Abstract

This article introduces a new efficient particle method for the numerical simulation of crystallization and precipitation at the pore scale of real rock geometries extracted by X-Ray tomography. It is based on the coupling between superficial velocity models of porous media, Lagrangian description of chemistry using Transition-State-Theory, involving underlying grids. Its ability to successfully compute dissolution process has been established in the past, and is presently generalized to precipitation and crystallization by means of adsorption modeling. Numerical simulations of mineral CO₂ trapping are provided, showing evidence of clogging/non-clogging regimes, and one of the main results is the introduction of a new non-dimensional number needed for this characterization.

Keywords: Digital Rock Physics (DRP), Crystallization, Mineral trapping, CO₂ storage, Precipitation, Clogging, Lagrangian methods, Superficial velocity, Pore-scale modeling.

1 Introduction

Studying reactive flows in porous media is essential to manage the geochemical effects arising from CO₂ capture and storage in natural underground reservoirs. While long-term predictions are commonly modeled at the field scale [Class et al., 2009], pore-scale approaches meanwhile provide insights into local geochemical interactions between the injected CO₂ and the aquifer structure [Payton et al., 2022]. Through mathematical homogenization of the sub-micrometer porous medium and appropriate modeling, one can simulate the reactive processes that occur at the pore scale and predict their impact on the macro-scale properties, as developed in Allaire et al. [2010], Allaire and Hutridurga [2012]. Geochemical processes are critical components for understanding the mineral trapping mechanisms and local evolving interfaces within the porous environment. In this sense, investigating the impact of such reactive processes provides insights into reservoir safety submitted to chemical interactions that may compromise the aquifer structure. Pore-scale modeling of reactive flow hence appears as a complementary mean to field scale studies wherein homogenization theory bridges the gap between these scales.

In this context, several geochemical mechanisms play a critical role in the CO₂ sequestration process and mainly involve precipitation, crystallization, and dissolution phenomena. On one side, carbonate precipitation and crystallization ensure efficient capture of the injected CO₂ in the form of minerals such as calcite, aragonite, or dolomite: this is referred to as mineral trapping, which informs about the storage capacities of the reservoir. These processes significantly impact the flow within the porous media at the pore scale, leading to restructuring of the flow path and morphological changes that alter, *inter alia*, the pore size distribution and the roughness of the interface due to partial or complete clogging of pore throats. Such alterations at the micro-scale subsequently alter the estimation of the macro-scale properties, namely the porosity and permeability, and thereby require investigations to ensure wise management of the underground reservoir structures. On the other side, the reverse chemical process can also occur, resulting in carbonate mineral dissolution due to an acidification of the aqueous solution. This may compromise not only the efficiency of the trapping mechanisms, leading to an increase of both porosity and permeability,

*Corresponding author: philippe.poncet@univ-pau.fr

but also the integrity of the reservoir cap rock, and is, therefore, of great interest to prevent acute leakage issues. In this sense, one needs reliable estimations of the macro-properties changes due to these overall geochemical processes at the pore scale, to manage their impact on the reservoir scale modeling of CO₂ storage. This can be achieved through, first, efficient DNS of reactive flows at the pore-scale and, subsequently, by embedding uncertainty concerns on the quantification of the petrophysical properties. In the present article, we address the first point with a focus on precipitation and crystallization modeling for CO₂ mineral storage into carbonate porous media.

Pore-scale investigation of reactive geochemical systems has garnered interest over the past decades based on imaging processes and laboratory experiments [Menke et al., 2015, Noiriél and Renard, 2022, Siena et al., 2021]), numerical simulations [Payton et al., 2022, Soulaïne et al., 2018], and a combination thereof [Molins et al., 2021, Noiriél and Soulaïne, 2021]. In this sense, image-based DNS coupling μ CT characterization of a porous sample REV with efficient scientific computing and numerical method appears as a promising tool to query the impact of reactive processes on real rock geometries. The current work relies on such a semi-Lagrangian approach, which handles a Lagrangian description of the chemistry with underlying grid methods for the hydrodynamic, based on the superficial velocity formalism introduced in the 1980s in Quintard and Whitaker [1988]. The latter makes it possible to account for the involvement of the porous matrix in the overall flow process through a micro-continuum description of the medium. In this sense, one considers an intermediate state between the full resolution of each individual solid grain and the completely averaged continuum representation of the porous media at Darcy's scale. This establishes two-scale models that are widely used in hydrodynamics pore-scale modeling and μ CT image-based DNS, as shown in Molins et al. [2021], Panga et al. [2005], Soulaïne et al. [2017]. The present semi-Lagrangian formalism has been successfully employed in the context of carbonate dissolution at the pore scale [Etancelin et al., 2020] and extensively benchmarked against state-of-the-art numerical alternatives, as detailed in Molins et al. [2021].

The other contributions of this article lie in the modeling aspects of CO₂ mineral trapping under the form of calcite crystal aggregates at the pore scale. Precipitation kinetics of calcite have been historically studied since the 1970s from the experimental and theoretical sides in Chou et al. [1989], Lasaga [1981], Plummer et al. [1978], and this has commonly established Transition State Theory (TST) as an efficient and straightforward way of predicting mineral reaction rate. Indeed, the deterministic TST is currently one of the most widely used models in reactive transport codes and DNS, detailed in Molins et al. [2012], Noiriél et al. [2021, 2016], Steefel et al. [2015]. However, several doubts have risen in the research community about using such a deterministic approach for predicting crystal growth rates. In particular, comparison with experimentally determined growth rates has highlighted a wide range of discrepancies, querying the reliability of the TST model for overall crystallization processes, introduced in Hellevang et al. [2013], Pham et al. [2011]. Meanwhile, probabilistic approaches, which find their origins in classical nucleation theory and the probabilistic nature of the precipitation and crystal growth mechanisms, have been developed in Masoudi et al. [2021], Nooraiepour et al. [2021], Wolthers et al. [2012]. These models make it possible to incorporate, *inter alia*, the effects of induction time characterizing the onset of the nucleation, the ionic affinities of the growing sites, and attachment frequencies of the ionic species involved in the reaction. Such attachment frequencies are, especially, significant for modeling surface adsorption and crystal aggregation that largely hinges on the surrounding porous structure in the sense that kinks or corners, for instance, are experimentally identified as preferential growing sites. However, such a geometrical dependency of the crystal aggregation is commonly neglected in most models, which makes it difficult to predict the spatial distribution of the new crystals.

Therefore, we developed a two-step crystallization process wherein nuclei generation relies on a deterministic TST model before considering the probabilistic mineral aggregation — crystal growth — into the pore interface. The latter accounts for adsorption frequencies of the precipitate to the growth sites, which is weighted by a non-uniform probability of attachment rate depending on local mineral volume fraction. In this sense, we incorporate local geometrical dependency at the pore scale in the overall crystallization model, which is crucial to ensure reliable prediction of pore clogging. We subsequently use this model for calcite crystallization into a carbonate porous medium, arising from μ CT observations, and investigate both the impact on the macro-scale properties evolution and the effects of several dominant regimes on the precipitation and crystal growth patterns. In this sense, we propose a characterization of the crystallization regime based on three distinct dimensionless numbers, including, for the first time, the effects of nuclei adsorption — or crystal aggregation — in this regime characterization. We demonstrate

that the first nucleation process and the crystal aggregation through surface adsorption play a critical role in the pore-clogging and precipitation patterns.

The present manuscript is structured as follows. The section 2 introduces reactive flow model at the pore-scale of rocks. First, the Darcy-Brinkman-Stokes model including to the Kozeny-Carman correlation terms in order to model highly heterogeneous medium at its pore scale, naturally meaningful for evolving fluid-solid interface defining the pores structure. Second, the transport-reaction-diffusion of chemical species. In section 3, we detail our particle method for highly heterogeneous diffusion arising from Archie’s law in the two-scale description of the medium. The application of such models to the precipitation and the crystallization for the CO₂ mineral trapping is described in section 4. It includes the implementation and its HPC features on hybrid architectures, *i.e.* coupling CPU and GPU devices, for the present application, detailed in section 4.4. The related numerical results are discussed in section 5 in terms of clogging or non-clogging regimes of crystallization.

2 Models in reactive microfluidics

The present section focuses on the modeling of reactive hydrodynamics in the context of CO₂ mineral storage and presents the mathematical model used to simulate reactive processes at the pore scale. We first introduce the so-called Darcy-Brinkman-Stokes formulation for microfluidic flows based on superficial velocity formalism. We subsequently incorporate transport-reaction-diffusion equations modeling the geochemical interactions between the different species involved. Finally, we present an alternative formulation in velocity-vorticity for the hydrodynamics equation, which ensures the fluid incompressibility condition.

2.1 Darcy-Brinkman-Stokes: a superficial velocity formalism at the pore scale

We introduce a spatial domain $\Omega \subset \mathbb{R}^n$, $n = 1, 2, 3$ which corresponds to the porous medium described at its pore scale. This sample description involves a pure fluid region Ω_F , also called void-space and assumed to be a smooth connected open set, and a surrounding solid matrix Ω_S itself considered as a porous region. This region is seen as complementing the full domain Ω , which in practice represents the computational box of the numerical simulations such that $\Omega_F = \Omega \setminus \overline{\Omega_S}$, and the internal fluid/solid interface is denoted Σ . We denote the computational domain boundary by $\partial\Omega$ and use $\Gamma_F = \partial\Omega \cap \Omega_F$ and

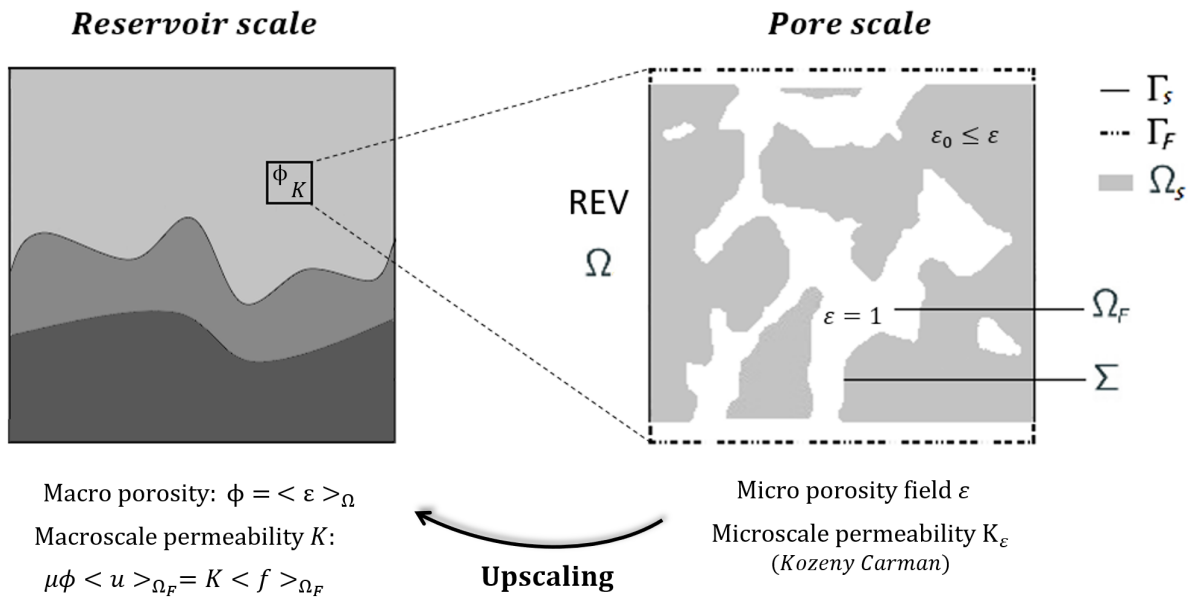

Figure 1: Upscaling from the pore-scale. Schematic representation of a reservoir or material scale structure, on the left, with its inherent averaged macro-properties ϕ and κ_0 computed on a representative elementary volume (REV). Local micro-continuum description of the pore-scale heterogeneity in this REV, on the right, along with its intrinsic micro-scale properties. These properties are the local micro porosity field ε and the micro-scale permeability K_ε , based on the Kozeny-Carman relationship developed in equation (2).

$\Gamma_S = \partial\Omega \cap \Omega_S$ to refer to the fluid and solid parts of the computational domain boundary, respectively, such that $\partial\Omega = \Gamma_F \cup \Gamma_S$ (see Figure 2.1 for instance).

The boundary conditions at the inlet and outlet faces, typically for a cubic computational domain $\Omega =]0, l[^3$ but not exclusively, either impose a prescribed flow rate \bar{u} on the velocity or satisfy periodic boundary conditions for a prescribed driving force f . The boundary conditions on the other lateral faces are systematically periodic since rock samples are commonly constrained in an impermeable solid casing when μ CT experiments are conducted. In this sense, it ensures a consistent numerical representation of the sample compared to the experiments. This also guarantees C^∞ regularity on the boundary even if the domain exhibit corners, since the problem can be formalized by considering the equivalence relationship with the quotient space $\Omega \equiv \mathcal{Q}/G$ where $\mathcal{Q} = \mathbb{R}^2 \times]0, l[$ and $G = l\mathbb{Z}^2 \times \{0\}$ (e.g. see Sanchez et al. [2019] for detailed configurations of acceptable domains).

From the μ CT images, we can also characterize the static pore-space structure, corresponding to the sample's initial state before any geochemical interactions. In this sense, we denote by $\varepsilon = \varepsilon_f = 1 - \varepsilon_s$ the micro-porosity field defined on Ω , given ε_f and ε_s respectively the volume fractions of void and solid according to usual notations from Soulaïne et al. [2017]. This defines a micro continuum description of the porous medium such that $\varepsilon = 1$ in the pure fluid region Ω_F and takes a small value in the surrounding matrix Ω_S . In fact, the local micro-porosity ε is assumed to have a strictly positive lower bound $\varepsilon(x, t) \geq \varepsilon_0 > 0$ for all (x, t) in the spatiotemporal domain $\Omega \times [0, T_f]$ for a final real-time $T_f > 0$ in the reactive process. This lower bound ε_0 characterizes the residual porosity of the porous matrix, potentially unresolved due to X-ray μ CT imaging limitations (as discussed in Perez et al. [2022], see also Figure 2.1). In practice, we assume throughout this work $\varepsilon_0 = 5\%$.

Such a two-scale description of the local heterogeneities in the carbonate rocks is appropriate to simulate the pore-scale physics and establish the governing flow and transport equations in each distinct region. Indeed, although the hydrodynamic of a viscous flow in a pure fluid region is commonly quantified through the Navier-Stokes equation, we can formulate the problem on the whole domain Ω based on the two-scale micro continuum description of the medium. We, therefore, consider the model on the superficial velocity u introduced and derived rigorously by Quintard and Whitaker in the late 80s [Quintard and Whitaker, 1988] and commonly used until nowadays [Lasseux et al., 1996, Molins et al., 2021, Soulaïne et al., 2017, Wood et al., 2007]:

$$\varepsilon^{-1} \frac{\partial \rho u}{\partial t} + \varepsilon^{-1} \operatorname{div}(\varepsilon^{-1} \rho u \otimes u) - \varepsilon^{-1} \operatorname{div}(2\mu D(u)) + \mu^* K_\varepsilon^{-1} u = f - \nabla p \quad (1)$$

along with the divergence-free condition $\operatorname{div} u := \nabla \cdot u = 0$. It is noticeable that this incompressibility condition should be changed when considering evolving porous structures to account for density variations, especially in the context of fast dissolution or nucleation [Soulaïne et al., 2018]. Indeed, this only depicts that crystal nucleation within a liquid volume, for instance, drastically increases the density and induces divergence effects in its neighborhood. Nevertheless, the divergence-free condition can be assumed to remain if the characteristic time of fluid/solid interface changes is way larger than the hydrodynamics time scale [Soulaïne et al., 2017], which is the case for our study. In equation (1), the notation $D(u)$ refers the shear-rate tensor $D(u) = (\nabla u + \nabla u^T)/2$, μ is the dynamic viscosity, p is the volumic pressure, f the volumic driving force and ρ the fluid density. The related viscosity μ^* usually coincides with the fluid viscosity μ but may be different in order to account for viscous deviations.

The quantities ρ , μ , μ^* and f are assumed to be constant. The quantities ε , ρ , μ and p are scalar fields; u , its rotational $\omega = \nabla \times u$, f and ∇p are vector fields, while $D(u)$ and K_ε are matrices.

The permeability K_ε refers to the micro-scale permeability and depends on the local micro-porosity field ε . In fact, the permeability of the micro-porous domain is modeled by the empirical Kozeny-Carman relationship [Carman, 1937, Carrier, 2003, Kozeny, 1927]:

$$K_\varepsilon^{-1} = \kappa_b^{-1} \frac{(1 - \varepsilon)^2}{\varepsilon^3} \quad (2)$$

where κ_b is the bulk permeability, which can be taken as a coarse estimation of the reference macro-scale permeability κ_0 . For instance, Soulaïne et al. [2017] estimated that four orders of magnitude below the permeability are required for κ_b to ensure adherent boundary conditions at the pore interface. In this article, we consider both K_ε , κ_b and κ_0 as scalars, meaning we restrict ourselves to the isotropic case although this formalism can be extended to anisotropic porous media. The superficial velocity formulation (1)

defines a two-scale model that can be solved on the overall domain Ω — using, for instance, penalization principles — and retrieves the usual Navier-Stokes equation in the pure fluid region Ω_F (since $K_\varepsilon^{-1} = 0$ for $\varepsilon = 1$). Depending on the flow regime hypothesis, one can also encounter simplified versions of equation (1) wherein some terms can be neglected. In the context of pore-scale simulations, in particular, the inertial effects become negligible compared to viscous forces due to low Reynolds number, denoted Re . The latter is a characteristic dimensionless number defined as:

$$\text{Re} = \bar{u}L/\mu, \quad (3)$$

where \bar{u} and L are respectively the characteristic velocity and length of the sample. The characteristic length L can be related to average pore throat diameters and, therefore, we typically fall within the assumption $\text{Re} \ll 1$ throughout this manuscript.

At low Reynolds numbers and for highly viscous Darcian flows, equation (1) hence reduces to the following DBS model:

$$-\text{div}(2\mu D(u)) + \mu \kappa_b^{-1} \frac{(1-\varepsilon)^2}{\varepsilon^2} u = \varepsilon(f - \nabla p), \quad \text{in } \Omega \quad (4)$$

where $\mu^* = \mu$ for sake of readability. In the present work, we consider this DBS equation (4), which is adequate in the flow regime hypothesis of low Reynolds number representative in pore-scale modeling. The DBS equation based on the superficial velocity is an efficient formalism to model the hydrodynamic in multi-scale porous media, and account for heterogeneous porosity levels.

2.2 Reactive flow model: general formulation

The DBS flow model (4) needs to be complemented by transport-reaction-diffusion equations of the different species involved in the geochemical processes. These equations are derived from the mass balance of the chemical species [Soulaine et al., 2017], and can be written under the form:

$$\frac{\partial \varepsilon \tilde{C}_k}{\partial t} + \text{div}(u \tilde{C}_k) - \text{div}(\alpha_k(\varepsilon) \varepsilon \nabla \tilde{C}_k) = \dot{m}_k / M_k, \quad (5)$$

where $\tilde{C}_k = \rho_f \bar{\omega}_{f,k} / M_k$ is a concentration per unit of fluid with M_k the molar mass and \dot{m}_k the rate of mass transfer for the k^{th} species. We follow here the notations introduced by Quintard and Whitaker in Quintard and Whitaker [1988], and afterward used by Soulaine et al. [2017], where ρ_f is the fluid density and $\bar{\omega}_{f,k}$ is the mass fraction of the k^{th} component averaged on the fluid phase. The term $\alpha_k(\varepsilon)$ is a space-variable effective diffusion coefficient and accounts for a reduced diffusion in the surrounding porous matrix due to the tortuosity effect, which is usually quantified using Archie's law [Archie, 1942]:

$$\alpha_k(\varepsilon) = D_{m,k} \varepsilon^\eta. \quad (6)$$

In this empirical relationship, η refers to the tortuosity index and $D_{m,k}$ to the molecular diffusion of the considered species [Wakao and Smith, 1962]. We finally introduce $C_k = \varepsilon \tilde{C}_k$, so that the equation (5) is written:

$$\frac{\partial C_k}{\partial t} + \text{div}(\varepsilon^{-1} u C_k) - \text{div}(D_{m,k} \varepsilon^{1+\eta} \nabla(\varepsilon^{-1} C_k)) = R_k(\mathbf{C}), \quad (7)$$

which is no more than a superficial modeling of the chemistry, that is to say C_k is the amount of moles per unit of volume while \tilde{C}_k is the amount of moles per unit of fluid volume. The notation $R_k(\mathbf{C})$ refers to a function (without differential operators) that models the rate contribution of the chemical reactions for the k^{th} component, where we denote by $\mathbf{C} \in \mathbb{R}^{N_s}$ the vector of the concentrations C_k of all the N_s chemical species. We distinguish N_m mobile species, and N_i immobile species such that $N_s = N_m + N_i$. The k^{th} rate contribution $R_k(\mathbf{C})$ is, practically, the balance of kinetics of all reactions involving the k^{th} species. The sign of individual reaction rates lies in the nature of the species k considered, either positive for a chemical product or negative for a reactant.

The model (7) is the formalism that we retain for the aqueous species in the liquid phase. In particular, this model highlights a superficial gradient operator denoted $\nabla^\varepsilon := \varepsilon \nabla \varepsilon^{-1}$ involved in the heterogeneous diffusion arising from the Archie's law. One should notice that the superficial gradient can become highly sensitive at the mineral boundary, mainly due to jumps in the porosity levels on either side of

the interface, and thus will require special considerations to adequately manage evolving medium under reactive processes.

Concerning the solid phase of concentration $C_{(s)}$ (e.g. the k^{th} component in vector \mathbf{C}), which we assume contains only one chemical species of molar volume v ($N_i = 1$), it is not subject to transport or diffusion, so that

$$\frac{\partial C_{(s)}}{\partial t} = R_k(\mathbf{C}). \quad (8)$$

This solid concentration is subsequently linked to the micro-porosity ε by the relation $C_{(s)} = (1 - \varepsilon)/v$, so one gets

$$\frac{\partial \varepsilon}{\partial t} = -vR_k(\mathbf{C}). \quad (9)$$

In the case of a typical reaction involving a unique solid $X_{(s)}$ of molar volume v , and two aqueous species Y and Z in the liquid phase, with their respective positive stoichiometric coefficients χ_i and following, for instance, the general chemical reaction:

we define the vector of concentrations $\mathbf{C} := (C_1, C_2, C_3)^T = ([X_{(s)}], [Y], [Z])^T \in \mathbb{R}^3$. Since there is only one reaction, one gets a unique kinetic balance written as $R_i(\mathbf{C}) = \pm\chi_i R(\mathbf{C})$, with $R(\mathbf{C})$ the kinetic rate. By default, we assume a positive sign for the solid species, so that one follows the convention $R(\mathbf{C}) < 0$ for the forward reaction corresponding to the solid $X_{(s)}$ dissolution, while $R(\mathbf{C}) > 0$ for the reverse reaction, e.g. precipitation and crystallization processes. The sign for the aqueous species subsequently depends on its interaction with the solid $X_{(s)}$: we get a positive sign for species Y , which is either consumed or produced in the same way as the solid, and a negative sign for species Z , which behaves oppositely. The reaction rate $R(\mathbf{C})$ can involve many concentrations, specific areas, chemical activities, equilibrium constants, etc. (see Sect. 4 thereafter for practical examples and further details).

Along with its boundary and initial conditions, the model for reaction (10) defines a set of partial differential equations modeling reactive flows at the pore scale:

$$\left\{ \begin{array}{ll} -\text{div}(2\mu D(u)) + \mu\kappa_b^{-1} \frac{(1 - \varepsilon)^2}{\varepsilon^2} u = \varepsilon(f - \nabla p), & \text{in } \Omega \times]0, T_f[\\ \frac{\partial C_1}{\partial t} = \chi_1 R(\mathbf{C}), & \text{in } \Omega \times]0, T_f[\\ \frac{\partial C_2}{\partial t} + \text{div}(\varepsilon^{-1} u C_2) - \text{div}(D_{m,2} \varepsilon^{1+\eta} \nabla(\varepsilon^{-1} C_2)) = \chi_2 R(\mathbf{C}), & \text{in } \Omega \times]0, T_f[\\ \frac{\partial C_3}{\partial t} + \text{div}(\varepsilon^{-1} u C_3) - \text{div}(D_{m,3} \varepsilon^{1+\eta} \nabla(\varepsilon^{-1} C_3)) = -\chi_3 R(\mathbf{C}), & \text{in } \Omega \times]0, T_f[\\ \varepsilon = 1 - v C_1, & \text{in } \Omega \times]0, T_f[\\ + \text{adequate boundary and initial conditions, along with } \text{div } u = 0 \end{array} \right. \quad (11)$$

which is strongly coupled, since u and \mathbf{C} depend on each other by means of the micro-porosity changes ε during the chemical process. It is also possible to straightforwardly substitute C_1 with ε in this system (11). Finally, one can notice that the reactive system (11) is valid on the whole domain Ω , whether the local state is fluid or not. In the pure fluid region, this system indeed converges toward a Stokes hydrodynamic model coupled with a standard transport-diffusion equation. Mathematical modeling of reactive hydrodynamics at the pore-scale can be expressed under the general form of the PDE system (11) coupling DBS with transport-diffusion-reaction equations. It is noticeable that the micro-porosity ε remains in the range $[\varepsilon_0, 1]$ which provides a well-posed Darcy-Brinkman-Stokes equation for the flow due to the expressions of Kozeny-Carman term and reaction formula.

This can be extended naturally to systems of reactions involving as many aqueous species in the liquid phase as needed, and involving potentially several solid — in this case the porosity is a linear combination of solid species. Most of the configurations studied in this article involve solid calcite — or calcium carbonate — whose concentration is denoted $C_{\text{CaCO}_3(s)}$ or $[\text{CaCO}_3]$, and whose molar volume is given by $v = 36.93 \times 10^{-3} \text{ L.mol}^{-1}$.

2.3 A velocity-vorticity formulation

Two distinct approaches are successfully used in the literature to solve numerically the DBS equation (4), namely the velocity-pressure or velocity-vorticity formulations [Hume and Poncet, 2021, Lamichhane, 2013, Molins et al., 2021, Philippe Angot, 2018]. The latter, inherited from vortex methods [Chatelain et al., 2008, Cottet et al., 2000, El Ossmani and Poncet, 2010, Hejlesen et al., 2015] introduces the vorticity field ω which is intrinsically related to the fluid velocity u through the relation:

$$\omega = \nabla \times u. \quad (12)$$

Several advantages arise when considering the velocity-vorticity formulation that regards the PDE unknowns (u, ω) and can be interpreted as describing the local spinning motions generated by the flow constraints. First of all, one can benefit from the velocity projection on divergence-free fields, and thereby analytically ensures the incompressibility condition $\text{div } u = 0$. Secondly, this formalism can be effectively coupled with splitting strategies that sequentially separate the resolution of distinct physical phenomena, such as convection and diffusion. Finally, this also makes it possible to eliminate the pressure unknown from the momentum equation by applying the curl operator on the DBS equation, which reads as follows:

$$-\mu \Delta \omega + \mu \kappa_b^{-1} \nabla \times \left(\frac{(1-\varepsilon)^2}{\varepsilon^2} u \right) = \nabla \varepsilon \times (f - \nabla p) \quad (13)$$

given the assumption $\nabla \times f = 0$. Developing the curl of the Kozeny-Carman term, one gets the following expression:

$$\nabla \times \left(\frac{(1-\varepsilon)^2}{\varepsilon^2} u \right) = \frac{(1-\varepsilon)^2}{\varepsilon^2} \omega + 2(\varepsilon - 1) \varepsilon^{-3} \nabla \varepsilon \times u \quad (14)$$

which, in practice, exhibits terms that become dominant compared to $\nabla \varepsilon \times (f - \nabla p)$. In this sense, the right-hand side in the vorticity formulation of the DBS equation (13) is usually neglected [Etancelin et al., 2020, Molins et al., 2021].

Equation (13) is then supplemented with an equation that retrieves the velocity field from the related vorticity, and results in the relation:

$$-\Delta u = \nabla \times \omega \quad (15)$$

based on the incompressibility condition. In practice, the previous Poisson equation (15) is not straightforwardly considered, and one relies on an alternative using a stream function $\psi : \Omega \subset \mathbb{R}^3 \rightarrow \mathbb{R}^3$ (a vector potential) solution of:

$$\begin{cases} -\Delta \psi = \omega, & \text{in } \Omega \\ + \text{boundary conditions such that } \text{div } \psi = 0 \text{ on } \partial\Omega. \end{cases} \quad (16)$$

The condition $\text{div } \psi = 0$ on $\partial\Omega$ is essential to ensure the overall incompressibility condition of the stream function on Ω and thereby identify $u = \nabla \times \psi$. This requires satisfying appropriate boundary conditions, namely the following combination of homogeneous Dirichlet/Neumann conditions for a computational cubic domain $\Omega =]x_{\min}, x_{\max}[\times]y_{\min}, y_{\max}[\times]z_{\min}, z_{\max}[$:

$$\begin{cases} x = x_{\min} \text{ OR } x = x_{\max} & : \psi_y = \psi_z = \frac{\partial \psi_x}{\partial n} = 0, \\ y = y_{\min} \text{ OR } y = y_{\max} & : \psi_x = \psi_z = \frac{\partial \psi_y}{\partial n} = 0, \\ z = z_{\min} \text{ OR } z = z_{\max} & : \psi_x = \psi_y = \frac{\partial \psi_z}{\partial n} = 0. \end{cases} \quad (17)$$

Such boundary conditions ensure $(\nabla \times \psi) \cdot n = 0$, $\text{div } \psi = 0$ and $\psi \times n = 0$ at the same time, where n is the normal field at the interface, and consequently lead to a zero average velocity field lifted by a prescribed flow rate \bar{u} oriented in the flow direction. Indeed, given $u = \bar{u} + \nabla \times \psi$, one gets:

$$\langle u \rangle_{\Omega} = \frac{1}{|\Omega|} \int_{\Omega} u \, dv = \bar{u} + \frac{1}{|\Omega|} \int_{\partial\Omega} \psi \times n \, ds = \bar{u}, \quad (18)$$

which replaces the setting of the driving force f by a prescribed flow rate, managed through the lifted vector \bar{u} .

Finally, using the stream function ψ analytically ensures the divergence-free condition on the velocity as $\text{div } u = \text{div}(\nabla \times \psi) = 0$. Overall, the velocity-vorticity formulation (13) of the DBS equation is subsequently coupled with the transport-reaction-diffusion PDE system developed in Sect. 2.2 to model reactive hydrodynamics at the pore-scale.

3 Method: hybrid grid-particle scheme (semi-Lagrangian)

The present work relies on a semi-Lagrangian numerical method, mixing Eulerian and Lagrangian formalism, to tackle dynamically evolving porous media due to reactive micrometric processes. Such a semi-Lagrangian approach has been successfully used for simulations of calcite dissolution at the pore scale in Etancelin et al. [2020] and extensively benchmarked against state-of-the-art numerical alternatives in Molins et al. [2021].

A Lagrangian formalism consists of describing the flow motion through the observation along time of a large number of fluid particles, with their attached intrinsic properties and spatially varying positions [Brenier and Cottet, 1995, Cottet and Mas-Gallic, 1990]. Each particle is then tracked throughout the evolving mechanism (transport, diffusion, ...) to measure variations in the main properties (velocity, concentration, ...). On the contrary, from the Eulerian point of view, the previous property changes are characterized on a predetermined spatial grid along the dynamical process. This section is dedicated to presenting this hybrid formalism, which is subsequently improved to account for the heterogeneous diffusion of the chemical reactants through the porous matrix.

The particle formulation is especially well-suited for transport-dominant phenomena as it avoids the explicit discretization of convective terms and alleviates the consideration of their related stability constraints — namely the CFL conditions which constrains the time step for a given spatial discretization. The lack of regularity in the particle distributions throughout the dynamic process is, however, a recurring problem of Lagrangian methods. Indeed, as the particle positions move according to the flow field gradients, accumulation or scarcity issues in the particle distribution commonly occur. This, thereby, requires periodic remeshing steps to avoid this problem and not to lose information: namely, one proceeds two successive interpolations from the disorganized particle structure to a regular grid and subsequently from the grid to the new particle distribution [Chatelain et al., 2008, Cottet and Koumoutsakos, 2000, Magni and Cottet, 2012].

This is particularly suitable for hybrid approaches, wherein dedicated solvers can be straightforwardly implemented in the Eulerian context before performing the remeshing step. This also allows a representation of the quantities of interest on the grid, which can be coupled with domain decomposition or mesh adaptation methods. Hybrid grid-particle formalism has, thereby, garnered considerable interest in addressing multiple complex phenomena in CFD and geosciences [Beaugendre et al., 2012, Chatelain et al., 2007, Chatelain and Poncet, 2013, Cottet, 1990]. Besides, incorporating high-order and compact support interpolation kernels makes it possible to reduce the overall computational complexity of the remeshing steps while keeping accurate predictions of the numerical solution. The choice of the interpolation kernels is, however, important to ensure a robust numerical method and guarantee properties such as mass conservation and sign-preservation of the interpolated quantities [Magni and Cottet, 2012]. Improvements of the interpolation kernels, especially for applications to dissolution processes at the pore scale, have been investigated by Etancelin et al. [2020]. Such improvements focused on sign preservation and accurate high-order interpolation through a correction step of the potential over-diffusive effects resulting from the remeshing step. This provides a well-established hybrid grid-particle framework that can robustly address pore-scale reactive flows.

In the present work, we aim to benefit from the main advantages of both approaches to model reactive hydrodynamics at the pore scale. We will, thereby, use a Lagrangian description for the chemical equations — including the heterogeneous diffusion operator and reactant transport — with an underlying regular grid for solving the DBS equation in its velocity-vorticity formulation. To do so, we describe in this sections this original numerical scheme, by detailing its components and how they are linked together:

- Subsection 3.1 describes the Lagrangian formalism of reaction-diffusion-transport equations and its resulting dynamical system (the particle formalism): it requires a velocity field to transport particles and the computation of a heterogeneous diffusion,
- Subsection 3.2 shows how this velocity, solution to the Darcy-Brinkman-Stokes, can be computed

by an operator-splitting strategy using the algorithm 1/ Brinkman penalization 2/ Diffusion using improved PSE 3/ Projection on divergence-free fields,

- Subsection 3.3 details the computational method for the required heterogeneous diffusion (that is to say space and time variable diffusion, including the space mapping based on the porosity field), and shows how its original formalism from Degond and Mas-Gallic [1989] is improved to become intrinsically second order.

3.1 Reactive dynamical system with particles

In this section, we present the Lagrangian formulation dedicated to the resolution of the reactive dynamical system (11) detailed in Sect. 2.2, and more specifically to the transport-reaction-diffusion equation (7).

We define a set of N_p fluid particles covering the computational domain Ω and characterize as triplets $(C_i, x_i, v_i)_{i=1..N_p}$ of species concentrations $C_{i,k}$ ($k = 1..N_m$ indexing the N_m chemical species), positions $x_i \in \Omega$ and volumes v_i , where i refers to the particle index. This mathematically introduces the particle description, denoted C^h , of the concentration fields as follows:

$$C^h(t) = \sum_{i=1}^{N_p} C_i(t) v_i(t) \delta_{x_i}(t) \quad (19)$$

which only depends on time t , and where δ refers to the Dirac function. The Lagrangian formulation of equation (7) can then be written using the particle description (19):

$$\begin{cases} \frac{dC_{i,k}}{dt} = R_k(\mathbf{C}_i(t)) + [\text{div}(\alpha_k(\varepsilon)\nabla^\varepsilon C_k)]_{x_i(t)} & \forall k = 1..N_m \\ \frac{dx_i}{dt} = [\varepsilon^{-1}u]_{x_i(t)} \\ \frac{dv_i}{dt} = 0 \end{cases} \quad (20)$$

given the incompressibility condition $\text{div } u = 0$ and the notations introduced in Sect. 2.2. This results in a dynamical system over the particles whose positions are controlled by the field $\varepsilon^{-1}u$, and volumes remain constant under divergence-free conditions. The main advantage of such a Lagrangian formulation (20) is that the transport term $\text{div}(\varepsilon^{-1}u C_k)$ vanishes along with its stability condition and, thereby, the method presents the ability to use arbitrary large time steps. This is, especially, of great interest when the CFL condition on the transport term induces a stronger constraint on the time step compared to the diffusion stability condition.

The velocity field u in (20) arises from the solution of the DBS equation which is solved on an underlying Cartesian grid and coupled with the Lagrangian formulation of the chemical PDE system. Regarding such a strong coupling between these equations, one needs to interpolate on the grid the particle description of the solid chemical species — namely $C_{\text{CaCO}_3(s)}^h$ — which is related to the micro-porosity field ε and consequently involved in the DBS model. Similarly, the velocity field subsequently needs to be interpolated on the particles to solve the Lagrangian set of chemical equations. This requires a convolution with high-order remeshing kernels with compact supports [Etancelin et al., 2020, Magni and Cottet, 2012]). The dynamical system (20) is finally integrated using standard numerical methods for ODE, such as explicit Runge-Kutta, while the diffusion term $\text{div}(\alpha_k(\varepsilon)\nabla^\varepsilon C_k)$ is approximated through the PSE method, detailed in Sect. 3.3.

In the present work, we incorporate in the semi-Lagrangian workflow the consideration of robustly estimating Archie’s law term through such a particle-based PSE method. In this sense, we make it possible to fully address the superficial gradient ∇^ε approximation with heterogeneous diffusion throughout the porous matrix.

3.2 Splitting operator strategy

The semi-Lagrangian formalism introduced in the previous Sect. 3.1 intrinsically relies on splitting strategies. Time-splitting methods, also known as fractional time-step algorithms, arise in many fields of computational science related to physics-based models and have been developed by Chorin [1973]

in the context of vortex methods for the Navier-Stokes equation. Such methods have been widely investigated afterward to separate the resolution of distinct physical phenomena and render more efficient algorithms [Beale and Majda, 1981, Cottet and Koumoutsakos, 2000, El Ossmani and Poncet, 2010, Faragó, 2008]. Indeed, one of the main advantages of splitting strategies is one can use different approaches for the distinct parts of the overall model, namely either a Lagrangian or Eulerian formulation. This also straightforwardly extends to the choice of the numerical solver available for each component, allowing the use of the most efficient, accurate, and robust schemes independently.

The first natural splitting arising in workflow, thereby, lies in the semi-Lagrangian formalism itself, wherein we do not consider solving the overall PDE system at once. We rather separate the transport-diffusion-reaction dynamics in its Lagrangian formulation from the pore-scale hydrodynamic resolved on the underlying Cartesian grid. The hydrodynamic part, composed of the DBS equation in the velocity-vorticity formulation, is also solved through a time-splitting method. In this sense, we approximate the solution of (13) by the limit in time of the evolution equation

$$\frac{\partial \omega}{\partial t} - \mu \Delta \omega + \mu \kappa_b^{-1} \nabla \times \left(\frac{(1 - \varepsilon)^2}{\varepsilon^2} u \right) = 0, \quad (21)$$

together with $\omega = \nabla \times u$, using a three-step operator splitting strategy coupled with a fixed-point algorithm. This means that considering a sequence (u_m, ω_m) of velocity-vorticity we aim to successively perform, over a time interval $[t_m, t_{m+1}]$ with $t_m = m\delta t$, Brinkman penalization, diffusion, and projection on divergence-free fields. The latter is achieved through the reconstruction of the velocity field u based on the stream function ψ (see Sect. 2.3). In practice, these three steps are specifically defined as:

- The Brinkman iteration given by the ordinary differential equation $\frac{\partial u}{\partial t} + \mu \lambda(\varepsilon)(u + \bar{u}) = 0$ with prescribed flow rate \bar{u} and $\lambda(\varepsilon) := \kappa_b^{-1}(1 - \varepsilon)^2 \varepsilon^{-2}$, whose exact solution after a δt is generated by

$$\Lambda(u) := e^{-\mu \lambda(\varepsilon) \delta t} (u + \bar{u}) - \bar{u}$$

- The vorticity diffusion iteration, $\frac{\partial \omega}{\partial t} - \mu \Delta \omega = 0$, solved using an implicit Euler scheme given by the operator

$$\mathcal{D}_\omega(u) := [I - \mu \delta t \Delta]^{-1} (\nabla \times u)$$

- The projection step $\Pi(\zeta) = \nabla \times ((-\Delta^{-1})\zeta)$ which takes as ζ the right-hand side of the Poisson equation $-\Delta \psi = \zeta$ satisfying the boundary conditions (17), and followed by $u = \nabla \times \psi$.

Overall, this leads to the full iteration of the Brinkman-Diffusion-Projection splitting $\Pi \circ \mathcal{D}_\omega \circ \Lambda$ over a time step $[t_m, t_{m+1}]$, which reads as follows:

$$u_{m+1} = \Pi \circ \mathcal{D}_\omega \circ \Lambda(u_m) \quad (22)$$

and whose consistency has been theoretically discussed in Hume and Poncet [2021]. One should notice that this projection step is not a projection by pressure gradient correction as in Chatelin and Poncet [2013], but an operator that takes the vorticity field ω and retrieves a divergence-free velocity field whose mean velocity is zero. The final velocity field is subsequently given by

$$u = \bar{u} + \lim_{m \rightarrow \infty} u_m \quad (23)$$

whose average is \bar{u} and satisfies the Kozeny-Carman relation inside the solid region.

From a numerical perspective, we consider the exact treatment of the Brinkman term, a fourth-order finite difference scheme for the discrete curl operator, and FFT solvers for the vorticity diffusion and stream function recovery. Using FFT avoids matrix assembly procedure and, therefore, consists of efficient solvers in terms of computational time and memory storage requirements. Besides, the complexity of such algorithm scales as $\mathcal{O}(N_p \log(N_p))$, where N_p is recalled to refer to the number of particles. Finally, a stopping criterion on this fixed point algorithm is also defined based on the relative residual norm on the velocity, which manages the convergence of the pore-scale hydrodynamics toward a stationary state.

The updated velocity u_{m+1} is subsequently interpolated from the grid to the particles and used for solving the Lagrangian reactive system, which is split into convective/remeshing and diffusive/reactive

steps. Regarding the convection, the particle trajectories are pushed to the next step through a directional advection, given the field $\varepsilon^{-1}u$ according to the Lagrangian formulation (20), and are then remeshed to avoid stagnation issues. The purpose of such a directional splitting is to reduce the dimensionality of the overall advection problem by considering several one-dimensional equations, and is developed in Cottet et al. [2014], Magni and Cottet [2012]. The particle remeshing is also addressed using directional treatment of the multidimensional convolution. This means that within a time step $[t_m, t_{m+1}]$, the joint step of advection/remeshing of the particles is successively performed by alternating the spatial directions [Etancelin, 2014, Keck, 2019]. This presents the advantage of significantly improving the computational efficiency of the method and allows the use of high-order remeshing kernels with large stencils while maintaining a minimal cost compared to multidimensional cases. This is also well-suited to parallel implementation on GPU architecture. The dimensional splitting is addressed, in practice, by a second-order Strang formula [Strang, 1968] and coupled with a second-order Runge-Kutta for time integration. The diffusion/reaction step is finally solved by means of a second-order explicit Runge-Kutta scheme along with PSE approximation of the heterogeneous diffusion operator. Once the Lagrangian formulation of the chemistry has been fully updated and remeshed on the underlying grid, one starts pushing the DBS hydrodynamics to the next sequential step of these temporal iterations.

Such an operator splitting strategy, in the context of a semi-Lagrangian approach, has been applied to the modeling of dissolution processes on a 2D synthetic calcite core and validated against state-of-the-art alternatives and experiments in Molins et al. [2021]. This has also been used in Etancelin et al. [2020] on real porous media structures at the pore scale to investigate the dissolution of 3D carbonate rocks arising from μ CT scans. Nonetheless, these previous works assumed that the superficial gradient ∇^ε involved in the heterogeneous diffusion could be approximated by the gradient operator, and subsequently addressed this Archie's law term with standard finite differences schemes. In Sect. 3.3, we intend to alleviate this assumption and, therefore, improve the semi-Lagrangian method by incorporating in the workflow a PSE approximation of the heterogeneous diffusion.

3.3 Particle-Strength-Exchange method and Archie's law approximation

The PSE method consists in the approximation of a diffusion operator $\text{div}(\mathbf{L}\nabla f)(x)$ with $x \in \Omega \subset \mathbb{R}^n$ and \mathbf{L} a positive symmetric matrix, accounting for heterogeneous diffusion for instance. The main idea is then to approximate the diffusion by an integral operator, more suitable for particle methods:

$$Q^\xi \cdot f(x) = \int_{\Omega} \sigma^\xi(x, y) (f(y) - f(x)) dy \quad (24)$$

where the kernel σ^ξ is supposed to be symmetric and satisfies some moment conditions, detailed thereafter. In the Lagrangian formulation, a particle approximation of the function f , denoted f^h , is also introduced based on the particle triplet (f_i, x_i, v_i) , such that:

$$f^h = \sum_{i=1}^{N_p} f_i v_i \delta_{x_i} \quad \text{where} \quad f_i = f(x_i) \quad (25)$$

where x_i and v_i are respectively the particle positions and volumes, while δ_{x_i} refers to the Dirac measure at position x_i . With such a N_p -particle representation of the function f , a discrete version of the operator Q^ξ is obtained by using the particles as quadrature points where h refers to the characteristic distance between particles. This results in the following quadrature expression, called Particle-Strength-Exchanges:

$$Q^\xi \cdot f^h(x_k) = \sum_{x_l \in \mathcal{S}(x_k)} \sigma^\xi(x_k, x_l) (f_l - f_k) v_l. \quad (26)$$

where $\mathcal{S}(x_k) := \text{Supp}(\sigma^\xi(x_k, \cdot))$ refers to the set of points in the support of the kernel function σ^ξ .

In appendix A, we detail that we can explicitly compute two constants γ_1 and γ_2 based on a given scale ξ and a given function Θ (named *stencil generator*) such as

$$\sigma^\xi(x, y) = \frac{1}{\xi^{n+4}} \Theta\left(\frac{y-x}{\xi}\right) \frac{\mathbf{m}(x) + \mathbf{m}(y)}{2} : (x-y)^{\otimes 2}. \quad (27)$$

Figure 2: **Mesh convergence analysis of the OpenCL implementation of the PSE method:** Error norm $\|E_{TR}\|_{RMS}$ with respect to the mesh step size h for heterogeneous diffusion operator with a spatially varying diffusion matrix \mathbf{L} . The convergence analysis is performed for mesh resolutions going from 32^3 to 256^3 .

with

$$\mathbf{m} = c_0 \mathbf{L} - c_1 \text{Tr}(\mathbf{L})\mathbf{Id}_3 + \mathbf{H} \quad (28)$$

where

$$c_0 = \frac{2(\gamma_1 + 2\gamma_2)}{\gamma_1^2 + \gamma_1\gamma_2 - 2\gamma_2^2}, \quad c_1 = \frac{2\gamma_2}{\gamma_1^2 + \gamma_1\gamma_2 - 2\gamma_2^2}, \quad \text{and } H_{ij} = \left(\frac{\gamma_1^2 - \gamma_1\gamma_2 - 6\gamma_2^2}{\gamma_2(\gamma_1^2 + \gamma_1\gamma_2 + 2\gamma_2^2)} \right) (1 - \delta_{ij})L_{ij} \quad (29)$$

where δ_{ij} is the Kronecker symbol. As the convergence of the original PSE method introduced in Degond and Mas-Gallic [1989] depends on the scale ξ as $\mathcal{O}[(h/\xi)^2]$ – which becomes $\mathcal{O}(1)$ when ξ is adapted linearly to h –, the present discrete corrected version developed in Poncet [2006] and Schrader et al. [2012] is intrinsically second order convergence $\mathcal{O}(h^2)$.

This computational method of diffusion is used to compute the Archie's law, involving a tortuosity index η in the heterogeneous diffusion operator

$$\mathcal{D}(\varepsilon, C) := \text{div}(\varepsilon^{1+\eta}\nabla(\varepsilon^{-1}C)) \quad (30)$$

involved in the PDE system (11). In this case, one gets a particular expression for the diffusion matrix $\mathbf{L} = \varepsilon^{1+\eta} \mathbf{I}_3$ with \mathbf{I}_3 the identity matrix in \mathbb{R}^3 , which finally leads to the discrete renormalization of the PSE scheme approximating the Archie's law diffusion operator (30) reads as follows:

$$Q^\xi \cdot f^h(x_k) = \frac{1}{\xi^7} \sum_{l \sim k} (f_l - f_k) \Theta \left(\frac{x_l - x_k}{\xi} \right) \frac{(c_0 - 3c_1)}{2} (\varepsilon^{1+\eta}(x_k) + \varepsilon^{1+\eta}(x_l)) |x_l - x_k|^2 v_l \quad (31)$$

where $|\cdot|$ is the Euclidean norm in \mathbb{R}^3 and $f_\bullet := \varepsilon^{-1}(x_\bullet)C(x_\bullet)$. The overall formula (31) accounts for the heterogeneous diffusion and ensures the accurate management of the chemical reactant penetration, given by its concentration field C , within the porous matrix. Indeed, one of the main advantages of the PSE scheme is that it includes all the lattice neighborhoods in the computation of the heterogenous diffusion, unlike crossed FD. Finally, this guarantees the strict conservation of the reactant exchanges between the fluid portion and the porous matrix.

In order to validate the implementation, we consider the approximation of a diffusion operator $\text{div}(\mathbf{L}\nabla f)$ on a domain $\Omega \subset \mathbb{R}^3$ with a spatially varying diffusion matrix

$$\mathbf{L}(x, y, z) = (1 + \cos^2(x))\mathbf{I}_3$$

and a function f given by $f(x, y, z) = \sin(x) \sin(y) \sin(z)$. This ensures three-periodic boundary conditions on the domain $\Omega =] - \pi; \pi[{}^3$. Direct computation of the exact solution provides

$$\operatorname{div}(\mathbf{L}\nabla f)(x, y, z) = -3f(x, y, z) - 5 \cos^2(x)f(x, y, z)$$

and a mesh convergence analysis is performed, studying the error norm against the mesh step h , for mesh resolutions going from 32^3 to 256^3 . Introducing the discrete error vector Err , defined for each point $X_k \in \mathbb{R}^3$ of the grid by

$$\text{Err}_k := \operatorname{div}(\mathbf{L}\nabla f)(X_k) - Q^\xi \cdot f^h(X_k),$$

we compute for each mesh resolution the RMS norm $\|\text{Err}\|_{\text{RMS}}$ inherited from the functional \mathbb{L}^2 -norm on Ω . The value of $Q^\xi \cdot f^h$ is defined on every particles by formulae (26) or (63), despite the fact that f^h is a measure function, that is to say a combination of Dirac functions. We retrieve a second-order convergence curve presented in Figure 2.

4 Application to precipitation and crystallization

CO_2 mineral storage in natural underground reservoirs, such as saline aquifers, involves competing geochemical phenomena occurring at a large variety of scales. Among them, mineral dissolution and precipitation play crucial roles. On one side, studying the dissolution of native carbonate species, already present in the aquifers, provides insight into potential leakage issues and queries the reservoir safety. On the other side, CO_2 trapping under the form of carbonate precipitates and crystals informs on the storage capacities of the reservoir. These geochemical processes also induce changes in the macro-scale properties of the subsurface material, including permeability and porosity evolutions, that need to be investigated to ensure sustainable management of the reservoir structures.

In this section, we develop mathematical models for calcite precipitation and crystallization at the pore scale, with special considerations on the reaction rate expressions arising in the PDE system (11). Numerical simulations are performed within the HySoP platform [Etancelin et al., 2022] along with PSE treatment of the heterogeneous diffusion on accelerated GPU devices and address porous sample arising from X-ray μCT observations. This enables the investigations of macro-scale property changes along the CO_2 mineral trapping on real 3D rock geometries, which is an important component in the overall study of CO_2 storage.

4.1 The Transition State Theory: from Dissolution to Precipitation Modeling

Dissolution of the injected CO_2 in the aqueous phase of deep underground reservoirs will affect the pH of the formation water through the following series of chemical reactions:

Indeed, once the CO_2 has dissolved into water and established a first equilibrium under the form of the weak acid H_2CO_3 , the H_2CO_3 species dissociates successively to bicarbonate HCO_3^- and carbonate CO_3^{2-} ions as the pH increases. These chemical reactions are pH-dependent, and the distribution evolutions of all these carbonate species are displayed in Figure 3 against the pH of the solution. In alkaline media, the chemical reactions (32c) and (32d) can, therefore, join together to read as follows:

such that carbonate ions are the main carbonate species present in the solution. Such transformations in the ionic species composition of the aquifer water will considerably impact the original mineral structure through chemical rock-water interactions such as carbonate dissolution and precipitation.

Figure 3: **Distribution diagram of aqueous carbonate species against pH solution from Bohn et al. [1980] and Turk et al. [2015].** Species distributions are represented as a fraction of total dissolved carbonate. The grey dotted lines highlight the transition pH of the chemical equilibria from equation (32).

Historically, the dissolution and precipitation kinetics of calcite in the context of CO_2 injection have been studied since the 1970s, both from the experimental and theoretical sides. Plummer et al. [1978] investigated the influence of several parameters on the forward reaction rates of calcite dissolution under far-from-equilibrium conditions. Among these parameters, one finds the partial pressure of CO_2 denoted P_{CO_2} , the hydrogen ions activities denoted a_{H^+} — directly related to the pH — and the temperature. Their experimental work was subsequently extended by Chou et al. [1989] using a fluidized bed reactor to compare the dissolution kinetics mechanisms between various carbonate minerals — involving *inter alia* calcite, aragonite, and dolomite — at 25°C . One should notice that these experiments were conducted under laboratory conditions in terms of pressures and temperatures, in opposition to the current abilities of *in situ* experiments to manage realistic reservoir conditions [Andrew et al., 2013, Wigand et al., 2008]. Nonetheless, these experimental studies have highlighted three kinetic mechanisms occurring simultaneously in the process of calcite dissolution due to CO_2 injection. Such mechanisms are given by the following chemical reactions:

where the notations K_i , $i = 1...3$ refer to forward reaction rate constants, depending on the temperature [Busenberg and Plummer, 1986, Plummer and Busenberg, 1982, Plummer et al., 1978], and K_{-3} is the backward reaction rate corresponding to the reverse calcite precipitation process in equation (34c). They experimentally identified both the forward and backward reaction rates and established the validity of kinetic models for carbonate dissolution and precipitation in comparison to thermodynamics theoretical considerations.

Meanwhile, mineral reaction rates were, indeed, theoretically investigated by Lasaga [1981] using the Transition State Theory (TST), originally formulated by Eyring [1935]. Since then, this formalism has successfully been extended [Aagaard and Helgeson, 1982, Lasaga, 1984, Steefel and Lasaga, 1994] and widely accepted in current kinetic geochemical models [Etancelin et al., 2020, Molins et al., 2012, Steefel et al., 2015]. In this context, the reaction rates are commonly expressed as the product of far-from-equilibrium terms, involving the activities of the chemical species in solution, with an affinity term written as a function of the Gibbs free energy change ΔG for close to the equilibrium conditions. Considering the chemical model of calcite dissolution (34) suggested by Plummer et al. [1978] and Chou et al. [1989]

and the vector of concentrations \mathbf{C} , the reaction rate arising from TST writes:

$$R(\mathbf{C}) = A_s(K_1 a_{\text{H}^+} + K_2 a_{\text{H}_2\text{CO}_3} + K_3) \left(\frac{a_{\text{Ca}^{2+}} a_{\text{CO}_3^{2-}}}{K_{\text{eq}}} - 1 \right) \quad (35)$$

where K_{eq} is the equilibrium constant of the reaction, also called the solubility product, A_s is the reactive surface area of the mineral — in m^{-1} . The notations $a_{\bullet} = \gamma_{\bullet} C_{\bullet}$ refer to the dimensionless species activities with γ_{\bullet} and C_{\bullet} , respectively, their activity coefficients and molar concentrations — whose unit is $\text{mol} \cdot \text{m}^{-3}$. It follows that the micro-porosity changes reads as:

$$\frac{\partial \varepsilon}{\partial t} = -\nu R(\mathbf{C}), \quad (36)$$

given equation (8) from Sect. 2.2 and the relation $C_{\text{CaCO}_3(\text{s})} = (1-\varepsilon)/\nu$. Denoting by $Q = a_{\text{Ca}^{2+}} a_{\text{CO}_3^{2-}}$ the ion activity product, one obtains the following relation between Q and the Gibbs energy change [Aagaard and Helgeson, 1982, Lasaga, 1984]:

$$\Delta G = RT \ln \left(\frac{Q}{K_{\text{eq}}} \right) \quad (37)$$

with T the temperature in Kelvin K, and R the universal gas constant in $\text{J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1}$. The sign of the reaction term $R(\mathbf{C})$ in (35) is driven by the sign of $\ln(Q/K_{\text{eq}})$ that is negative for dissolution and positive for precipitation, which is consistent with the convention from Sect. 2.2.

From now on, we focus on the concern of calcite precipitation and crystallization resulting from CO_2 injection based on the series of homogeneous reactions (32) along with the mineral-solute interaction given by equation (34c). In practice, we enforce a pH greater than 10.33 such that the carbonate ions CO_3^{2-} are the predominant species (see Figure 3). This enables the restriction of the overall set of chemical reactions (32) to merely consider the equation (34c) in the sense that we assume the intermediate reactions as instantaneous and conservative — without loss of quantity of matter. Such an assumption is acceptable, in practice, since fluid-mineral reaction rates are usually slower than intra-aqueous reaction rates. Therefore, the initial concentration of carbonate ions, denoted $C_{\text{CO}_3^{2-}}(x, t=0)$ for $(x, t) \in \Omega \times [0, T_f]$ following the notations introduced in Sect. 2, is directly related to the partial pressure of injected CO_2 by means of the Henry law. The latter states, at a constant temperature, the relation between the amount of dissolved gas in a solute and its partial pressure based on Henry's law constant denoted K_H , which depends on the gas and temperature, such that for the CO_2 at 25°C one gets:

$$C_{\text{CO}_2(\text{aq})} = \frac{P_{\text{CO}_2}}{K_H} \simeq C_{\text{CO}_3^{2-}}(x, t=0) \quad (38)$$

where $K_H = 29.41 \text{ L} \cdot \text{atm} \cdot \text{mol}^{-1}$. Considering such an alkaline medium — with $\text{pH} > 10.33$ — also results in the treatment of the chemical reaction (34c) as completely irreversible which corresponds to far-from-equilibrium conditions modelling the calcite precipitation chemical reaction:

where the subscript p here refers to the precipitate form of the calcite product. In this case, the rate constants $K_1 = K_2 = 0$ in (35) and the affinity term dependent on the Gibbs energy satisfies the condition $\ln(Q/K_{\text{eq}}) \gg 0$ — corresponding to a supersaturated solution — so that we obtain an overall reaction rate for the calcite precipitation which reads as:

$$R_{\text{prec}}(\mathbf{C}) = K_{-3} A_s a_{\text{Ca}^{2+}} a_{\text{CO}_3^{2-}} \quad (40)$$

where $K_{-3} = K_3/K_{\text{eq}}$, which theoretically results from the TST law in equation (35) and has been experimentally validated, *inter alia*, by Chou et al. [1989].

Therefore, in the following, we rely on the kinetic formulation of the mineral precipitation given by equation (40), considering the rate laws determined by laboratory experiments [Chou et al., 1989] and normalized by the reactive surface area of the mineral A_s [Plummer et al., 1978]. As the geometry evolves, the micro-porosity ε and the reactive specific area A_s , associated with the porous structure, also change. These evolutions are taken into account in the reaction rates management and the hydrodynamic modeling of the reactive process (see the overall PDE system (11) in Sect. 2.2). The calcite precipitation reaction is subsequently supplemented with a crystallization model which is elaborated in the next Sect. 4.2.

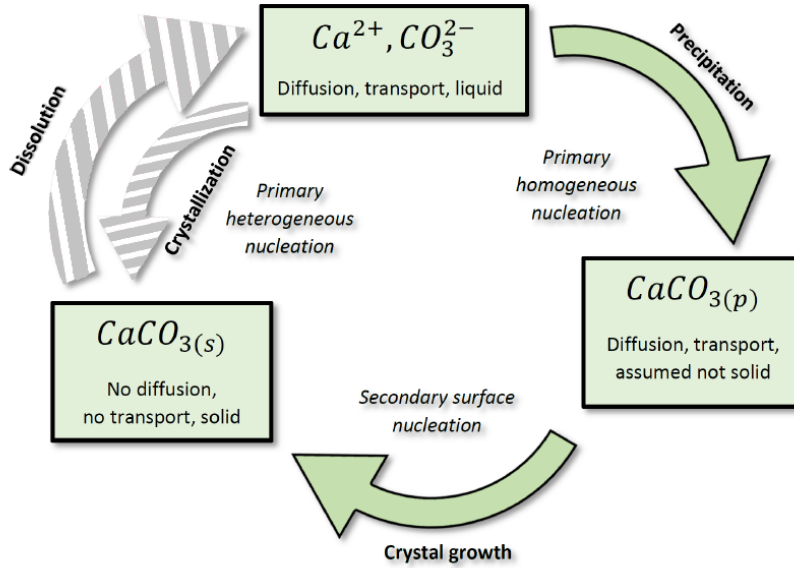

Figure 4: **Overall reactive diagram of the reversible chemical equation (34c) and two-step calcite crystallization process.** This diagram represents the chemical interactions between the different ionic species (Ca^{2+} and CO_3^{2-}), the calcium carbonate precipitate $\text{CaCO}_3(p)$ and mineral crystal $\text{CaCO}_3(s)$ and accounts for both dissolution, precipitation crystal growth processes. In the numerical applications (see Sect. 5), we mainly address the green part of this diagram that highlights the two-step modeling of the calcite crystallization process.

4.2 Crystal growth modeling: a two-step process

Crystal growth kinetics involves complex mechanisms occurring simultaneously and depending, *inter alia*, on the concentration of the constituent ions in the solute, but also on attachment frequencies of the ions or precipitates to lattice growth sites [Nielsen and Toft, 1984, Wolthers et al., 2012]. Indeed, the growth rate is first controlled by advection and diffusion of the Ca^{2+} and CO_3^{2-} ions to the crystal surface coupled with a surface adsorption process that largely hinges on the crystal lattice shape. For instance, the growth of crystal aggregates is more likely to occur near kinks or corners [Nielsen and Toft, 1984, Yoreo and Vekilov, 2003]. Mineral heterogeneity of the pore interface is also an important factor that influences the crystal growth location and morphology, providing preferential sites [Lioliou et al., 2007]. This first process is commonly called primary heterogeneous nucleation, for which the crystallization reaction is catalyzed by the solid surface of the porous medium. In the absence of solid interface, crystal clusters can also form spontaneously in the solute, which is known as primary homogeneous nucleation and is closely related to the supersaturation state of the solution in order to initiate the nucleation — namely satisfying the condition $\ln(Q/K_{\text{eq}}) \gg 0$. Finally, secondary nucleation occurs in the presence of existing crystals and is more likely to generate large crystal aggregates at the mineral surface. Overall, calcite crystallization results from a combination of all these previous phenomena.

In this section, we consider a two-step crystallization process wherein calcite precipitates, also referred to as nuclei and denoted $\text{CaCO}_3(p)$, are first generated within the solute during the so-called nucleation stage according to the chemical equation (39). These precipitates are subsequently aggregated at the mineral surface through adsorption phenomena during the crystal growth step. This sequential crystallization process is described in Figure 4, where the notation $\text{CaCO}_3(s)$ stands for the calcite crystal. In the applications developed in Sect. 5, we consider that the solid matrix of the 3D porous sample has a similar carbonate nature to the calcite crystal generated, though rock mineral heterogeneities can be integrated into the numerical framework as prospects. From now on, we refer to precipitation as the primary homogeneous nucleation and we investigate the surface attachment of the calcite precipitate, $\text{CaCO}_3(p)$, based on an autocatalytic process to model calcite crystal growth, referred to as the secondary surface nucleation in Figure 4. In the reaction scheme from Figure 4, we account for the precipitate diffusion and advection until the solid boundary where it leads to crystal growth through adsorption

Porosity and probability of crystallization

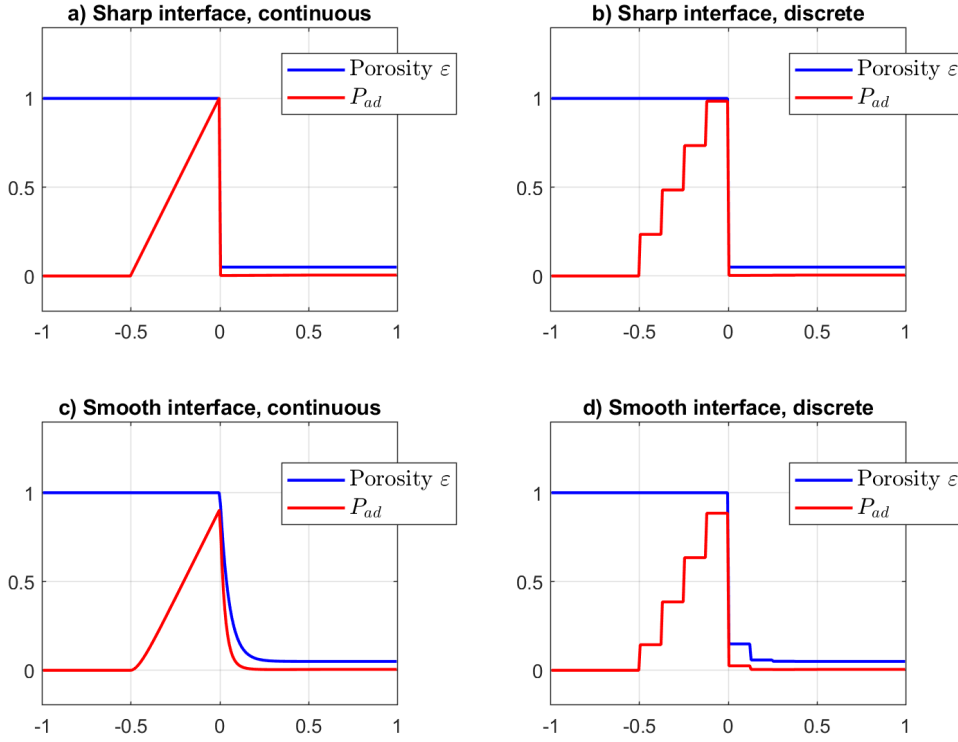

Figure 5: **Probability of attachment rate $P_{ad} = C(1 - \varepsilon W_h)\varepsilon^m$ for crystal growth modeling in 1D different contexts.** Synthetic continuous and discrete (at the voxel size) representation of a 1D porous medium, with a residual micro-porosity in the porous matrix $\varepsilon_0 = 5\%$ for $x > 0$, for sharp and smooth interface. The probability values are computed based on equation (42).

phenomena. Besides, we neglect the direct crystallization process induced by the solute diffusion to the solid matrix and the so-called primary heterogeneous nucleation.

In the literature, two distinct approaches are mainly developed when considering precipitation and crystal growth modeling altogether. The former can be regarded as "deterministic models" relying on the TST modeling developed in Sect. 4.1. Noiriel et al., for instance, investigated the effects of pore-scale precipitation on permeability through a combination of X-ray μ CT experiments and "deterministic" modeling [Noiriel et al., 2021, 2016]. They also derived crystal growth rates directly from the μ CT through an imaging comparison between the beginning and end of the precipitation experiment. In this case, only two μ CT scans were performed, and therefore, the process should be understood as distinct from 4D μ CT experiments incorporating time dynamics. Such experimental identification of crystal growth rates can, however, be prone to intrinsic imaging limitations [Perez et al., 2022] and result in wide discrepancies in the reaction rate estimations. Nonetheless, their results showed satisfactory agreement between the experiments and numerical experiments for precipitation processes into fractures [Noiriel et al., 2021]. Alternative modeling approaches lie in the probabilistic nature of nucleation or crystal growth and are referred to as "probabilistic models" [Fazeli et al., 2020, Masoudi et al., 2021, Nooraiepour et al., 2021]. Wolthers et al., for instance, developed a probabilistic approach for calcite crystal growth based on the nature of the kink sites depending on their ionic affinities and attachment frequencies of the constituent ions [Wolthers et al., 2012]. Estimations of such adsorption frequency ranges can also be found in the literature [Christoffersen and Christoffersen, 1990, Nielsen, 1984]. Finally, while it is commonly established experimentally that crystal growth occurs preferentially at kinks and corners of the surface lattice, few models incorporate the geometrical dependency of the crystal aggregation in the reaction rates [von Wolff et al., 2021].

In the present article, we propose a new approach coupling a deterministic model for the precipitation, which directly depends on the supersaturation ratio following the TST formalism, and a probabilistic formulation of the crystal growth process. The latter accounts for the adsorption frequencies of the precipitate to the growth sites with a coefficient, quantifying the physical probability of attachment rate, denoted P_{ad} , which relies on a locally averaged mineral volume fraction. In this formalism, one obtains

	0,316	0,031	0,037	0,031	0,633	
	0,105	0,316	0,021	0,316	0,422	
	0	0,105	0,105	0,105	0,316	
	0	0	0	0,105	0,422	
	0	0	0,105	0,316	0,031	
Ω_F	$\varepsilon = 1$					ε_0 Ω_S

Figure 6: **Impact of the probability of attachment rate P_{ad} for crystal growth modeling.** Synthetic representation of a discrete (at the voxel size) porous medium with smooth interface (to be compared with Figure 5), with a rock matrix micro-porosity $\varepsilon_0 = 5\%$. The probability values are computed based on equation (42) and include the one-neighborhood (e.g. the red square).

the crystal growth reaction rate, which is expressed as:

$$R_{\text{crys}}(\mathbf{C}) = K_c P_{ad} C_{\text{CaCO}_3(\text{p})} \quad (41)$$

with K_c the adsorption frequency (expressed in s^{-1}). This makes it possible to include the geometrical dependency in the crystal growth reaction rate through the relation

$$P_{ad} = C(1 - \varepsilon * W_h)^m, \quad (42)$$

where $W_h(x) = h^{-d} W^{\otimes d}(x/h)$ is the rescaled kernel based on a local averaging kernel W , so that $(1 - \varepsilon * W_h)\varepsilon$ is enhanced in the layer close to the fluid/solid interface and depending on the solid proportion in the neighborhood (see Figures 5 and 6).

In the case of K_c being a production of crystal volume per unit of volume and time, then the normalization coefficient C satisfies $1/C = \langle (1 - \varepsilon * W_h)\varepsilon^m \rangle_{\Omega}$ so that P_{ad} is a probability distribution, and the index m describes the ability to decrease strongly the reaction rate inside the solid in the spirit of the Archie's law (in practice $m = 2$ is suitable). In the case of K_c being the local production of crystal at the fluid/solid interface, which is the case considered in the present study, then C satisfies

$$1/C = (1 - \varepsilon_0)/2 \quad (43)$$

so that P_{ad} is a point-wise probability of capture by the crystal. This is based on the jump between ε_0 and 1 through a sharp interface, with a factor 1/2 (half the integral of the kernel W , which can be slightly adjusted for concave interface as shown in Poncet [2007]). This convolution-based formulation is appropriate for a crystallization process and is inspired by the gradient-based technique from Luo et al. [2012] and Soulaire et al. [2017] that locates the first layer on the solid side and is suitable for dissolution processes. In practice, the local averaging kernel W can be as simple as $W = \mathbb{1}_{[-1,1]}/2$ or Gaussian in a continuous description, or approximated by its discrete formulation $W = (\delta_{-1} + \delta_0 + \delta_1)/3$, or even with weighting in order to modulate the length of capture with respect to the grid size.

The Figure 5 shows different probability distributions in 1D with a residual micro-porosity in at $\varepsilon_0 = 5\%$ (in the area $x > 0$), for sharp and smooth fluid/solid interface, and for the continuous and discrete formulations described above. The resulting probability values in 2D are represented in Figure 6 for a synthetic example with smooth interface and discrete formulation (to be compared to the 1D version of Figure 5.d), where the residual micro-porosity in Ω_S is estimated to $\varepsilon_0 = 5\%$ as well.

4.3 Final system of PDEs

Finally, we define the vector of concentrations

$$\mathbf{C} = (C_{\text{CaCO}_3(\text{s})}, C_{\text{CaCO}_3(\text{p})}, C_{\text{CO}_3^{2-}}, C_{\text{Ca}^{2+}})$$

and consider the reactions rates $R_{\text{prec}}(\mathbf{C})$ and $R_{\text{crys}}(\mathbf{C})$ respectively given by formula (40) and (41). Overall, the calcite crystallization modeled as a two-step process of precipitation and crystal growth, according to the reaction scheme from Figure 4, writes:

$$\left\{ \begin{array}{ll} -\text{div}(2\mu D(u)) + \mu\kappa_b^{-1} \frac{(1-\varepsilon)^2}{\varepsilon^2} u = \varepsilon(f - \nabla p), & \text{in } \Omega \times]0, T_f[\\ \frac{\partial C_{\text{CO}_3^{2-}}}{\partial t} + \text{div}(F(C_{\text{CO}_3^{2-}})) = -R_{\text{prec}}(\mathbf{C}), & \text{in } \Omega \times]0, T_f[\\ \frac{\partial C_{\text{Ca}^{2+}}}{\partial t} + \text{div}(F(C_{\text{Ca}^{2+}})) = -R_{\text{prec}}(\mathbf{C}), & \text{in } \Omega \times]0, T_f[\\ \frac{\partial C_{\text{CaCO}_3(\text{p})}}{\partial t} + \text{div}(F(C_{\text{CaCO}_3(\text{p})})) = R_{\text{prec}}(\mathbf{C}) - R_{\text{crys}}(\mathbf{C}), & \text{in } \Omega \times]0, T_f[\\ \frac{\partial C_{\text{CaCO}_3(\text{s})}}{\partial t} = R_{\text{crys}}(\mathbf{C}), & \text{in } \Omega \times]0, T_f[\\ \varepsilon = 1 - v C_{\text{CaCO}_3(\text{s})}, & \text{in } \Omega \times]0, T_f[\\ + \text{adequate boundary and initial conditions, along with } \text{div } u = 0 \end{array} \right. \quad (44)$$

where $F(C_\bullet) = \varepsilon^{-1} u C_\bullet - \alpha_\bullet(\varepsilon) \nabla^\varepsilon C_\bullet$ is the advective and diffusive flux given the notations from Sect. 2.2. The reactive hydrodynamic model (44) ensures that part of the precipitate, generated in the solute through homogeneous nucleation, is transferred to the mineral surface by adsorption. One should notice that in this model the precipitate $C_{\text{CaCO}_3(\text{p})}$ is both advected and diffused. Such diffusion enables to account for the interaction of the precipitates with potential unresolved roughness or features in the porous matrix Ω_S .

In the next section 5, we apply this two-step crystallization model to DNS of CO_2 mineral trapping into a real rock geometry at the pore-scale. We investigate the morphological changes in the porous matrix structure, the clogging of pore throats, and the evolution of the macro-scale properties, namely the porosity and permeability.

4.4 High-Performance-Computing aspects

One of the major constraints when dealing with a semi-Lagrangian formulation lies in the ability of the computational framework to handle an overall hybrid approach in terms of grid-particle formalism, numerical methods, multi-grid resolutions, and hardware devices. Indeed, Cottet et al. [2009] suggested a semi-Lagrangian method coupled with hybrid grid resolutions to address a multi-scale transport problem of a passive scalar. The scalar is discretized on a sub-grid compared to the velocity and vorticity fields and enables the accurate prediction of the small-scale effects. Finally, considering hybrid computing methodologies makes it possible to distribute the distinct parts of an overall problem to different types of hardware architectures. This formalism, therefore, exploits the advantages of each method individually according to the characteristics of the problem.

Nonetheless, implementing such a hybrid approach requires a highly flexible computational framework that gathers a wide range of numerical methods and, therefore, benefits from their intrinsic strengths. One also needs libraries incorporating effective parallel computing tools and able to address, *inter alia*, hybrid CPU-GPU programming. In this section, we present the HPC framework considered to address this DNS of pore-scale reactive flows for CO_2 mineral trapping into carbonate rocks.

The library HySoP is a high-performance computing platform [Etancelin et al., 2022], jointly developed at LMAP (Laboratoire de Mathématiques et de leurs Applications, UMR 5142 CNRS, UPPA), LJK (Laboratoire Jean Kuntzmann, Alpes-Grenoble University, UMR 5224 CNRS), and M2N (Laboratoire Modélisation mathématique et numérique, Conservatoire National des Arts et Métiers – CNAM, Paris, EA 7340 CNRS). The library, originally developed to address flow simulations based on remeshed

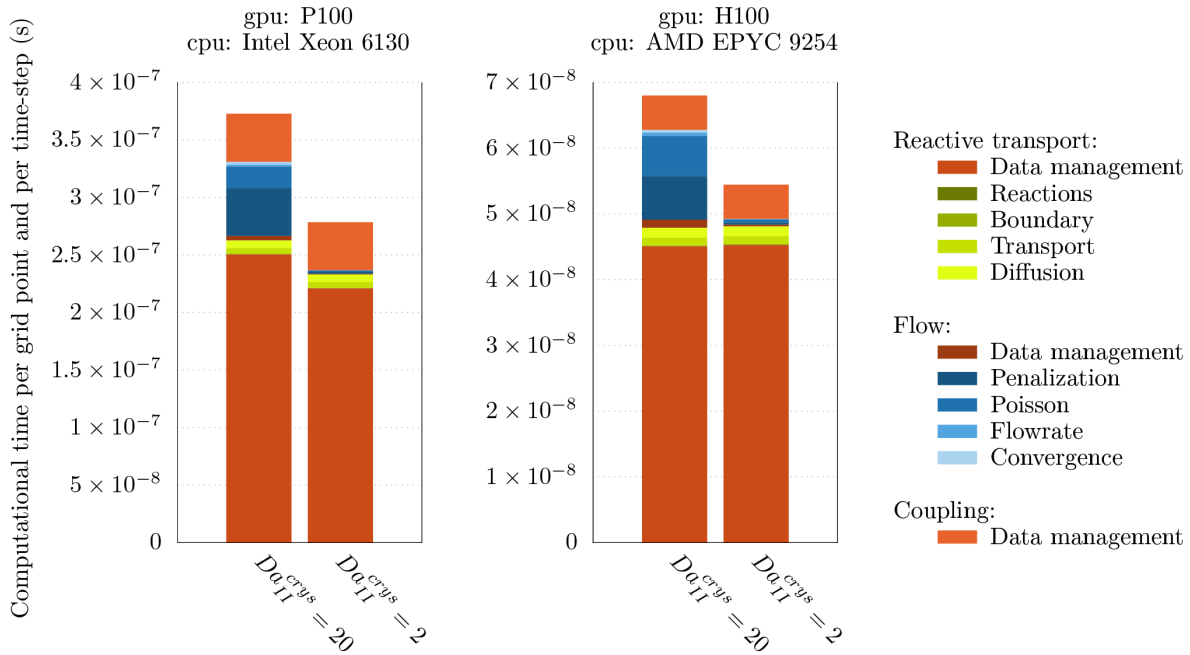

Figure 7: **Performances in various hardware configuration and discretization:** The considered hardware is NVIDIA P100 and H100 GPUs and 16-cores Intel Xeon 6130 cpus and 24-cores AMD EPYC 9254. The computational time is splitted according to the algorithm steps, including operator splitting and data management. Both cases where run with $Pe = 4.47$ (see section 5 for details).

particle methods on hybrid multi-CPU and multi-GPU architectures, was initiated by the work of Etancelin [2014] and has been successfully extended to a larger scope of HPC applications including dissolution at pore-scale [Etancelin et al., 2020].

The entire code is structured around the operator splitting strategy that defines the different operators involved in a problem (at a high level of abstraction), and afterward, enables the discretization of these operators, which are solved using the most appropriate numerical method (at a lower level of abstraction). The overall problem is formally described through an acyclic graph that expresses the operators interactions in the splitting formulation through data dependencies [Etancelin, 2014, Etancelin et al., 2020, Keck, 2019]. Even if the code is mainly written in Python, the numerical methods are either implemented using compiled language that enables threads parallelism (using OpenMP on CPU and OpenCL on accelerators) or taken from external libraries. User interface enables building together both numerical methods provided with HySoP on cartesian grid and user defined Python functions. In the latter, performances are obtained provided the usage of interfaces to compiled language (*i.e.* among others f2py, swig, cython, numba, ...). A complementary distributed parallelism is naturally available using domain decomposition implemented with a Message Passing Interface library (MPI).

One of the core features of HySoP is to target hybrid computing using both CPU and GPU. The latter was made possible by the emergence, in the 2000s, of the so-called GPGPU concept, which integrates the GPU as a CPU co-processing partner targeting accelerated performances. The choice of OpenCL was made to cope with portability of the performances as a generic multicore architecture programming standard [Stone et al., 2010]. The initial GPU computing feature was latter enhanced with code generation from templates or symbolic mathematical expressions together with auto-tuning tanks to micro-benchmarks at run time [Keck, 2019]. *Just-in-time* compiling is extensively used to achieve performance portability and lazy specification of kernel parameters which known as challenging problem widely dependent on the hardware architecture [Dolbeau et al., 2013].

The previous numerical method have been implemented on a hybrid computing strategy. Darcy-Brinkmann-Stokes equation is solved on CPU architecture using full MPI parallelization technique while all the reactive and transport part is computed using OpenCL on GPUs.

Overall profiling is represented on Figure 7 for two cases of the next section. Results are showing that recent hardware is capable of better performances without any changes in the code. We benefit here from OpenCL code generation and micro-benchamarks on accelerator and usual compiler optimizations

for CPU part. Significant variation appears in computational time associated to flow steps because larger Da_{II}^{crys} implies more intense geometrical changes and then reorganization of main flowpath, as described later in section 5. One can notice the quite large proportion of computational time spend in data management specially for reactive transport part. It corresponds to ghosts layers that handle boundary conditions and whole data transposition in order to get the first varying index identical to the current direction of directional splitted advection and remeshing operator. Ghosts layer widths are quite large due to large CFL numbers handled here. Data management on GPU has been identified as a known bottleneck of the code and would be investigated in future high performance computing engineering efforts.

5 Results and discussion on clogging/non-clogging effects

The present section focuses on the effects of calcite crystallization on changes in the pore geometry, macro-properties, and flow at the pore scale in the context of CO_2 mineral trapping. We consider a pore-scale geometry obtained by microtomography measurements from Sheppard and Prodanovic [2015] and freely available on the Digital Rocks data portal, which includes *inter alia* μ CT datasets of limestone, glass bead pack, and Castlegate sandstone. The numerical simulations are performed on the Castlegate geometry at a resolution of 128^3 with a voxel size of $5.6\mu m$, which represents a numerical sub-sample of about $L = 0.7168mm$. We assume, as previously introduced in Sect. 4.2, that the porous matrix is of identical mineral nature as the crystal generated along the reactive process and, thereby, consider that the sub-sample is composed of calcite. While including mineral heterogeneities as perspectives, we here hypothesize the homogeneity of the mineral structure within the sample. Finally, the specific area is numerically estimated for this sample to get, at the initial state, $A_s = 8300m^{-1}$, and is afterward updated along the reactive process.

Numerical simulations are performed under atmospheric conditions in terms of pressure and temperature and rely on the experimental identification of the reaction rate constants, arising from the literature [Chou et al., 1989]. We consider isothermal conditions with a temperature of $T = 25^\circ C$ and an injection of CO_2 with a partial pressure of $P_{CO_2} = 3.15 \times 10^{-2} bar = 2.96 \times 10^{-2} atm$ — which is about 100 times greater than the partial pressure of CO_2 in the atmosphere. Given Henry’s law constant for the CO_2 at $25^\circ C$, and under the assumption of a highly alkaline medium — with $pH > 10.33$ — we estimate from equation (38) that the initial concentration of carbonate ions is given by $C_{CO_3^{2-}}(x, t = 0) = 1 \times 10^{-3} mol.L^{-1}$.

The calcium initial concentration is subsequently determined based on the equilibrium constant $K_{eq} = 10^{-8.48}$ [Chou et al., 1989, Plummer and Busenberg, 1982] to ensure a far-from-equilibrium precipitation regime given by the supersaturation condition $Q \gg K_{eq}$. In this sense, we assume that the medium pore space is initially filled with a saturated solution wherein the initial concentration of calcium ions is $C_{Ca^{2+}}(x, t = 0) = 1 \times 10^{-1} mol.L^{-1}$. Therefore, in our case, the saturation in calcium ions Ca^{2+} initially present in the domain is not a limiting factor of the precipitation reaction, and we consider a continuous calcium injection that maintains the supersaturation constraint. Actually, in order to maintain this supersaturation, we will assume that the concentration in Ca^{2+} remains constant at its initial value. Comparable initial conditions and assumptions have been employed in investigating dissolution experiments by Maes et al. [2022], wherein the sample core was initially flooded with a brine solution that had previously reached equilibrium with supercritical CO_2 .

Regarding the reaction rate constant for the precipitation, we rely on the experimental identification from Chou et al. [1989] such that:

$$K_{-3} = \frac{K_3}{K_{eq}} = \frac{6.6e-7}{10^{-8.48}} = 199 mol.m^{-2}.s^{-1} \quad (45)$$

while adsorption frequencies K_c commonly encountered in the literature range from 1×10^3 to $1 \times 10^8 s^{-1}$ [Christoffersen and Christoffersen, 1990, Nielsen, 1984, von Wolff et al., 2021, Wolthers et al., 2012]. In practice, we set for the numerical simulations $K_c = 1 \times 10^3 s^{-1}$, the molecular diffusion $D_m = 1 \times 10^{-9} m^2.s^{-1}$ for all the species and the prescribed flow rate $\bar{u} = 1e-3 m.s^{-1}$.

Investigating the different precipitation patterns and regimes relies on the definition of well-established characteristic dimensionless numbers, namely the Peclet and (second or catalytic) Damköhler numbers respectively denoted Pe and Da_{II} [Noiriel et al., 2021, Soulaire et al., 2017, Steefel and Lasaga, 1990]. However, in the context of the joint precipitation and crystal growth modeling, we define two distinct

Damköhler numbers characterizing each process and respectively denoted Da_{II}^{prec} and Da_{II}^{crys} . These dimensionless numbers are subsequently defined as:

$$Pe = \frac{\bar{u}L}{D_m}, \quad Da_{II}^{\text{prec}} = \frac{K_{-3}\gamma_{\text{CO}_3^{2-}}A_sL^2}{D_m} \quad \text{and} \quad Da_{II}^{\text{crys}} = \frac{K_cL^2}{D_m} \quad (46)$$

where \bar{u} and L are respectively the characteristic velocity and length of the sample, and the activity coefficient of the carbonate ions is $\gamma_{\text{CO}_3^{2-}} = 1 \times 10^{-3} \text{ m}^3 \cdot \text{mol}^{-1}$. The characteristic length L can be related to pore size [Steeffel and Lasaga, 1990], though it is commonly set as $L = \sqrt{\kappa_0}$ provided an experimental or numerical estimation of κ_0 [Soulaine et al., 2017]. The latter alternative is applied here, with an estimation of $\kappa_0 = 2 \times 10^{-11} \text{ m}^2$ for the porous sample considered.

Therefore, the first crystallization regime we investigate is characterized by the following dimensionless numbers $Pe = 4.47$, $Da_{II}^{\text{prec}} = 33.034$ and $Da_{II}^{\text{crys}} = 20$. Precipitation and crystallization of calcite lead to a significant decrease in the macro-scale permeability and porosity, resulting from flow path disruptions at the micro-scale through partial or complete clogging of pore throats. This can also affect the roughness of the mineral interface and the pore-size distribution of the sample and, thereby, contribute to influencing the sample hydrodynamics properties. In particular, we observe these effects at the pore scale in Figure 8 along the reactive process and for several physical times t going from 2h45 to $T_f = 6\text{h}56$. On the right side of Figure 8, we depict partial views of the porous sample's morphology, illustrating the changes in pore structure over the reaction time, along with the micro-porosity field ε within the porous matrix Ω_S . On the left side, we represent along a slice in the main flow direction (taken at $z = -0.0168\text{mm}$), the local variations on the micro-porosity with respect to the initial state — before the reaction process — given by $\varepsilon(t) - \varepsilon(0)$. Initially, we notice that higher micro-porosity variations are more likely localized at the mineral interfaces but also near thin pore throats. These variations subsequently lead to pore-clogging and reorganization of the main flow pathway (see Figure 8c). In Figure 9b, we investigate the effects of such micro-scale changes on the evolution of the petrophysical properties at the macro-scale, namely the porosity ϕ and permeability κ_0 (upscaled quantities from figure 2.1). The results are consistent with the expected decrease along the CO_2 mineral trapping process but also highlight sharp permeability drops, which characterize the pore-clogging phenomena. Finally, in order to identify more clearly the crystallization pattern in this particular regime, we display in Figure 9a an isosurface of the micro-porosity variation between the final and initial times. This illustrates that micro-scale variations occur preferentially in a compact and non-uniform manner in the first inlet part of the domain while following the individual ramifications in the pore structure.

We subsequently investigate the impact of different dominant regimes on the overall two-step crystallization process. To do so, we consider both transport dominant cases with $Pe = 4.47 > 1$ and diffusion dominant cases with $Pe = 0.447 < 1$, coupled with two different crystal growth regimes characterized by $Da_{II}^{\text{crys}} = 2$ and $Da_{II}^{\text{crys}} = 20$. One should notice that the effect of precipitation Damköhler Da_{II}^{prec} changes are not analyzed since this number, characterizing the first homogeneous nucleation regime, is a limiting factor of the crystallization process from Figure 4. In this sense, we assume in all the previous cases that $Da_{II}^{\text{crys}} < Da_{II}^{\text{prec}}$ which guarantees a supersaturation state suitable to the development of crystal aggregates on the mineral surface.

To the best of our knowledge, considering that the crystallization regime can be driven by three distinct dimensionless numbers is one of the contributions of the present article. Indeed, most of the regime diagrams presented in the literature mainly characterize precipitation patterns according to the Pe and Da_{II}^{prec} dimensionless numbers, which implies neglecting the effects of nuclei adsorption at the mineral surface in the different regime configurations [Tartakovsky et al., 2007, Yang et al., 2021]. However, our results indicate that both homogeneous calcite nucleation (the precipitation step in Figure 4) and growth stages are important in the development of precipitation and crystallization patterns. In particular, we establish that the crystal growth Damköhler number Da_{II}^{crys} has a non-negligible impact on precipitation pattern and porosity variations along the reactive process, regardless of the other dimensionless numbers Pe and Da_{II}^{prec} commonly investigated. Indeed, Figures 10b and 10d highlight two distinct crystallization regimes at similar Pe and Da_{II}^{prec} , but with a ten times smaller adsorption frequency K_c in Figure 10b which impact the Da_{II}^{crys} . Figure 10b shows that, for a small adsorption frequency K_c , the calcite precipitate is uniformly generated and advected along the main flow path direction (due to the transport dominant regime with $Pe > 1$) while the micro-porosity changes are minimal. This illustrates that the main flow path is maintained since few calcite nuclei aggregate to the mineral surface. By increasing the adsorption

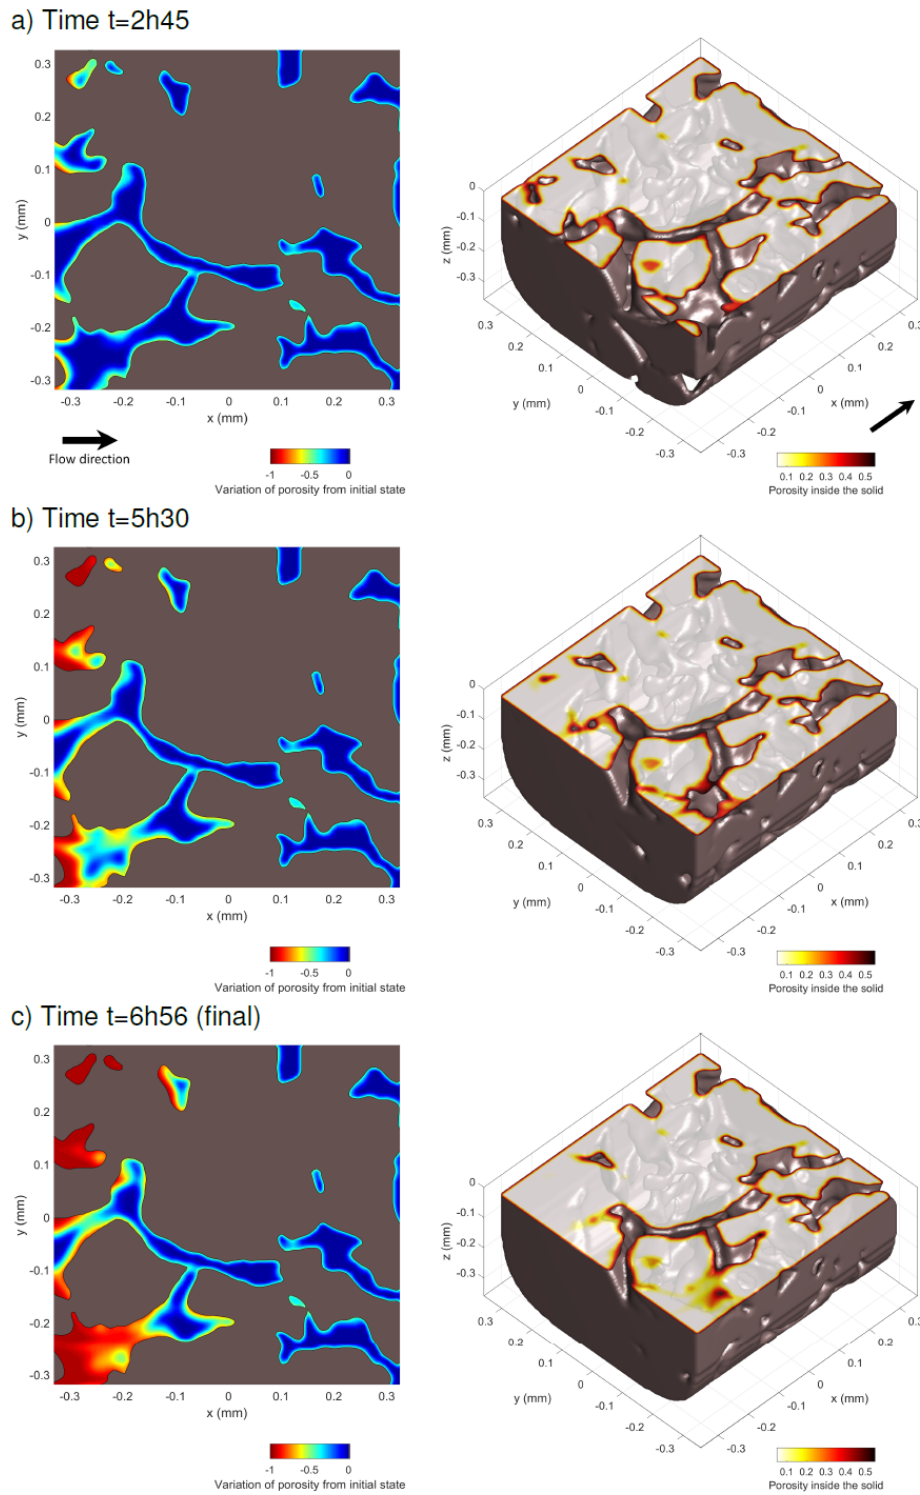

Figure 8: Time evolution of the sample geometry and micro-porosity at the pore scale, illustrating pore-clogging effects. Slice at $z = -0.0168$ of the porosity variations $\varepsilon(t) - \varepsilon(0)$ in the fluid region of the pore space for various times t , on the left. Partial view of the pore space structure as an isosurface of $\varepsilon(t)$ for several times t , on the right.

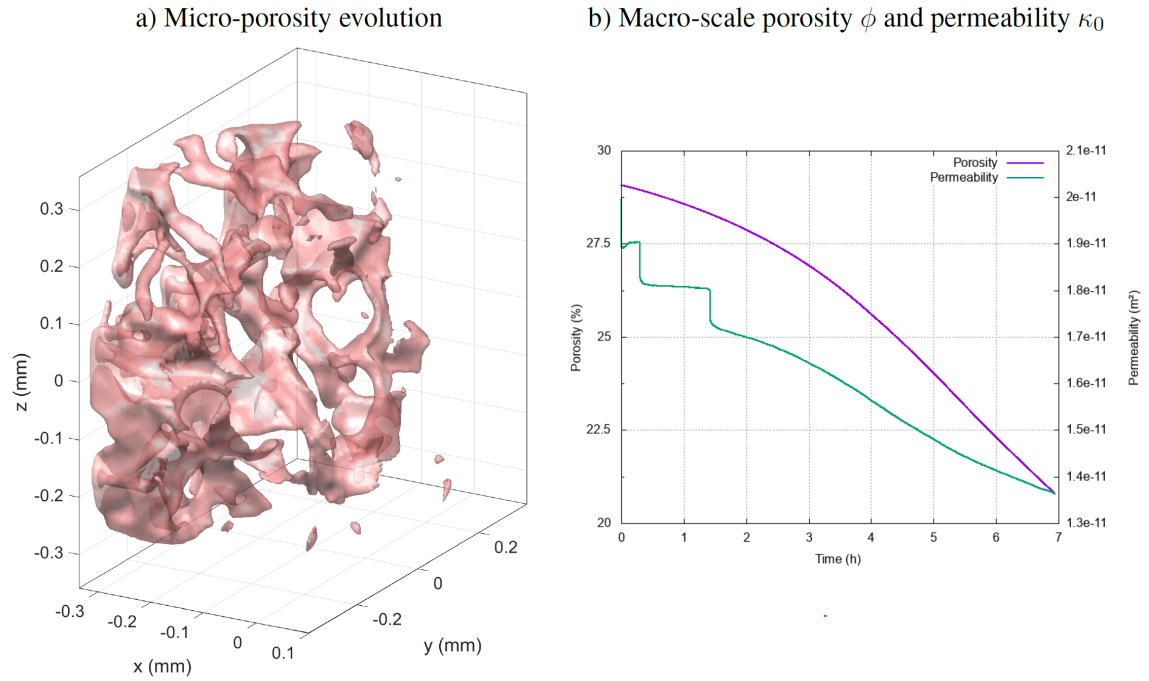

Figure 9: **Evolution of the sample properties along the reactive process:** a) Micro-porosity evolution represented by an isosurface of the porosity variation $\varepsilon(T_f) - \varepsilon(0)$ at half of its maximum value. Results after nearly 7h of precipitation and crystal growth, illustrating a non-uniform compact regime following the natural ramification of the sample. b) Evolution of the macro-scale properties, porosity ϕ and permeability κ_0 , along the two-step crystallization process from Figure 4.

frequency in Figure 10d, the precipitate formation concentrates on the inlet of the domain and is less subject to advection, while the micro-porosity changes become significant. On one side, this highlights pore-clogging that prevents further transport of the calcite nuclei. On the other side, we also notice a backward increase in calcite precipitates that accumulate behind the clogging after some time. The same analysis holds for Figure 10a and 10c, except we consider a diffusion dominant regime with $Pe < 1$, which means that the precipitate transport is reduced so that the nuclei formation and micro-porosity changes are even more constrained to the inlet boundary of the domain. The results presented in Figure 8 and 9 correspond to the crystallization regime identified by $Pe > 1$ and $Da_{II}^{crys} = 20$ in Figure 10d. In this sense, this confirms that the permeability drops observed in Figure 9b are characteristics of pore-clogging effects.

6 Concluding remarks

This article focused on developing an efficient DNS framework to address reactive flows at the pore scale in the context of CO_2 mineral storage. Indeed, the injected CO_2 will interact with the aquifer structure and eventually lead to mineral trapping in the form of calcite precipitates and crystals. These processes are interesting to study at the pore scale to ensure a comprehensive analysis of the local rock-fluid interactions and evolving pore structures. This can subsequently translate into meaningful estimations of the macro-scale properties changes and measure the impact of the geochemical processes on the natural underground reservoirs. In particular, precipitation and crystallization lead to a significant reduction in the macro-scale permeability and porosity, which result from partial or complete pore clogging and thus from a reorganization of the flow path at the micro-scale.

From a conceptual perspective, we developed a new crystallization model that efficiently combines a classical deterministic TST approach of the nucleation process with a probabilistic view of the crystal aggregation to the pore surface. This enables us to account for spatial and geometrical dependency in the crystal growth modeling through a probabilistic attachment rate depending on local mineral volume fraction. In this sense, we integrate the modeling of preferential growing sites that largely hinge on the surrounding pore arrangement. To the best of our knowledge, such considerations are here accounted for the first time to model crystallization processes in complex 3D geometries at the pore scale. Investigating

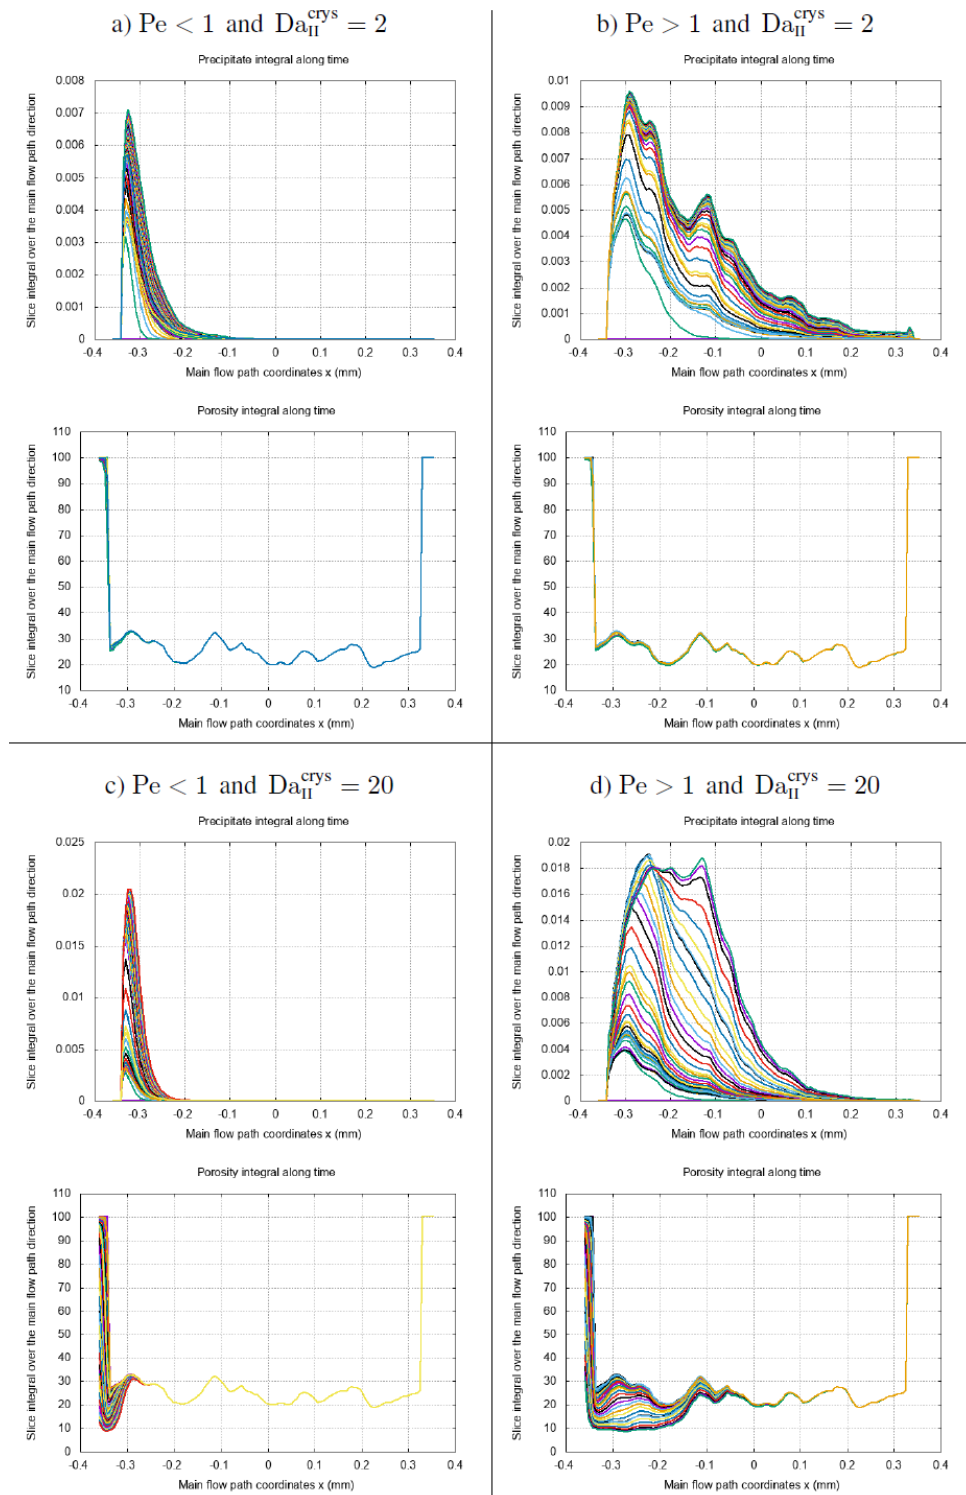

Figure 10: **Impact of the different crystallization regimes, with respect to the dimensionless numbers Pe and Da_{II}^{crys} .** Slice integrals of the precipitates and macro-porosity — computed over 2D YZ directional slices — plotted with respect to the main flow path direction coordinates x (in millimeters mm) and where each curve represents a distinct time in the reactive process.

probabilistic attachment rates based on the surrounding pore structure also ensures reliable prediction of pore-clogging at the pore scale. Finally, we demonstrate that the proper characterization of crystallization regimes both depends on the nucleation process and crystal aggregation. Indeed, we exhibit that the two commonly considered dimensionless numbers, Pe and Da_{II}^{prec} , are not sufficient to explain clogging effects and precipitation patterns. A novelty of the present manuscript is, therefore, that the crystallization regimes are characterized by three dimensionless numbers that include the effects of nuclei adsorption to the pore surface.

This reactive hydrodynamic model that consistently couples a Lagrangian formulation for the reaction equations with a grid-based approach for the flow using the DBS equation with the superficial velocity formalism. This semi-Lagrangian method is addressed through a splitting operator strategy coupled with high-order remeshing steps for grid-particle interpolations. This original numerical method introduced to solve this coupled model has been efficiently incorporated into the hybrid numerical framework HySoP and results in a CPU-GPU implementation of the method. It includes a robust estimation of the heterogeneous diffusion operator arising from Archie's law term in the reactive system.

At the same time, this article also demonstrated strong implications in the overall reactive system of several parameters that can be subject to a wide range of discrepancies. In particular, morphological features and kinetic parameters, such as the micro-porosity ε , specific area A_s , rate constants K_i , and adsorption frequencies K_c , have a significant impact on the reaction rates and the dynamical patterns.

Experimental determination of these parameters can range over several orders of magnitude and result in highly different regimes that drastically affect the estimation of the macro-scale properties: the adsorption frequencies K_c commonly found in the literature can range from 1×10^3 to $1 \times 10^8 \text{ s}^{-1}$ as shown in Christoffersen and Christoffersen [1990], Nielsen [1984], von Wolff et al. [2021], Wolthers et al. [2012]. Our present method has been shown to compute accurately the phenomena of crystallization and precipitation in different regimes, and will be used intensively in future works for inverse problems in order to get a robust and accurate estimation of such adsorption frequencies from experiments imaging.

A Original and discretization corrected particle strength exchange (DC-PSE) methods

This section concerns the theoretical aspects of the PSE method that finds its essence in estimating diffusion in a Lagrangian context with meshless and scattered particle structures. Since the original article from Degond and Mas-Gallic [1989], the PSE approach has appeared as an efficient numerical method for solving convection-diffusion problems with particles [Schrader et al., 2012] and has been successfully used in vortex methods [Cottet et al., 2000].

Several reviews have also extended its application to the Eulerian context, with structured grids, but also to hybrid grid-particles formalism while enhancing the accuracy of the original method by replacing continuous integration with discrete one, such as in Bergdorf et al. [2005], Poncet [2006], Schrader et al. [2010]. These novel PSE approaches, therefore, enable us to efficiently evaluate the heterogeneous diffusion operator arising from Archie's law in a Semi-Lagrangian context. In the following, we briefly review the general principles of this original method along with an overview of its successive improvements using discretization corrections.

A.1 Classical PSE formulation

The PSE scheme is then completely determined once the kernel σ^ξ is defined and exhibits its relation with the diffusion matrix \mathbf{L} . The original approach from Degond and Mas-Gallic [1989] suggests the following kernel choice

$$\sigma^\xi(x, y) = \frac{1}{\xi^2} \sum_{i,j=1}^n M_{ij}(x, y) \psi_{ij}^\xi(y - x), \quad (47)$$

where

$$\psi_{ij}^\xi(x) = \frac{1}{\xi^n} \psi_{ij} \left(\frac{x}{\xi} \right)$$

is a matrix cutoff function with ψ_{ij} symmetric and even, and $\mathbf{M} = (M_{ij}(x, y))$ a symmetric matrix to be determined. These hypotheses are of great interest as they guarantee the conservation property of the

operator Q^ξ based on symmetric exchanges. We then introduce the matrix $\mathbf{m}(x) := \mathbf{M}(x, x)$ and the moments of the cutoff functions ψ_{ij} given by:

$$Z_{ij}^\alpha = \int \psi_{ij}(x) x^\alpha dx, \quad (48)$$

for any i, j and multi-index α . It has been proved by Degond and Mas-Gallic that if some moment conditions are satisfied, namely the hypotheses (i) and (ii), we obtain the following convergence result [Degond and Mas-Gallic, 1989]:

Property 1 *We assume that there exists an integer $r \geq 2$ such that :*

(i) $Z_{ij}^\alpha = 0$ for $1 \leq |\alpha| \leq r + 1$ and $|\alpha| \neq 2$

(ii) for any integer k, l in $[1, n]$, we have $\sum_{i,j=1}^n m_{ij}(x) Z_{ij}^{e_k+e_l} = 2L_{kl}(x)$.

In addition of the previous hypotheses on matrices \mathbf{M} , \mathbf{m} and ψ , we assume the following regularities $\mathbf{M} \in W^{r+1,\infty}(\mathbb{R}^n \times \mathbb{R}^n)$, $\mathbf{m} \in W^{r+1,\infty}(\mathbb{R}^n)$ and $(1 + |x|^{r+2})\psi(x) \in L^1(\mathbb{R}^n)$. There exists a positive constant $C = C(\mathbf{M}, \psi)$ such that for any function $f \in W^{r+2,\infty}(\mathbb{R}^n)$

$$\|\operatorname{div}(L\nabla f) - Q^\xi \cdot f\|_{0,\infty} \leq C\xi^r \|f\|_{r+2,\infty}. \quad (49)$$

Several matrix cutoff functions have been investigated in Degond and Mas-Gallic [1989] but we mainly focus on the most suitable for practical use, which reads as:

$$\psi_{ij} = x_i x_j \Theta(x) \quad (50)$$

with Θ a smooth spherically symmetric function with fast decreasing, also called the stencil generator. Finally, one needs to define the second moments' matrix of Θ , denoted $\mathbf{A} = (a_{kl})$, and given by

$$a_{kl} = \int x_k^2 x_l^2 \Theta(x) dx, \quad k, l \in [1, n]. \quad (51)$$

In this case, one gets the existence of a matrix $\mathbf{m}(x)$ such that the hypotheses (i) and (ii) of Property 1 are satisfied if and only if \mathbf{A} is an invertible symmetric matrix and, for any k, l $k \neq l$, we have $a_{k,l} \neq 0$. The matrix $\mathbf{m}(x)$ is then defined by (see Lemma 1 in Degond and Mas-Gallic [1989]):

$$m_{kl}(x) = a_{kl}^{-1} L_{kl}(x), \quad \text{for } k, l \in [1, n], k \neq l \quad (52)$$

$$\sum_{i=1}^n a_{ki} m_{ii}(x) = 2L_{kk}(x), \quad \text{for } k \in [1, n] \quad (53)$$

which is a fundamental result of the original PSE article. In 3D applications, for instance, one can compute the matrix \mathbf{A} coefficients using spherical coordinates to obtain $a_{kk} = 3\gamma$ and $a_{kl} = \gamma$, if $k \neq l$, with γ expressed by:

$$\gamma = \frac{4\pi}{15} \int_0^\infty \tilde{\Theta}(r) r^6 dr \quad (54)$$

where the spherically symmetric function Θ is written $\Theta(x) = \tilde{\Theta}(|x|)$. Solving the problem given by equations (52) and (53) then explicitly provides

$$m_{kl} = \gamma^{-1} L_{kl}, \quad \text{if } k \neq l, \quad \text{and} \quad m_{kk} = \gamma^{-1} L_{kk} - \frac{\gamma^{-1}}{5} \operatorname{Tr}(\mathbf{L}), \quad (55)$$

which also writes

$$\mathbf{m} = \gamma^{-1} \mathbf{L} - \frac{\gamma^{-1}}{5} \operatorname{Tr}(\mathbf{L}) \mathbf{Id}_3. \quad (56)$$

When the conditions (52) and (53) are satisfied and in the case of a kernel defined with a spherical-symmetric function Θ such as in (50), the method provides at least second order approximation of the diffusion operator (see Property 1) which is suitable for any particle distribution in a Lagrangian context.

One should notice that in practice the method is limited to second-order convergence for positive kernel σ^ξ [Cortez, 1997, Degond and Mas-Gallic, 1989].

Finally, to make the approximation operational, it remains to define the relation between \mathbf{M} , \mathbf{m} , \mathbf{L} , and Θ . A usual approach is to consider the matrix $\mathbf{M}(x, y) = (\mathbf{m}(x) + \mathbf{m}(y))/2$ and for ψ given by (50), one gets the following kernel formula:

$$\sigma^\xi(x, y) = \frac{1}{\xi^{n+4}} \Theta\left(\frac{y-x}{\xi}\right) \mathbf{M}(x, y) : (x-y)^{\otimes 2}. \quad (57)$$

This entirely specifies the numerical scheme by combining the equations (26), (57), and (56). This original formalism is based on continuous integration of the second moments of Θ through the equation (54) and is second order consistent in the sense $\mathcal{O}[(h/\xi)^2]$.

A.2 Discrete renormalized PSE scheme and application to Archie's law

Alternatives relaxing this constraint on convergence result in replacing the continuous moment integration with discrete moment conditions, which is referred to as discretization correction of the PSE scheme. The latter has been successfully developed for several state-of-the-art applications including mesh-free scenarios with arbitrary particle distributions, uniform Cartesian grids, and also in hybrid formulations involving both an underlying grid along with the particles, detailed in Bergdorf et al. [2005], Bourantas et al. [2016], Schrader et al. [2010], Zwick et al. [2023].

The consistency of the original PSE scheme can be improved to $\mathcal{O}(h^2)$ by using discrete integration when particles are distributed over a uniform grid [Poncet, 2006]. The main idea is to replace (51) by the matrix of discrete second-order moments, which subsequently leads to a distinct evaluation of the matrix \mathbf{m} . One introduces the following coefficients using discrete integration:

$$\gamma_1 = \sum_{x \in \mathbb{J}} x_k^4 \Theta(x) h^3, \quad k \in [1, 3] \quad (58)$$

$$\gamma_2 = \sum_{x \in \mathbb{J}} x_k^2 x_l^2 \Theta(x) h^3, \quad k, l \in [1, 3] \quad (59)$$

for $\mathbb{J} \subset h\mathbb{Z}^3$ a three-dimensional lattice, including at least one neighborhood of the current mesh point. One then gets similar equations as (52) and (53) with respect to the coefficients γ_1 and γ_2 , resulting in the characterization of \mathbf{m} . We introduce the matrix $\mathbf{H} = H_{ij}$ given by

$$H_{ij} = \left(\frac{\gamma_1^2 - \gamma_1\gamma_2 - 6\gamma_2^2}{\gamma_2(\gamma_1^2 + \gamma_1\gamma_2 + 2\gamma_2^2)} \right) (1 - \delta_{ij}) L_{ij} \quad (60)$$

where δ_{ij} is the Kronecker symbol, such that the matrix \mathbf{H} is zero when \mathbf{L} is diagonal or when $\gamma_1 = 3\gamma_2$. We thus obtain a discrete renormalization of the matrix \mathbf{m} which reads as follows:

$$\mathbf{m} = c_0 \mathbf{L} - c_1 \text{Tr}(\mathbf{L}) \mathbf{Id}_3 + \mathbf{H} \quad (61)$$

where

$$c_0 = \frac{2(\gamma_1 + 2\gamma_2)}{\gamma_1^2 + \gamma_1\gamma_2 - 2\gamma_2^2} \quad \text{and} \quad c_1 = \frac{2\gamma_2}{\gamma_1^2 + \gamma_1\gamma_2 - 2\gamma_2^2}, \quad (62)$$

and replaces the equation (56) in the original PSE version. Finally, this formulation with discrete integration is completely defined through the formula (57). This also leads to a better accuracy since this scheme is consistent in h^2 whereas the classical PSE method has a convergence in the sense that the error is of order $(h/\xi)^2$.

While the discrete renormalization of PSE method can be assimilated to a FD stencil on a uniform Cartesian grid and satisfies the same order of accuracy as standard FD schemes, one can query the motivation for using this seemingly complex approach. First of all, behind appearances, this method is easy to implement and not computationally expensive in the context of uniformly distributed grids. In 3D applications, for instance, one can summarize the PSE discrete formulation as follows

$$Q^\xi \cdot f^h(x_k) = \frac{1}{\xi^7} \sum_{l \sim k} (f_l - f_k) \Theta\left(\frac{x_l - x_k}{\xi}\right) \left[\sum_{i,j=1}^3 M_{ij}(x_k, x_l) (x_l - x_k)_i (x_l - x_k)_j \right] v_l \quad (63)$$

with the spherically symmetric function $\Theta(x) = 1/(1 + |x|^p)$ where $|\cdot|$ is the Euclidean norm in \mathbb{R}^3 . The formula (63) basically involves all the contributions of the mesh points of index l in the ξ -neighborhood of the current mesh point x_k , representing namely 26 neighbors in 3D for $\xi = h$ compared to merely 6 neighbors with standard crossed FD scheme. In practice, ξ is taken equal to h or $2h$, and the numerical results presented in this article are given with $p = 10$.
