed relatively homogeneously in the lung. Conversely, when
- 4 gravity is taken into account in the model, the hydrostatic stress take higher values in the dorsal
- 5 region, while they are close to 0 in the ventral region; as for the deviatoric stress, they are localized
- 6 in the dorsal region of the lung.

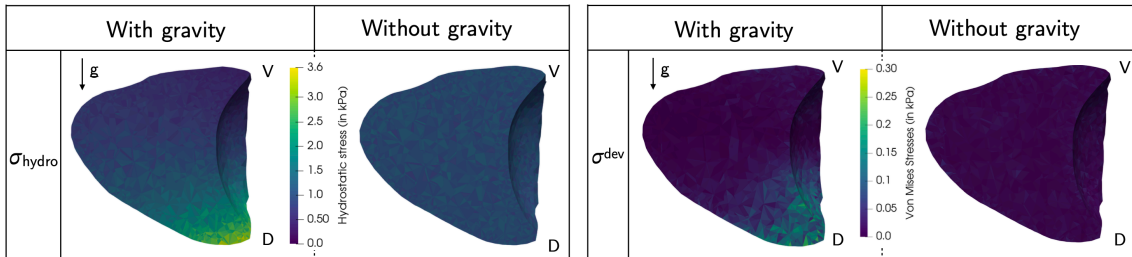

Figure 6: Sagittal maps of hydrostatic (left) and deviatoric (right) stresses, with and without gravity. When there is no gravity, the hydrostatic stresses and the deviatoric stresses are relatively homogeneous in the lung. When gravity is taken into account, higher hydrostatic and deviatoric stresses appear in the dorsal region.

7 3.3 Comparison with experimental data

- 8 In the previous Section, we saw that sagittal maps of porosity, strain and stress measures are
- 9 highly heterogeneous when gravity is taken into account. It therefore seemed important to study
- 10 such distributions, notably the strain distribution, in a more quantitative manner. Hence, we now
- 11 compare the regional strain distribution predicted by our model to the one measured in [Hurtado
- 12 et al. 2017], and then study the impact of some model parameters on such distribution.

1 Following [Hurtado et al. 2017], the strain quantities of interest — I_{1U} , I_{2U} and J_U — are first
 2 log-normalized. To do so, we first compute the maximum-likelihood estimators of the location and
 3 scale parameters of the distribution of each quantity of interest Q over the whole mesh:

$$\hat{\mu}_Q := \frac{1}{n} \sum_{k=1}^n \log(Q_k), \quad \text{and} \quad \hat{\sigma}_Q := \frac{1}{n} \sum_{k=1}^n (\log(Q_k) - \hat{\mu})^2, \quad (41)$$

4 where n is the number of mesh elements. Then, for each element we compute the log-normalized
 5 quantities of interest:

$$\hat{Q} := \frac{\log(Q) - \hat{\mu}_Q}{\hat{\sigma}_Q}. \quad (42)$$

6 Next, following the approach of [Hurtado et al. 2017; Nelson et al. 2023], we split the mesh in ten
 7 coronal zones, as shown in Figure 7—the first zone corresponds to the dorsal area (“D”) while the
 8 tenth zone corresponds to the ventral area (“V”). Finally, for each zone, we compute the mean of
 9 the normalized quantities of interest.

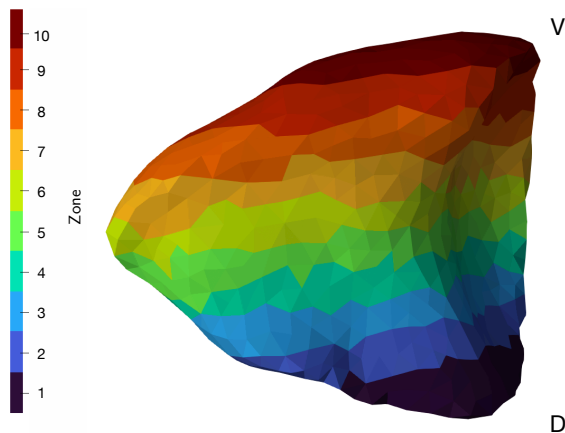

Figure 7: Definition of ten coronal zones in the right lung of a patient in supine position. The first zone corresponds to the dorsal area, denoted “D”, and the tenth zone corresponds to the ventral area, denoted “V”.

10 The log-normal distribution of the invariants in the ten coronal zones, obtained with our model
 11 (color) as well as measured by [Hurtado et al. 2017] (black boxes), is presented in Figure 8. Note
 12 that this figure only displays modeling results in the supine position (which corresponds to the
 13 experimental condition), and with gravity. Indeed, when gravity is not taken into account in the
 14 model, the three invariants are homogeneous across the coronal zones; moreover, they cannot be
 15 log-normalized as the scale parameter is equal to zero. The green curves represent the results for a
 16 purely linear reference pleural pressure ($H = 0$). The spatial evolution of the quantities of interest
 17 is consistent with the experimental data: the value of the invariants is larger in the dorsal area,
 18 and decrease as the region considered is closer to the ventral area. The values of the parameters
 19 used for this calculation can be found in Table 2. The parameters chosen were adjusted to fit
 20 better the data from [Hurtado et al. 2017].

21 In order to quantify the impact of the reference pleural pressure (which could be used to model
 22 ventral and thoracic breathing, as discussed in Section 2.2.3), we also considered cases with $H =$
 23 $H_1 := \pm 0.0050K$ (red and blue curves) and $H = H_2 := \pm 0.0065K$ (purple and yellow). The sign and
 24 magnitude of H does have an impact on the spatial evolution of the strain quantities of interest,
 25 with lower values in the dorsal region, larger ($H < 0$) or lower ($H > 0$) values in the central region,
 26 and larger ($H > 0$) or lower ($H < 0$) values in the ventral region.

27 3.4 Comparison with our previous model

28 In our former model [Patte, Genet, et al. 2022], gravity was not taken into account, even though
 29 some heterogeneity within the lung stress fields was induced by frictionless contact between the

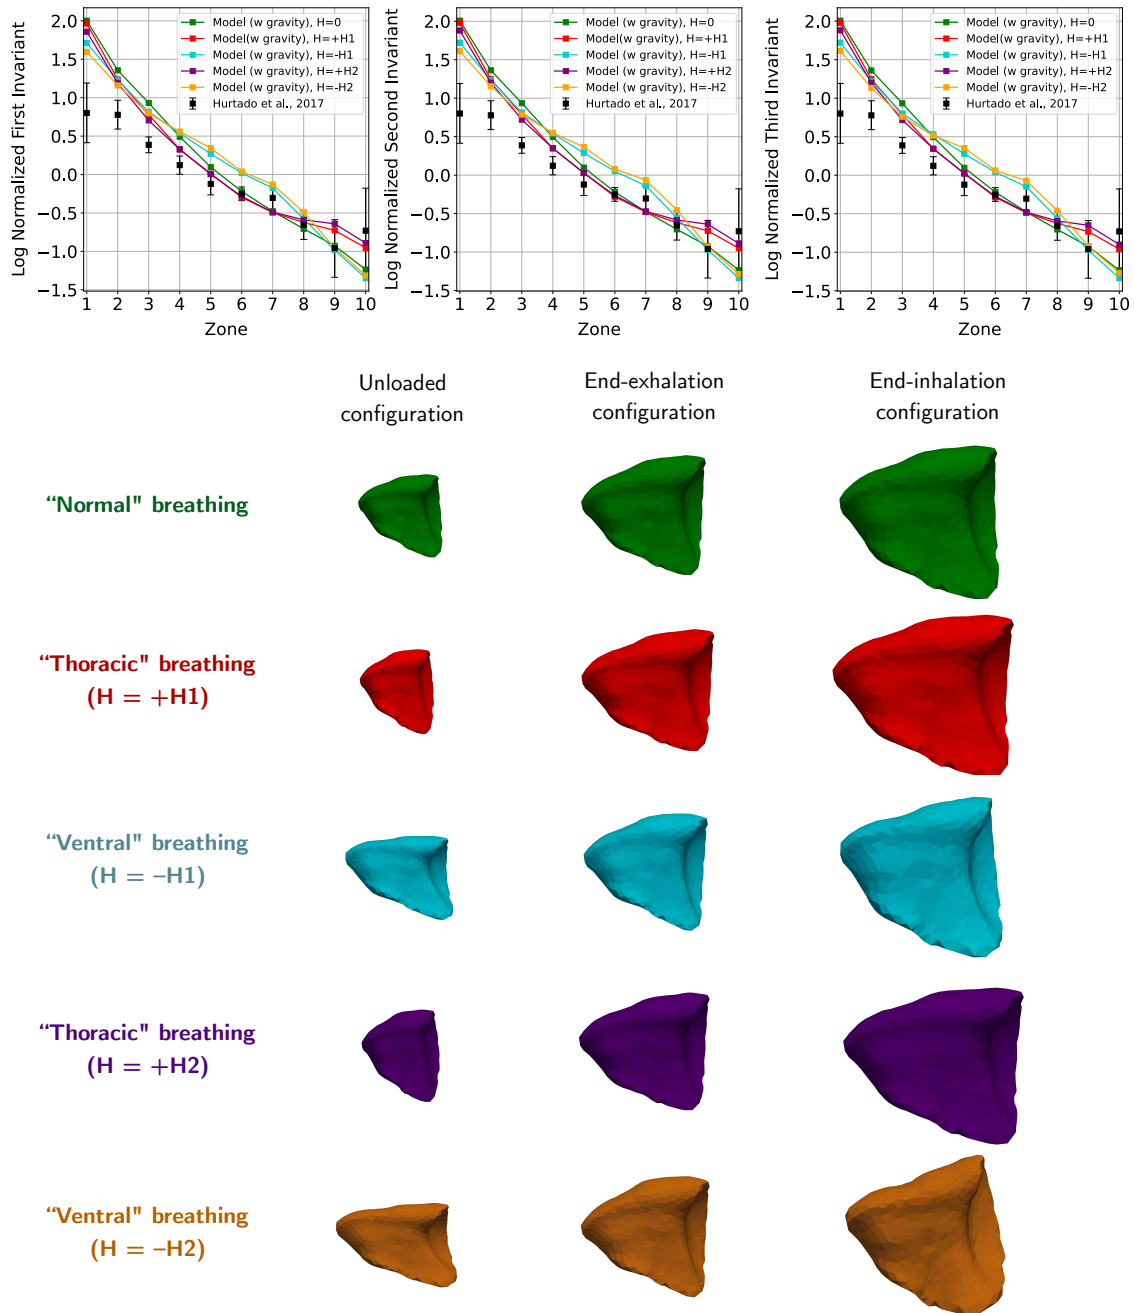

Figure 8: (a) Spatial distribution of the log-normal first invariant (left), second invariant (middle), and third invariant (right), for $H = 0$ (green curve), $H = +0.005K$ (red curve), $H = -0.005K$ (blue curve), $H = +0.0065K$ (yellow curve) and $H = -0.0065K$ (purple curve). Our results show that for the three invariants, the values are higher in the dorsal region, and decrease steadily until reaching their lowest value in the ventral region. Varying the reference pleural pressure also has an impact on the invariants distribution. (b) Illustration of the various steps of the calculation for the five cases.

1 lungs with the thoracic cage. We now compare this heterogeneity to the one obtained with our
 2 current model, which was just shown to be consistent with experimental observations.

3 Figure 9 presents the average values of the first, second and third invariants in each of the ten
 4 zones with our former model (green) and with our new formulation including gravity, in prone
 5 (red) and supine (blue) positions. Note that for the results obtained with our current model in
 6 prone and supine positions, the values of the parameters of material laws are chosen to be as close
 7 as possible to the parametrization used to obtain the results of [Patte, Genet, et al. 2022]; these
 8 values –presented in Table 1, with $\alpha = 0.16\text{kPa}$ – are slightly different from the ones chosen to
 9 generate the data of Figure 8, so that values of the green curves of Figure 8 are different from the
 10 values of the curves for the supine position of Figure 9. Nevertheless, with our former model, the
 11 average value for the three invariants in every zone remain almost the same. Conversely, with our
 12 current model, in the supine position the values for each invariant is higher in the dorsal region
 13 and decrease until reaching their lowest value in the ventral region, and vice versa in the prone
 14 position.

Figure 9: Spatial distribution of the first (left), second (center) and third (right) invariants with our former model and with our new formulation in prone and supine positions. In the former model, the average of the invariants remains roughly homogeneous in all zones, and does not vary in prone vs. supine position as there is no gravity in the model. With our new formulation, the strain invariants vary across the coronal zones, and the behavior in prone position differs greatly from the behavior in supine position.

15 4 Discussion

16 In the scope of this work, we assumed that gravity had a non negligible impact on the mechanical
 17 behavior of the lungs, and that it was partly responsible for the heterogeneity in breathing strain
 18 quantities of interest observed experimentally. We thus proposed a formulation of physiological
 19 boundary conditions allowing to take gravity into account. The results presented in this article
 20 seem to validate our initial hypothesis. We now discuss our results in details.

21 4.1 Computed pleural pressure distribution

22 The boundary conditions proposed in this paper lead to an heterogeneous pleural pressure applied
 23 onto the lungs, as presented in Figure 2, which corresponds to what is physiologically observed [Bar-
 24 rrau et al. 2022]. At end-exhalation, the values of the pressure distribution range from -0.1 kPa
 25 to -1 kPa , which is consistent with data that can be found in literature, as presented in Table 3.
 26 The maximum and minimum values we find seem to correspond to the range of values presented
 27 in [Tawhai et al. 2009] and [Kallet 2015]. However, our gradient is higher: -0.9 kPa with our
 28 results, for a gradient of -0.5 kPa in [Kallet 2015] and of -0.7 kPa in [Tawhai et al. 2009]. If our
 29 gradient is almost twice the gradient presented in [Kallet 2015], the authors however highlighted
 30 that there could be approximations in the values presented, notably due to measurement tech-
 31 niques. This could explain their low pressure gradient value. It is also possible that the pleural

1 pressure gradient we obtain is higher than what was observed in [Tawhai et al. 2009] and [Kallet
2 2015] because of the parametrization of our model. The value of our pleural pressure depends
3 indeed greatly on the expression of the reference pressure \tilde{p}_{pl} implemented. The constants in-
4 volved in the expression of \tilde{p}_{pl} (see Equation (30)) are indeed fixed here at "normal" values that
5 do not necessarily correspond to the data of a real patient. The values we chose could therefore
6 explain why our gradient is higher than [Tawhai et al. 2009]. The value we obtain seems however
7 reasonably close, especially considering that the pressure gradient varies greatly from one patient
8 to another. It is therefore possible that the difference in the values we obtained is solely due to
9 this high variability.

	Values from [Tawhai et al. 2009]	Values from [Kallet 2015]	Values from this paper
Min. value	-0.5 kPa	-0.1 kPa	-0.1 kPa
Max. value	-1.2 kPa	-0.6 kPa	-1.0 kPa

Table 3: Comparison of the values obtained for the porosity with values obtained in the literature.

10 We could not find data on the pleural pressure distribution at forced inspiration. The values we
11 obtain seem however consistent, with a gradient of pleural pressure remaining similar to the value
12 we obtained at end-exhalation (0.9 kPa). The form of the gradient is also consistent with what was
13 described in [Barrau et al. 2022]: the value is more negative in the ventral region than in the dorsal
14 region to balance gravity. When gravity is not taken into account, the pleural pressure of our model
15 is uniform in the lungs. This is consistent with the studies of [Michels et al. 1978] and [Bryan et al.
16 1966], who suggested that under 0G, the expansion of the lungs should be uniform.

17 4.2 Model response

18 4.2.1 Global pressure-volume response

19 We assumed that gravity had an impact on the global and local response of the lungs. In terms
20 of global response, we are particularly interested in the deformation and in the compliance of the
21 lungs, from which biomarkers could be derived in the future. The compliance of the lungs is very
22 dependent on the stiffness of the tissues, which can take a wide range of values, depending on the
23 considered individual. We therefore studied the pressure-deformation response of the right lung,
24 with and without gravity, for three different values of stiffnesses.

25 For the three values of stiffnesses studied, the results for the pressure-deformation curve are con-
26 sistent with [Patte, Genet, et al. 2022]: the higher the stiffness, the lower the compliance of the
27 lung. The impact of gravity on our generic lung also depends on the stiffness. For the highest
28 stiffness, the behavior of the lung is very similar with or without gravity, with a relative difference
29 between the two cases always under 0.6%. This could be expected, insofar as the stiffer the tissue,
30 the higher a force needs to be to have an impact on the behavior of the structure. As a result,
31 the impact of gravity is barely visible for the highest value of the stiffness. For lower stiffnesses,
32 the impact of gravity on the pressure-volume response is more noticeable, especially for smaller
33 values of pleural pressure. As could be expected, the lower the stiffness of the tissues, the higher
34 the impact of gravity.

35 For physiological values of the end-inhalation pleural pressure (i.e., above 1 kPa), its impact can
36 be considered to be much higher than the impact of gravity. The effect of gravity should therefore
37 not be visible for end-inhalation pressures ranging from 1 kPa to 2 kPa. However, the actual end-
38 inhalation and end-exhalation configurations are computed from the unloaded configuration, which
39 is itself computed from the generic end-exhalation configuration. Since the end-exhalation pres-
40 sure is not high enough to neglect gravity, the unloaded configuration is different with and without
41 gravity, which leads to different end-inhalation configurations, even with high end-inhalation pres-
42 sure values. Given the definition of our problem, the actual end-exhalation volumes (i.e., volumes
43 of the end-exhalation state computed with the porosity changes described in the Methods section)
44 are fairly close for all cases. This explains the difference observed in the Jacobian values with and
45 without gravity.

1 The relative difference of the deformation with and without gravity does however not vary signif-
2 icantly for the range of end-inhalation pressure studied. This is consistent with the observations
3 of [Sutherland et al. 1968], who hypothesized that the changes in lung compliance between 0G and
4 normal gravity should be visible for low pressure values (close to the values at forced expiration),
5 but not for typical values of the breathing cycle.

6 For the three cases studied, the Jacobian values are higher in the case without gravity than the case
7 with gravity. This is consistent with the results obtained by [Bondurant 1958], where the authors
8 showed that the compliance of the lungs decreased when the acceleration of gravity increased.
9 [Bettinelli et al. 2002] also showed that the compliance of the lungs was higher under 0G, and
10 smaller under normal gravity. Our results also seems consistent with our approach. Given our
11 definition of the problem, the actual end-exhalation volume of the lungs is very close with and
12 without gravity. At end-inhalation, however, the deformation of the lungs is higher when gravity is
13 taken into account, with, in particular, more compression, which is consistent with the observations
14 of [Seyfi Noferest et al. 2018]. Those deformations lead to a smaller end-inhalation volume, which
15 explains the higher Jacobians without gravity.

16 **4.2.2 Porosity distribution**

17 Determining accurately the porosity field of our model is a key issue, since porosity has an impact
18 on the behavior of the tissues, and therefore on the global and local response of the lungs. In
19 terms of applications, this result confirms that, when building personalized models in the clinical
20 setting, using patient-specific porosity fields, for instance extracted from clinical images, is critical
21 to obtain physiologically relevant models.

22 More precisely, Figure 4 illustrates the impact of gravity on the porosity distribution computed at
23 end-exhalation and at end-inhalation. Porosity increases compared to the unloaded configuration.
24 This is due to the air flowing in the lungs. To compute the end-exhalation configuration from the
25 unloaded configuration, the pleural pressure, which is negative, is applied onto the lung surface,
26 causing air to flow within the lung. It hence causes an increase of the porosity.

27 Our results show a real impact of gravity on the porosity distribution, especially at end-exhalation.
28 When no gravitational body force is applied, the pleural pressure is uniform (see Figure 2). It
29 is therefore reasonable to expect the same profile for the distribution at end-exhalation as in
30 the unloaded configuration. On the contrary, when gravity is taken into account, the porosity
31 distribution is wider, and has a form closer to a Gaussian. This is due to the boundary conditions
32 balancing gravity. Indeed, to balance gravity, the boundary pressure is higher (more negative) in
33 the ventral region than in the dorsal region. With gravity, the dorsal part of the lungs is therefore
34 in compression, which induces air to flow out. This results in a diminution of the fluid phase and
35 hence of the porosity. Similarly, the pressure implemented as boundary condition induces tensile
36 stresses in the ventral region to balance gravity. In this region, porosity therefore increases slightly.
37 This phenomena explain the more heterogenous distribution of porosity at end-exhalation when
38 taking gravity into account.

39 The impact of gravity on the porosity distribution is barely noticeable at end-inhalation. The
40 distribution is indeed almost the same with or without taking gravity into account. At end-
41 inhalation, the pleural pressure considered is six times higher than the pleural pressure considered
42 at end-exhalation. It is therefore reasonable to consider that at end-inhalation the impact of gravity
43 on the porosity distribution is negligible compared to the pleural pressure, which is visible on the
44 porosity distribution.

45 The values we obtain at end-exhalation and end-inhalation fall within the range of porosities
46 described in [DeGroot et al. 2018], where the average porosities considered are within 0.7 and 0.9.
47 Our values are also close to the values of [Yang et al. 2020], presented in Table 4. In this study,
48 the authors investigated the mean porosity for female and male patients during a full breathing
49 cycle.

50 Our values are slightly higher than the values presented in [Yang et al. 2020]—about 15% of
51 difference between our values and the values presented for females. However, their values are also

1 smaller than the values in [DeGroot et al. 2018]. This may result from the initial porosity chosen
 2 in this article, which was not detailed. The difference in porosity at end-inhalation can also be
 3 explained by the fact that the porosity they present in their work is measured during normal
 4 breathing, while the porosity we present in this study is at forced inhalation. The higher porosities
 5 in the dorsal area at end-exhalation are consistent with the results of [Gattinoni et al. 2023], who
 6 observed that the gas/tissue ratio was multiplied by 1.5 between the ventral area and the dorsal
 7 area.

	Female porosity from [Yang et al. 2020]	Male porosity from [Yang et al. 2020]	Mean porosity from this study
End-exhalation porosity	0.66	0.64	0.77
End-inhalation porosity	0.71	0.70	0.85

Table 4: Comparison of the values obtained for the end-exhalation pleural pressure with values obtained in the literature.

8 4.2.3 Strain distribution

9 In the results presented in Figure 5, we observe that the deformation is highly heterogeneous in the
 10 lung when gravity is taken into account. Both I_{1U} , I_{2U} , and J take higher values in the dorsal area
 11 when the patient is in supine position, which is consistent with results that have been observed
 12 in [Hurtado et al. 2017]. The deformations are globally higher in the dorsal region, which is also
 13 consistent with the observation of higher ventilation in the dorsal region for patients in supine
 14 position [West 2011].

15 [Tawhai et al. 2009] and [Gattinoni et al. 2023] also highlighted that the dorsal region was com-
 16 pressed and the ventral region more extended in supine position, which necessarily results in higher
 17 deformations between end-exhalation and end-inhalation in the dorsal region, the impact of gravity
 18 being less visible at end-inhalation than at end-exhalation. These observations are also supported
 19 by [Amelon et al. 2011], who highlighted that higher volume deformations should be expected in
 20 dorsal regions.

21 Gravity also induces shear stresses in the lungs, which are expected along the plane perpendicular
 22 to the application of gravity. The base being wider than the apex, higher deviatoric strains can be
 23 expected there. The localization of deviatoric strains at the base of the lungs could also resonate
 24 with the fact that IPF usually develops first at the base of the lungs and then spreads towards the
 25 apex.

26 When gravity is not taken into account, the deformations are homogeneous, which is consistent
 27 with observations of [Prisk 2014], who observed that ventilation and perfusion are heterogenous
 28 under normal gravity, but more homogeneous under 0G.

29 4.2.4 Stress distribution

30 Similarly, the maps of hydrostatic and deviatoric stresses display highly heterogeneous behaviors.
 31 The deviatoric and hydrostatic stresses are larger in the ventral part than in the dorsal part, as
 32 for the three reduced invariants. The distribution of the stresses is consistent with our proposed
 33 boundary conditions. Indeed, as a reaction to gravity, the pleural pressure is higher in the ventral
 34 region than in the dorsal region. The ventral region therefore experiences a higher tensile stress
 35 than the dorsal region, which explains the stress distribution.

36 4.3 Comparison with experimental data

37 Figure 8 shows that our results are very close to the data presented in [Hurtado et al. 2017], even
 38 though some details differ. In the results presented by [Hurtado et al. 2017], the value of the
 39 invariants increases between the ninth and the tenth region, while the values we present decrease.
 40 We assume it is due to the image registration process, in which the errors are typically higher
 41 close to the boundaries [Berberoğlu et al. 2021; Genet 2023]. Similarly, the values of our invariants

1 are significantly higher in the first region, which can partly be explained by the same phenomena.
2 Moreover, the parametrization (parameter values chosen, form of the pleural pressure, etc.) also
3 has an impact on the evolution of the invariants, which could explain the differences observed.
4 However, our results seem to display the same overall behavior.

5 Little data is available in the literature on the regional deformation of the lungs during ventral and
6 thoracic breathing. In this discussion, we will call non-specific breathing the breathing cycle that
7 does not represent costal nor thoracic breathing (green curve). During thoracic (red and purple
8 curves), the value of the invariants is smaller in the ventral and dorsal regions than for the non-
9 specific breathing, and globally higher in the mid-part of the lung. This can be explained by the
10 form of the expression of the thoracic breathing: the pressure is higher (i.e., less negative) in the
11 mid-part of the lung and smaller (i.e., more negative) at the apex and the base. Since the absolute
12 pressure is smaller in the mid-part of the lung, the deformation —length, surface and volume—
13 can be expected to be smaller as well, which can explain the behavior of the curve.

14 Even though the curve for the costal breathing (blue and brown curves) is different from the
15 non-specific breathing, it remains close to it. This is due to the form of the expression of costal
16 breathing, where the pressure is higher (i.e., less negative) at the base and the apex of the lung
17 than in its mid-part. The additional deformation introduced by the costal breathing can be ap-
18 proximated as a homogeneous deformation perpendicular to the direction of application of gravity.
19 The variation of the invariants in each zone therefore remains almost solely due to gravity, which
20 explains why the curve remains close to the non-specific breathing case. Nonetheless, these results
21 indicate that by adapting the reference pleural pressure, we should be able to represent highly
22 physiological boundary conditions with our model.

23 4.4 Comparison with our previous model

24 The implementation of gravity allows to take into account gravitational effects on the deformation
25 of the lungs compared to our former model. In particular, this implementation allows to investigate
26 various cases according to the orientation of gravity —e.g., prone, supine or upright positions—
27 . Figure 9 indeed shows that the deformation varies greatly according to the orientation of the
28 patient, which could not be taken into account in our former model. As discussed earlier, the
29 evolution of the invariants in supine position corresponds to data available in literature, which
30 allows us to validate our results.

31 5 Conclusion and perspectives

32 In this work, we proposed the formulation of novel pressure boundary conditions for the lungs
33 that balance gravity to verify the global equilibrium. This formulation is based on a constrained
34 minimization problem. The boundary conditions we propose aim at incorporating gravity in our
35 model, which has a non-negligible impact on the behavior of the lungs. It is however important
36 to highlight that taking gravity into account in our model is only justified by the range of pleural
37 pressure considered. Indeed, for larger pleural pressures, gravity would become negligible.

38 The formulation of our boundary conditions allowed us to study the impact of gravity on local and
39 global quantities. In particular, we could reproduce the data of [Hurtado et al. 2017], which allows
40 us to validate our data. We could also highlight the impact of gravity on various quantities, such
41 as the local changes of dimensions —length, surface and volume— between end-exhalation and
42 end-inhalation, the porosity, the pressure-volume response of the lungs, or the stress distribution.

43 We therefore achieved to formulate boundary conditions that remain physiological, and allow to
44 include phenomena caused by gravity, which is not always straightforward in biomechanics. This
45 is an important step forward in the improvement of our model. It indeed allows us to improve
46 the physiological relevancy of our model.
47

48 A next step to improve this work would be to study the expression of the reference pleural pres-
49 sure. Indeed, a simple expression for this pressure has been proposed in this article, but could

1 be improved. In particular, further investigations for taking properly into account diaphragmatic
2 and costal breathing should be conducted in the future. Another step of improvement would be
3 to include additional phenomena in our model, and to study their impact on the deformation of
4 the lungs when gravity is considered. In particular, we would like to increase the physiological
5 relevancy of our model by taking into account two fluid phases, air and blood, and one solid phase,
6 the lung parenchyma (currently, the fluid phase corresponds to the air and the solid phase to the
7 blood and lung parenchyma). Modeling the structural heterogeneities of the lungs, e.g., by incor-
8 porating the microstructure of the lungs and the airway tree in our macroscale model, would also
9 improve the model and provide additional information on the impact of gravity on lung behavior,
10 e.g., information on the impact of gravity on the deformation of the airway tree. Ultimately, we
11 would like to apply this model to clinical data, and in particular to data of patients with IPF;
12 this study could confirm whether gravity has an impact on patients presenting locally stiffer lung
13 tissues.

14 Taking gravity into account in the model could also improve the personalization process in dig-
15 ital twin-based biomedical applications. Gravity could indeed be helpful to decrease model and
16 estimation errors made during the identification of the parameters of our model [Patte, Genet,
17 et al. 2022; Laville et al. 2023], by considering images both in prone and supine positions during
18 the estimation process. Our boundary conditions are therefore a valuable improvement for the
19 personalization of the model, which could eventually help build a digital twin of the lungs. These
20 boundary conditions can be used in a wide variety of other lung models to improve their accuracy
21 and/or to study the impact of gravity in diverse phenomena, such as mechanical ventilation for
22 example [Sattari et al. 2023]. This could in particular help clinicians to improve patient care in
23 various diseases, such as IPF.

24 Acknowledgements

25 We would like to thank Patrick Le Tallec for the discussions we had about the formulation of our
26 boundary conditions. We would also like to thank the French National Research Agency (ANR) for
27 providing financial support to this project (Grants no: ANR-19-CE45-0007 and ANR-20-COV4-
28 0004).

1 A Impact of porosity distribution width and mesh size

2 A.1 Impact of porosity distribution width

3 In this appendix, we propose an additional study of the impact of a wider porosity distribution
4 in the unloaded configuration ($[0.3, 0.7]$) on the porosity distribution at end-exhalation and end-
5 inhalation, with and without gravity, presented in Figure A.1.

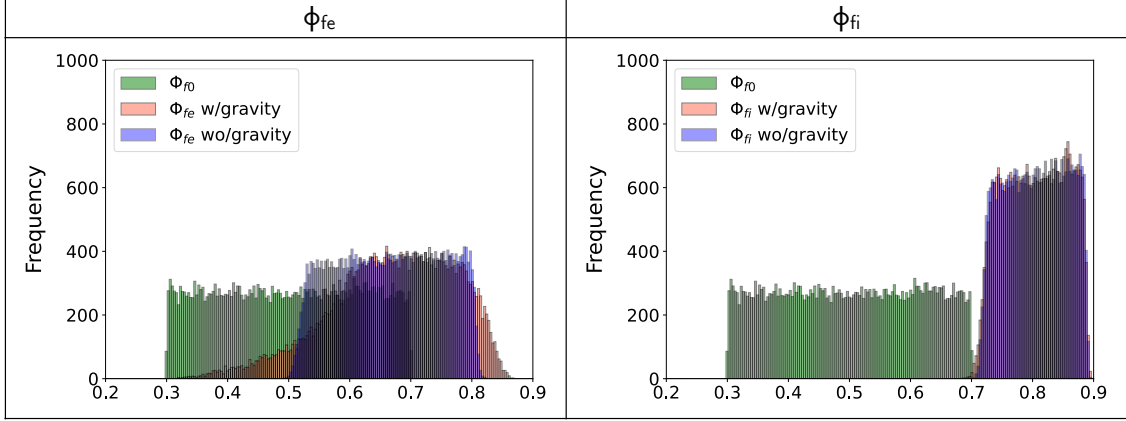

Figure A.1: Porosity distribution at end-exhalation (left) and at end-inhalation (right) for a porosity in the unloaded configuration following a uniform law ranging from 0.3 to 0.7.

6 The trends remain similar to what was observed in 4, but with wider distributions. The distribution
7 are centered on the same values as before, but range from 0.4 to 0.9 at end-exhalation with gravity
8 and 0.6 to 0.85 without gravity. At end-inhalation the porosity range from 0.72 to 0.9. The form
9 of the distributions therefore remains the same as before, even though they take values in a wider
10 range.

1 A.2 Impact of mesh size

2 We also include a brief convergence study of porosity distribution at end-exhalation and end-
 3 inhalation, with and without gravity, presented in Figure A.2. The results obtained in Figure 4
 4 are compared with results for a finer mesh (approximately 10 times as many elements). The
 5 distribution remains the same; the number of elements do not have an impact on the results.

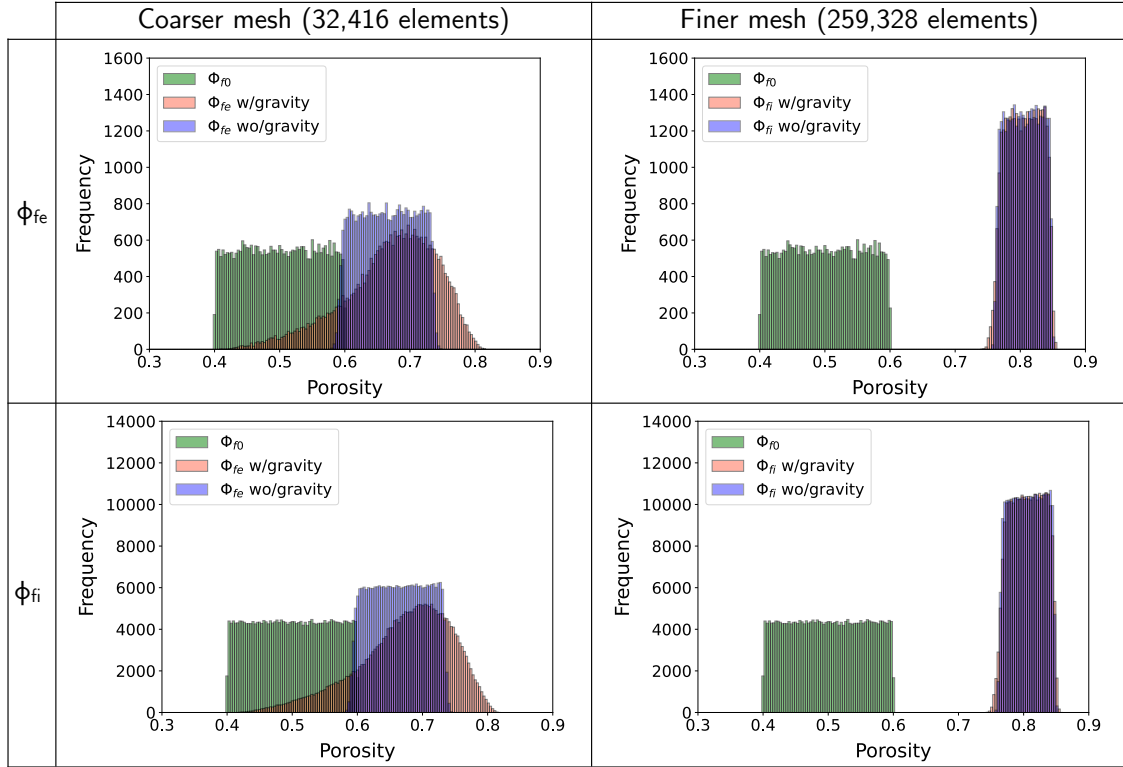

Figure A.2: Porosity distribution at end-exhalation (first row) and at end-inhalation (second row) for the mesh used in this article (left) and a finer mesh (right). The distribution is the same in the two cases. The results we obtained are converged.
