Abstract

The management of extensive bone loss remains a clinical challenge. Numerous studies are underway to develop a combination of biomaterials, biomolecules and stem cells to address this challenge. In particular, the systemic administration of antibodies against sclerostin, a regulator of bone formation, was recently shown to enhance the bone repair efficiency of dense collagen hydrogels hosting murine dental pulp stem cells (mDPSCs). The aim of the present study was to assess whether these antibodies, encapsulated and released from dense collagen hydrogels (DCHs), could promote craniofacial bone repair by local inhibition of sclerostin.

In vitro studies showed that antibody loading modified neither the hydrogel structure nor the viability of seeded mDPSCs. When implanted in a mouse calvaria critical-size bone defect, antibody-loaded DCHs showed repair capabilities similar to acellular unloaded DCHs combined with antibody injections. Importantly, the addition of mDPSCs provided no further benefit.

Altogether, the local delivery of anti-sclerostin antibodies from acellular dense collagen scaffolds is highly effective for bone repair. The drastic reduction in the required amount of antibody compared to systemic injection should reduce the cost of the procedure, making the here-proposed strategy a promising therapeutic approach for large bone defects repair.

Keywords: Bone tissue engineering; Monoclonal antibody therapy; Sclerostin; Collagen hydrogels; Dental pulp stem cells.

1. Introduction

Over the last 30 years, bone tissue engineering strategies have continuously improved the design of biomaterials with enhanced ability to promote osteogenesis through the combination of scaffolds, stem cells and biomolecules acting synergistically¹⁻⁵. Scaffolds aim to mimic and delimit a biological microenvironment to allow cell migration and proliferation^{6,7}. They can be prepared from a wide range of materials, which can be inert, bioactive or biological⁸. Their structure, mechanical stability and degradation kinetics can be varied to a large extent⁹. However, when implanted, scaffolds are susceptible to infection, especially because their limited vascularization can impede immune cells migration to the contaminated site^{10,11}. To promote biological response, scaffolds can be seeded with stem cells¹². Adult stem cells, including mesenchymal stem cells (MSCs), are preferred due to their safe profile compared to embryonic and induced pluripotent stem cells¹³. Adequately primed, they promote direct target tissue formation or indirect formation by secreting bioactive molecules^{14,15}. Autologous MSCs are the best candidates to avoid any immune response¹⁶. However, the number of available cells is limited by the process time, mainly restricting their use to planned medical procedures¹⁷. Active molecules, such as antibiotics, growth factors or antibodies, can also be added to the scaffold, targeting either host cells, seeded cells or both¹⁸⁻²⁰. Compared to systemic administration (e.g. intravenous dispensation), local delivery via a scaffold dispenses the medication close to the target site, reducing the total dose required and thus mitigating systemic adverse effects^{21,22}. The two associated primary challenges are to maintain the bioactivity of the molecules during the scaffold loading step, especially in the case of antibodies²³, and to adjust the release kinetics *in vivo*.

To restore bone defects, especially critical-size ones, using dense collagen hydrogels (DCH) as scaffolds is a promising approach^{15,24}. They are soft, biocompatible, biodegradable, and with a fibrillar density that can be similar to that of the native bone matrix²⁵⁻²⁷. They can be seeded with MSCs to promote bone repair by accelerating osteogenic differentiation²⁸. Dental Pulp Stem Cells (DPSCs) are a type of MSCs commonly used that can be differentiated into multiple lineages including bone-forming cells²⁹. Adequately primed and seeded into DCHs, they enhance bone repair *in vivo*^{15,24}. DPSCs are eligible candidates for craniofacial bone

1
2
3 therapy as they are derived from the same embryological origin as the skull bones, the neural
4 crest³⁰.

7 Bone cell activity is under the dependence of two main signaling pathways: (a) the SMAD(x)
8 pathway, with ligands such as BMP and TGF- β , and (b) the Wnt (wingless-related integration-
9 site)/ β -catenin pathway involving proteins such sclerostin, an inhibitor of this pathway^{31,32}.
10 Sclerostin is the protein encoded by the *SOST* gene, whose loss-of-function mutations lead in
11 uncontrolled bone apposition (hyperostosis corticalis generalisata disease)^{33,34}. Monoclonal
12 antibodies against sclerostin (Scl-Ab) were developed to increase bone formation and are
13 currently used to improve bone quality in osteoporosis and osteogenesis imperfecta, a rare
14 bone fragility disorder^{35,36}. Repeated systemic injection of Scl-Ab has already proven a
15 promising approach to favor bone healing³⁷. Monthly delivery of Sclerostin single-chain
16 antibody fragments loaded in poly(lactic-co-glycolic acid) (PLGA) microspheres was shown to
17 promote long-bone fracture healing in ovariectomized rats³⁸. In a step further, we have
18 recently shown that implementing a DCH scaffold, with or without mDPSCs, combined with
19 weekly intravenous (IV) injection of Scl-Ab over two months enhanced bone formation in a
20 calvarial critical bone defect³⁹. In addition, implementing a DCH seeded with *Sost* knock-out
21 (KO) mDPSCs in a wild-type (WT) mouse calvaria critical-size bone defect similarly promoted
22 bone formation, suggesting that the local inhibition of sclerostin may be sufficient to improve
23 bone healing³⁹. Taken together, these data suggest that the direct loading of the Scl-Ab into
24 the DCH could reproduce this local inhibition within the bone defect, reducing the global dose
25 delivered, thus limiting potential side effects such as mild reaction at the injection site, and
26 reducing the treatment cost³⁵.

44 Current research on antibody-loaded hydrogels focuses on PLGA, chitosan, alginate,
45 collagen, or hyaluronic acid-based scaffolds⁴⁰. Injectable antibody-loaded hydrogels were
46 developed for possible use in ocular drug delivery, cancer or stroke treatments⁴¹. Whereas
47 several antibody-releasing materials have been recently developed for subcutaneous
48 implantation^{42,43}, *in situ* placement of hydrogels loaded with full antibody for bone repair has
49 not been described yet. Therefore, in the present study, we aimed at assessing whether the
50 Scl-Ab loading of DCH scaffolds could improve the efficacy of bone regeneration in craniofacial
51 defects. To this end, we evaluated the antibody-loading capacity of DCH and the survival of
52 seeded mDPSCs at the selected doses. Critical craniofacial bone defects created in adult mice

1
2
3 were filled with Scl-Ab-loaded DCH, either cellularized with mDPSCs or acellular, and bone
4 formation was monitored within the defects. Ultimately, the best condition was compared to
5 the standard condition, e.g. mice treated with DCH combined with Scl-Ab IV injections.

13 **2. Materials and Methods**

14 *2.1. Ethical approval and animal management*

15
16
17 All experiments in this study were conformed to ARRIVE (Animal Research: Reporting of in
18 vivo Experiments) guidelines and were approved by the Animal Care Committee of the
19 Université Paris-Cité (APAFIS agreement # 24,297 N°2,019,022,017,023,656). Animals were
20 maintained according to the guidelines for ethical conduct developed by the European
21 Communities Council Directive (animal breeding agreement C92–049–01). All efforts were
22 made to minimize their pain or discomfort. Seventy-six ten-week-old male mice with a
23 C57BL/6 J genetic background were used for this study and were housed in stable conditions
24 (22 ± 2 °C) with a 12 h dark/light cycle and with ad libitum access to water and food.

35 *2.2. Isolation and culture of dental pulp stem cells (mDPSCs)*

36
37
38 Multi-colony-derived mouse dental pulp stem cells (mDPSCs) were obtained from the
39 molars of three-day postnatal (PN3) littermate WT mice using a protocol adapted from
40 Gronthos et al.²⁹. Briefly, murine molar gems were collected under sterile conditions and
41 incubated at 4 °C for 45 min in phosphate-buffered saline (PBS) containing 100 U.mL⁻¹
42 penicillin/streptomycin (Gibco, Hampton, USA) and 250 µg.mL⁻¹ fungizone (Gibco), and then
43 in PBS containing 3 mg.mL⁻¹ type I collagenase (Worthington Biochem, Freehold, NJ, USA) and
44 2 U.mL⁻¹ dispase I (Roche, Mannheim, Germany) in a shaking incubator (at 37 °C) for one hour.
45 The isolated cells were then plated on 0.1 % gelatin-coated dishes in Minimum Essential
46 Media-alpha (Gibco) supplemented with 20 % v/v fetal bovine serum (FBS) (Gibco), 100 U.mL⁻¹
47 Penicillin/streptomycin (Gibco), 2.5 ng. mL⁻¹ FGF-2 (PeproTech, Neuilly Sur Seine France),
48 10 ng mL⁻¹ BMP-2 (PeproTech) and maintained at 37 °C under 5% CO₂ atmosphere. The
49 medium was changed after two days, then three times a week. The required cell number for
50 *in vivo* experiments was reached after two to three passages.

2.3. Dense Collagen Hydrogel (DCH) preparation

Plastically compressed collagen gels were used as three-dimensional scaffolds and prepared as previously described^{39,44}. Briefly, 1.8 mL of a sterile rat-tail tendon type I collagen solution at a protein concentration of 3.5 mg.mL⁻¹ in 0.1% acetic acid, obtained as previously described,⁴⁵ was mixed with 0.4 mL of 10X Dulbecco's Modified Eagle Medium (DMEM) and 0.4 mL 10X NaHCO₃. Neutralization was achieved by drop-wise addition of 0.1 N NaOH until pH = 7.4. After neutralization, the mixture was completed to 4 mL with Minimum Essential Media-alpha (Gibco), with or without mDPSCs at a seeding density of 2x10⁶ cells per mL, with or without Scl-Ab (Setrusumab, BPS804; kind gift from Mereo Biopharma (London, UK)) and was ice-cold mixed. The mixture was then dispensed into a four-well plate. After gelling (30 min at 37 °C), highly hydrated hydrogels were placed on a stack of blotting paper, nylon, and stainless steel meshes as described in Coyac et al⁴⁴. Dense collagen hydrogels (DCH) were produced by the application of an unconfined compressive stress of 2 kPa for five min to remove excess casting fluid.

For *in vivo* experiments, hydrogels were prepared with or without antibodies, and with or without cells. Scl-Ab loaded DCHs were prepared with two different concentrations of antibody in the initial solution, 0.2 mg.mL⁻¹ and 2 mg.mL⁻¹, hereafter-termed low dose (Ld) and high dose (Hd), respectively. Cell seeding density was always 2x10⁶ cells per mL. After compression, DCHs were circularly cut (four mm in diameter, in aqueous medium) and kept up to 24 h at 37 °C under 5% CO₂ in serum-free medium before implantation. DCHs were kept in a serum complemented with Scl-Ab at the same concentration as the initial solution.

The antibody was reconstituted with water for injection (WFI). For injection, the stock solution was diluted in saline solution³⁹.

2.4. Characterization of the DCH

To assess the volume of the DCH before and after compression, 20 µL per DCH of a barium sulphate suspension (0.1 g.mL⁻¹, Micropaque, GUERBET lab) were added to obtain radio dense samples (n=8). DCHs were imaged before and after compression using an X-ray micro-CT

1
2
3 device (see below). Using DICOM image stacks, the DCH were segmented, and their volumes
4 assessed using AVIZO software (v2019.1, ThermoFisher Scientific).
5
6

7 Gels were imaged before and after compression by Scanning Electron Microscopy (SEM).
8 Gels were fixed with 4% paraformaldehyde (PFA) in phosphate-buffered saline (PBS). After
9 rinsing with a 0.1 M cacodylate/0.6 M sucrose buffer, they were dehydrated in water:ethanol
10 solutions of increasing alcohol content and dried using supercritical CO₂. Samples were
11 sputter-coated with a gold layer (15 nm) and imaged using a Hitachi S-3400 N SEM microscope
12 operating at 10 kV.

16
17
18
19
20

21 2.5. *Assessment of the Scl-Ab distribution, loading and release kinetics*

22 To evaluate the distribution of the antibody within the hydrogel, 100µg of Scl-Ab was
23 labelled using the SiteClick Antibody Labelling Kit (S10467) from Invitrogen. Briefly, it consists
24 of a three-step workflow: modification of the carbohydrate domain of the antibody, azide
25 attachment to the antibody and conjugation with a DIBO-modified R-phycoerythrin. The
26 labelled Scl-Ab was added to unlabelled Scl-Ab to produce a Hd DCH (n=1), resulting in a
27 hydrogel containing 5% labelled Scl-Ab (100µg labelled /2mg total Scl-Ab) prior to
28 compression. After plastic compression, the hydrogel was imaged by confocal microscopy.
29
30
31
32
33
34
35
36

37 To assess Scl-Ab loading of the hydrogels after compression, DCH were digested in a
38 solution of 225 µL of PBS and 25 µL of type I collagenase (290 U.mg⁻¹). An Enzyme Linked
39 Immuno-Sorbent Assay (ELISA) (ABCAM ab195215 – IgG Human SimpleStep ELISA Kit) was
40 then performed according to the recommendations of the manufacturer. Each measure was
41 done in duplicate with each condition in triplicate. A solution of collagenase alone and one of
42 collagenase with a known concentration of antibody were used as controls. The results were
43 adjusted with the OD of the collagenase solution. The concentration of the
44 collagenase/antibody solution was in the range of the initial solution (3.5 mg.mL⁻¹). Plates
45 were read on an Infinite 200 M-Plex plate reader (Tecan).
46
47
48
49
50
51
52
53

54 To study Scl-Ab release kinetics from the hydrogels, they were placed immediately after
55 compression in 0.5 mL of PBS at 37°C. After 3, 6, 9, 24, 31, 57, 82 and 101 hours, 0.15 mL of
56 solution was removed and replaced by 0.15 mL of PBS. The antibody concentration in each
57
58
59
60

1
2
3 sample was measured by ELISA. To assess the possible effect of cellularization on Scl-Ab
4 release, similar experiments were performed using mDPSCs-seeded hydrogels.
5
6
7
8

9 2.6. *In vitro assessment of cell viability*

10
11 Cell viability and distribution within the dense collagen scaffolds were assessed using the
12 Live/Dead[®] cell viability-cytotoxicity assay (Invitrogen, Carlsbad, CA, USA) at 24 hours with a
13 confocal laser scanning microscope (IXplore Spinning 522 Roussy), and using Alamar Blue
14 assay (Invitrogen, Carlsbad, CA, USA) at days 1, 7, 14, 21 and 28. For the Live/Dead assay,
15 image acquisition was performed in IMAG'IC Facility, member of the National Infrastructure
16 France BioImaging (ANR-10-INBS-04). Images from the Live/Dead assay were analyzed with
17 Fiji⁴⁶. Alamar blue assay was performed and analyzed following the manufacturer instructions.

28 2.7. *Surgical implantation*

29
30 Mice were anesthetized (100 mg/kg b.w. of ketamine and 10 mg/kg b.w. of xylazine
31 hydrochloride, both from Centravet Alfort, Maisons-Alfort, France). In each individual, scalp
32 skin was incised to visualize the periostium. A 3.5 mm diameter calvaria critical-sized defect⁴⁷
33 was created on each side of the parietal bone using a mucosa punch (Helmut Zepf 08.920.13)
34 attached to a slow speed hand piece operating at 3000 rpm, under constant irrigation with
35 sterile saline solution (NSK – Viva Ace). Special care was taken for the sagittal suture
36 preservation, and minimal invasion of the dura mater. After gently removing the circular bone
37 plug, DCH were implanted in each of the two bone defects (same DCH condition in the two
38 defects)⁴⁷. Two control groups were performed: defect left empty and sham, which consisted
39 in skin opening without bone removal. Each animal was randomly allocated per cage and per
40 group. Wound closure was achieved by a suturing (skin) using absorbable sutures (Vicryl Rapid
41 4.0, Ethicon, Johnson & Johnson). Immediate post-operative care included analgesia with
42 buprenorphine (0.02 mg/kg b.w.). After surgery, mice were housed by 4 under constant
43 conditions. Wound healing progress, material exposure or other complications were
44 monitored daily. Body weights were monitored regularly to ensure proper feeding before and
45 after surgery. Mice were euthanized at the end of the eight-week intervention period, i.e., at
46 the age of 18 weeks.

2.8. *Micro-X-ray computed tomography (Micro-CT) examination of samples.*

For bone regeneration exploration, mice were anesthetized (isoflurane, induction at 2–2.5 % under airflow of 0.8–1.5 L.min⁻¹; 11.5 % under 400–800 mL.min⁻¹ thereafter) and were imaged using an X-ray micro-CT device (Quantum FX Caliper, Life Sciences, Perkin Elmer, Waltham, MA) hosted by the PIV Platform, URP2496, Montrouge, France. The X-ray source was set at 90 kV for the voltage and 160 μ A for the intensity. Tri-dimensional images were acquired with an isotropic voxel size of 20 μ m. Tri-dimensional rendering was subsequently extracted from DICOM image stacks using CTvox rendering software (v3.3.1, Bruker microCT). Before quantification, image stacks were reoriented using DataViewer (Skyscan, release 1.5.6.2, Kontich, Belgium) to the center of the defect. Then, quantification of the regenerated bone was performed with a cylindrical shape volume of interest of 3.5 mm of diameter and 1 mm height, using CT-Analyzer software (Skyscan, release 1.20.8.0, Kontich, Belgium). An adaptative thresholding was performed with a radius of two, between 364.34 and 560.82 mgHA.cm⁻³ (HA: Hydroxyapatite). To reduce background, open/close morphological operations (radius = 1) were performed on the segmented bone. Bone volume fraction BV/TV (BV: Bone volume and TV: Total volume) (%), total porosity (%) and Bone Mineral Density (BMD, mgHA.cm⁻³) were used to quantify and characterized newly repaired bone. Since the regenerated bone is mainly a compact bone, trabecular thickness Tb.Th (mm), trabecular number Tb.N (one per mm) and trabecular separation Tb.Sp (mm) were not described as they apply to trabecular bone only⁴⁸.

2.9. *Histology, histomorphometry*

At two months, mice were sacrificed for histological analysis. Half heads were fixed for 36 hours in 4% paraformaldehyde at 4°C under constant agitation. After preservation only of the calvaria and adjoining brain, the hard tissue demineralization was obtained using a microwave (KOS, Milestone, Shelton, CT, USA) in a 4.13% EDTA (pH 7.4) solution changed every 2 days for 2 weeks. The samples were subsequently embedded in Diawax (Diapath), serial sagittal sections of 5 μ m were cut with a microtome. Deparaffinized sections were stained with Masson's trichrome.

1
2
3 The remaining two-months non-decalcified samples were fixed in 70 % vol/vol ethanol for
4 24 h at 4°C, dehydrated in graded ethanol solutions and embedded at -20 °C in methyl-
5 methacrylate resin (Merck & Co., Whitehouse Station, NY). Five- μ m thick deplastified calvaria
6 bone sample sections were sequentially cleared in an alcohol gradient and in water then
7 stained with von Kossa staining or processed for alkaline phosphatase (ALP) enzyme-
8 histochemistry and for tartrate-resistant acid phosphatase (TRAP) revelation⁴⁹. Von Kossa
9 staining was used to visualize mineralized bone by using silver nitrate (Sigma). TRAP was
10 detected by using Naphtol ASTR phosphate (Sigma) and Fast Red TR Salt (Sigma) to reveal
11 osteoclasts; non osteoclastic acid phosphatase was inhibited by adding 100 mM L(+)-tartaric
12 acid (Sigma, St Louis, MO) to the substrate solution. ALP was detected by using Naphtol ASTR
13 Phosphate, NN-Diméthylformamide, Fast Blue RR Salt and MgCl₂.

14

Second harmonic generation microscopy offers the possibility to image collagen without
staining, as previously described⁵⁰. The calvaria imaging was performed using a multiphoton
inverted stand Leica SP8 DIVE microscope (Leica Microsystems GmbH, Wetzlar, Germany)
located at the IMAG'IC core-facility at the Institut Cochin, Paris. The laser source used for
generating second harmonic (SHG) and two photon-excited fluorescence (TPEF) signals was a
Ti:Sapphire Chameleon Ultra (Coherent, Saclay, France) tuned at 810 nm. The laser beam was
circularly polarized, and excitation and collection of SHG and TPEF signals were performed
using a Leica Microsystems HCX IRAPO 25 \times /0.95 W objective. Signals were detected in epi-
collection using 405/15 nm and 525/50 bandpass filters, respectively, by NDD PMT detectors
(Leica Microsystems) with a constant voltage supply. LAS X software (Leica, Germany) was
used for laser scanning control and image acquisition.

2.11. Confocal microscopy

1
2
3 Imaging was performed using a Leica Microsystem SP8X confocal microscope (Leica
4 Microsystems GmbH, Wetzlar, Germany) located at the IMAG'IC core-facility at the Institut
5 Cochin, Paris, with a x20 objective (0.75NA, dry), an image size of 512x512 pixels, a Z step of
6 2 μ m, an excitation wavelength of 565nm with a 5% gain and a detection range between 578
7 and 610nm. Z acquisition was performed over 500 μ m. LAS software (Leica, Germany) was
8 used for laser scanning control and image acquisition.

18 2.12. Statistical analyses

19
20 Numerical variables are expressed as the mean \pm standard deviation (SD). The statistical
21 analyses were performed using Prism software version 9.0.2 (GraphPad software, La Jolla, CA).
22 The normality of the distribution was tested with the D'Agostino Pearson omnibus normality
23 test and the homogeneity of variance was tested with the Fisher F test. For multiple
24 comparisons, when data was following a normal distribution with variances significantly
25 different between groups, a Brown-Forsythe and Welch ANOVA parametric test allowing the
26 comparison between more than two independent samples was performed. If the distribution
27 was not following a normal distribution, a Kruskal-Wallis test was performed. For in vivo
28 experiments, as two defects were performed for each animal, the bone defect was considered
29 as the statistical unit. Differences were considered significant at $P < 0.05$. A Šídák's multiple
30 comparisons correction was performed for multiple comparisons.

44 3. Results

45 3.1. Scl-Ab loading and release from DCH

46
47
48 Collagen hydrogels prepared from 1 mL solution at 1.6 mg.mL⁻¹ of collagen were densified
49 by plastic compression^{28,44}. Before compression, the hydrogels (n=4) had a mean base
50 diameter of 15.4 \pm 0.6 mm and mean thickness of 2.5 \pm 0.2 mm. After compression, there was
51 no significant change in the gel diameter (16.0 \pm 0.5 mm). The thickness was significantly
52 different with a *ca.* 11-fold reduction (0.23 \pm 0.02 mm) (Fig. 1A, S1A, S1B). The mean volume
53 of the hydrogels before plastic compression was 410 \pm 40 mm³ compared to the initial volume
54 of 1000 mm³ before gelling. The mean volume of the DCH (after compression) was 60 \pm 20
55
56
57
58
59
60

1
2
3 mm³ (Fig. 1B). This corresponds to a final collagen concentration of 23 mg.mL⁻¹ in the DCH.
4
5 SEM imaging showed that the uncompressed hydrogel consisted in a highly porous fibrillar
6
7 network. After compression, the porosity decreased without modification of the fiber
8
9 diameter (50 ± 10 nm) (Fig. 1C).

10
11 Confocal imaging showed a homogeneous spatial distribution of labelled Scl-Ab within the
12
13 Hd DCH, accounting for 5% of the image area (5% in the initial solution), with the presence of
14
15 focal dots and aggregates. (Fig. 1D). In sharp contrast, no signal was found in the absence of
16
17 Scl-Ab (data not shown).

18
19 Increasing amounts of Scl-Ab were introduced in the collagen solution after neutralization.
20
21 As seen in Fig.1D, the amount of loaded antibody in the final DCH increased linearly with initial
22
23 antibody amount until reaching a plateau for an initial antibody amount of *ca.* 1 mg leading to
24
25 *ca.* 0.2 mg of Scl-Ab within the DCH (Fig. 1E). Based on these results, two concentrations were
26
27 selected for the rest of the study: (a) one before the plateau, at 0.2 mg.mL⁻¹ in the initial
28
29 solution, corresponding to 0.008 mg in the DCH (low dose, Ld) and (b) one at the beginning of
30
31 the plateau, at 2 mg.mL⁻¹ in the initial solution, corresponding to 0.2 mg in the DCH (high dose,
32
33 Hd). Concentration exceeding 2 mg.mL⁻¹ (Hd) in the initial solution were considered to create
34
35 a DCH with an unpredictable final Scl-Ab content as suggested by the large standard deviation
36
37 of the measurements.

38
39 Regarding the release kinetics of the antibody from the DCHs in a PBS solution at 37°C, a
40
41 burst occurred in the first 9 hours to reach a plateau asymptotic to the initial loading, 0.008
42
43 mg and 0.2 mg for (a) and (b), respectively. Sampling was stopped at 24 hours for the Ld
44
45 hydrogel because the plateau was reached as soon as the 9th hour, at least in the sensitivity
46
47 range of the ELISA (Fig. 1F).

50 3.2. *Scl-Ab loaded DCH implantation potentiates the outcomes of bone reparation* 51 52 *strategy.*

53
54 A first *in vivo* experiment was designed to test the efficacy of the two different Scl-Ab
55
56 loadings, 0.2 mg.mL⁻¹ (Ld) and 2 mg.mL⁻¹ (Hd), within acellular DCH (Fig.2). Four-mm-DCH cut
57
58 from the main DCH were implanted in mouse calvaria critical defects and bone formation was
59
60 monitored for 2 months. Defects filled with acellular Scl-Ab-loaded DCHs were compared with

1
2
3 either empty defects or defects filled with unloaded acellular DCH (Fig. 2A). Micro-CT follow-
4 up revealed an almost complete closure of the defects in mice treated with the Scl-Ab-loaded
5 DCH at high dose at 60 days compared with the other conditions, getting closer to the sham
6 (Fig. S2A). Quantitative analysis of bone formation showed that the BV/TV was significantly
7 higher for the Hd DCH condition compared to (a) the Ld DCH, (b) the DCH alone condition (at
8 60 days: $11 \pm 4 \%$ vs (a) $9 \pm 4 \%$, $p < 0.05$, vs (b) $6 \pm 3 \%$, $p < 0.001$), and to the empty defect (at
9 30 days, $1 \pm 1 \%$, $p < 0.01$; at 60 days: $2 \pm 1 \%$, $p < 0.0001$) (Fig. 2B). In contrast, no significant
10 difference was found between Ld DCH and DCH alone, whereas at both time points,
11 significantly increased bone formation was found in these two conditions compared to the
12 empty defects. Similar results were found for bone mineral density (Fig. S7A) and for bone
13 total porosity (Fig. 2C). Both micro-CT and histology analysis revealed that, in DCH groups,
14 bone formation occurred mainly within the hydrogel, with sparse formation from the edges
15 of the defects. In the Hd DCH, the resulting mineralized tissue was histologically comparable
16 to a fully functional bone (Sham condition, Fig. S2B and C), with organized layers of collagen,
17 bone marrow and red blood cells, osteocytes within the mineralized matrix and the gradual
18 resorption of the DCH (Masson trichrome – Fig. 2D, SHG – Fig. 2E and S3), bordering
19 osteoblasts (ALP activity) with an osteoid matrix, and osteoclasts (TRAP activity) (Fig. 2F). In
20 the Ld DCH and DCH alone groups, the remaining DCH was surrounded by either newly formed
21 bone or cell-rich connective tissue (Fig. S4).

3.3. *Addition of mDPSCs within the Scl-Ab loaded DCH does not improve bone healing*

22
23
24
25
26
27
28
29
30
31
32
33
34
35
36
37
38
39
40
41
42
43
44
45
46 We next assessed whether the addition of mDPSCs within the DCH, either with or without
47 antibody, would improve bone formation within the defects, compared to the acellular Hd
48 DCH (Fig. 3A). At both time points, a significant ($p < 0.05$) and very significant ($p < 0.01$) higher
49 BV/TV was calculated in the acellular Hd DCH group compared to the three cellularized DCH
50 conditions (Fig. 3B). Similar results were found for the total bone porosity (Fig 3C) and for bone
51 mineral density (Fig. S7B). Histological analysis of the newly formed mineralized tissue at 60
52 days revealed a functional bone tissue in the four conditions (Fig. 3D and S5), with enhanced
53 ALP and TRAP activities around the bone repaired area (Fig. 3E). However, in the mDPSCs-
54
55
56
57
58
59
60

1
2
3 seeded DCH conditions, non-mineralized DCH areas were colonized by elongated cells that
4 followed the orientation of the collagen fibers, whereas, in the acellular condition, the non-
5 mineralized DCH areas were deprived of cells (Fig. S6).
6
7
8
9

10 3.4. *In vitro studies of SclAb – mDPSCs interactions within the DCH*

11
12
13 As bone formation was not improved by the addition of mDPSCs, we assessed whether the
14 addition of the antibody altered either cell survival or proliferation within the DCH by *in vitro*
15 experiments. The live/dead assay at 24 hours presented no significant difference between
16 mDPSCs-seeded DCH loaded with 0.2 and 2 mg.mL⁻¹ Scl-Ab (dead/live cell ratio of 0.05 ± 0.05,
17 0.4 ± 0.2 and 0.03 ± 0.02, respectively) with a homogeneous cell repartition for both dead and
18 living cells (Fig. 4 A and B). Alamar Blue assay presented no significant difference at 0, 7, 14,
19 21 and 28 days, with a mean reduction rate between 30 and 40 % (Fig. 4C). We also
20 hypothesized that the presence of mDPSCs may influence the release of the Scl-Ab from the
21 DCH. However, no significant difference was found between the release kinetics profiles in Hd
22 DCH and mDPSCs-Hd DCH (Fig. 4D).

33

34 3.5. *Scl-Ab loaded DCH are as efficient as non-loaded DCH associated with Scl-Ab IV* 35 *injection.*

36
37
38 Ultimately, we sought to compare the effect of the local delivery of the antibody versus its
39 systemic injection previously reported in Maillard et al³⁹. For this purpose, bone formation
40 within defects filled with acellular Hd DCH was compared to defects filled with acellular DCH
41 combined with weekly injections of Scl-Ab. MicroCT analysis did not reveal significant
42 difference between the two groups at both 30 and 60 days (BV/TV: 9 ± 4 % vs 10 ± 5 %, porosity
43 91 ± 4 % vs 90 ± 5 % respectively) (Fig. 5A, B and C). Same results were found for bone mineral
44 density (Fig. S7C). Masson-trichrome staining showed a well-organized fully functional bony
45 tissue (Fig. 5D), with a high osteoblast activity and osteoclast activity within the defects of
46 both conditions (Fig. 5E) and parallel layers of collagen (SHG – Fig. 5F).

56 4. Discussion

57
58
59
60

1
2
3 Craniofacial lesions constitute a major public health issue as they are source of disabilities
4 for patients and are very costly for health care systems⁵¹. There is a real need to develop
5 innovative treatments to repair these lesions, especially in the growing field of tissue
6 engineering^{52,53}. Inhibiting Sclerostin is one of the therapeutic approaches currently
7 developed for the treatment of unbalanced bone remodeling conditions³⁵. Setrusumab
8 (BPS804) is one of these anti-Sclerostin monoclonal antibodies. It has been granted Rare
9 Pediatric Disease Designation by the FDA for osteogenesis imperfecta treatment and was
10 evaluated in a randomized phase 2a trial for this disease³⁶. Another anti-sclerostin monoclonal
11 antibody, Romozosumab, has already been FDA and EMA-approved to treat osteoporosis^{54,55}.
12 In the craniofacial bone context, we have previously reported that the systemic injection (IV)
13 of Scl-Ab enhanced bone regeneration in critical size defects filled with dense collagen
14 hydrogels, either acellular or cellularized with DPSC³⁹. However, the weekly injection of
15 monoclonal antibodies is expensive, may not be devoid of side effects, and seems difficult to
16 promote for the treatment of a localized, even extensive, bone defect³⁵. The aim of this study
17 was therefore to assess whether the loading of Scl-Ab directly within dense collagen
18 hydrogels, allowing for local delivery of these antibodies, could improve their bone
19 regeneration capacity.
20
21
22
23
24
25
26
27
28
29
30
31
32
33

34
35 The design of hydrogels for the delivery of monoclonal antibodies has so far mainly
36 considered these hydrogels as temporary supports for the delivery of the therapeutic
37 molecule^{23,40}. However, in the case of bone repair, these hydrogels must also play the role of
38 a scaffold to fill the defect until new bone formation occurs. In particular, the possibility of
39 using such scaffold for a dual function, *i.e.* antibody delivery and cellular hosting, in the context
40 of tissue engineering has, to our knowledge, not been investigated so far.
41
42
43
44
45

46
47 In this context, type I collagen hydrogels appear particularly suitable as they are widely
48 used for bone tissue engineering, most often in combination with bioactive particles, such as
49 hydroxyapatite or bioglass⁵⁶⁻⁵⁸. However, collagen physical hydrogels are known to be poor
50 drug delivery systems, mainly due to their high porosity and rapid biodegradation, at least at
51 low density^{59,60}. To address these issues, chemical modifications of the collagen fibers to
52 enhance their affinity for the drug or even to achieve their covalent grafting, have been
53 described^{61,62}. Here, we hypothesized that using dense collagen networks exhibiting smaller
54 pore size and slower biodegradation rates could improve their suitability as delivery systems.
55
56
57
58
59
60

1
2
3 However, only few methods leading to dense collagen hydrogels (DCH) are also compatible
4 with cell encapsulation^{25,63,64}. Among them, the plastic compression process has been shown
5 to be effective hosts for a large number of cells^{29,65–69}. In particular, it was shown to be
6 compatible with the 3D immobilization of DPSC, that exhibiting mineralization capacity in vitro
7 and bone repair activity in vivo^{15,24,39,44}. However, the use of DCH for the delivery of antibodies
8 or any other type of protein has not yet been described in the literature.
9

10
11
12 For the present project, as a first step, plastic-compressed collagen hydrogels appeared to
13 be the most reproducible approach to deliver the monoclonal antibodies, while promoting
14 bone formation^{65,70,71}. Other materials have been used previously to design scaffolds for
15 delivery of biomolecules and enhancement of bone repair, such as hyaluronic acid (HA),
16 chitosan, alginate, or a combination of these^{20,72}. Collagen-based hydrogels have been shown
17 to promote cell invasion compared to hyaluronic acid-based hydrogel⁷³. Chitosan hydrogels
18 were shown to require fine-tuning of their degradation rate to promote bone repair⁷⁴,
19 whereas DCH appeared to be less sensitive to initials conditions⁶⁵. In the event of scaffold
20 contamination during implantation, collagen naturally degrades, unlike non-absorbable
21 materials such as alginate^{75,76}, which require surgical removal⁷⁷. In the future, it will be
22 important to test these materials associated or not with DCH in order to better control the
23 delivery of the monoclonal antibodies.
24
25
26
27
28
29
30
31
32
33
34
35

36
37 Here, structural investigations of the hydrogels before and after compression have
38 evidenced that the densification process leads to a decrease in the collagen network volume
39 by a factor of *ca.* 10. At the same time, the amount of antibody within the collagen gel at
40 saturation decreased by a similar factor. This suggests that the antibody did not interact
41 significantly with the collagen fibers but rather remained located within the pores of the
42 hydrogel. The spatial distribution of the antibodies supports this hypothesis, as they were not
43 distributed along the collagen fibers, but rather in dots or clusters with a uniform repartition.
44 Even though SEM images suggest a decrease in collagen network porosity after compression,
45 observable mesh size remains above several hundred nanometers, i.e. much larger than the
46 dimensions of antibodies (*ca.* 10 nm). As a result, the delivery process should occur by a simple
47 diffusion process, explaining the observed burst effect.
48
49
50
51
52
53
54
55
56
57

58 The optimal response was obtained with the highest concentration of the antibody. In this
59 condition, as well as in all other conditions where DCH was implanted, bone formation was
60

1
2
3 initiated within the hydrogel, from its border to its center. Whenever mineralization occurred
4 within the DCH, the new tissue displayed all the characteristics of bone tissue including
5 organized layers of collagen, osteoclast and osteoblast activity and robust well-distinguishable
6 vascularization, albeit at a much higher level with antibody-loaded DCH.
7
8
9

10
11 Eventually, we have shown that there was no significant difference in bone reparation
12 between the use of the antibody loaded DCH and the DCH alone with intravenous injection of
13 the antibody. In the IV group, a total of 12 mg of antibody was used per mice (50mg/kg for a
14 30 mg mouse, once a week over 2 months) compared to 0.025 mg per mouse in the Scl-Ab
15 loaded DCH group, delivered as a single dose. This very significant dose reduction should limit
16 reported side effects^{35,78,79}. Moreover, even if the encapsulation yield of the plastic
17 compression is low (*ca.* 10 %), the required antibody amount remains significantly lower than
18 for a systemic treatment, giving this method an economic advantage, especially to treat
19 localized bone defects, even critical.
20
21
22
23
24
25
26
27

28
29 Noticeably, seeding mDPSCs within the hydrogel did not improve neither bone formation
30 rate nor its quality compared to acellular DCH, even in the presence of the highest dose of the
31 antibody. mDPSCs with osteogenic orientation are supposed to provide growth factors that
32 will promote bone formation and to directly participate to bone repair by differentiating into
33 osteoblasts⁸⁰. However, regarding mDPSCs-seeded DCH, contradictory results are found in the
34 literature. On one hand, efficient bone repair was achieved after mDPSCs-DCH implantation
35 but the acellular scaffold had no significant bone healing capacity¹⁵. On the other hand, when
36 the acellular DCH alone did exhibit bone repair property, the addition of mDPSCs only slightly
37 improved bone formation³⁹. Here, the DCH alone showed some bone repair ability that was
38 greatly improved by the addition of the antibody alone. Thus, the released Scl-Ab seems to be
39 able to favor bone formation by interacting with the host cells at the vicinity of the defect.
40 Interestingly, another study comparing mDPSCs-seeded- and acellular bioglass-doped DCH
41 reported higher bone formation without cells⁸¹. Since the bone repair property of bioglasses
42 is also due to their ability to release bioactive species⁵⁸, they may also promote bone
43 formation by interacting with the surrounding tissue. Noteworthy, here, in the acellular gels,
44 scattered fragments of the implanted DCH were distinguishable and were devoid of cells
45 whereas, in the cellularized DCH, larger fragments of hydrogels were easily distinguished, with
46 cells oriented along the collagen fibers. This suggests that the implanted mDPSCs may
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 remodel the DCH and decrease its porosity, thereby delaying the mineralization process. In
4 contrast, in the looser acellular gels, host cells may be able to rapidly invade the implanted
5 scaffold and promote fast bone formation. Alternatively, more differentiated
6 osteoprogenitors or bone marrow stem cells might be compared to DPSC in the future in the
7 same model.
8
9
10
11

12
13 As a next step, it will be important to extend these experiments to more challenging in vivo
14 conditions. This study was conducted in a flat bone, which is not exposed to strong mechanical
15 constraints⁸². Thus our findings need to be evaluated in a more mechanically-challenged
16 bone, such as the mandible⁸³, which will require stronger scaffolds such as premineralized
17 collagen hydrogels. Furthermore, our experiments were conducted in young male mice with
18 an important healing potential. Our study must be repeated in both males and females as,
19 similarly to humans, female are more prone to fractures^{84,85}. More challenging systemic
20 conditions also have to be examined. Indeed, co-morbidities, such as diabetes, and poor
21 lifestyle (smoking or alcohol abuse, inactivity) increase the risk of delayed healing and non-
22 unions because of too poor and/or disrupted vascularization and an insufficient number of
23 skeletal progenitor cells. It remains to be determined whether, under these more demanding
24 conditions, (i) the local administration of the antibody still provides outcomes as positive as
25 the systemic treatment, (ii) the presence of MSCs could improve the healing process. In
26 parallel, increasing the Scl-Ab loading capacity of the DCH as well as achieving a better
27 temporal control of its delivery could further enhance bone regeneration. Further
28 improvement of the bone repair properties of the scaffold by incorporation of bioactive
29 particles can be also foreseen.

46

47 **5. Conclusion**

48
49 This study demonstrates that the local delivery of an anti-sclerostin monoclonal antibody
50 loaded in a dense collagen hydrogel can be as efficient the combination of the hydrogel with
51 IV injection of the antibody to promote robust craniofacial bone regeneration. In our context,
52 the addition of neural crest-derived mesenchymal stem cells did not further improve the
53 efficiency of the antibody-loaded hydrogel. The ease of preparation and use of these
54 biomaterials make them highly attractive candidates for rapid clinical application, particularly
55
56
57
58
59
60

1
2
3 for delayed bone repair after, for example, hemicraniectomy in young adults. Importantly, the
4 success of our strategy relies on the fact that the hydrogel plays a dual role, *i.e.* a scaffold to
5 temporary fill the bone defect and a reservoir for antibody delivery. This paves the way to the
6 design of improved biomaterials combining intrinsic bone repair capability and ability to
7 locally deliver monoclonal antibodies for the treatment of localized bone defects.

Figure legends.

Figure 1. Characterization of the collagen hydrogel before and after compression, distribution, loading capacity and release kinetics of Sclerostin-antibody. **A:** View in two-dimensions of the segmentation of a radio-dense hydrogel (addition of barium sulfate) before (left) and after (right) compression, showing that the hydrogel thickness is decreased but its diameter is preserved. **B:** Volume of the hydrogels after and before compression, indicating a 6-fold decreased (mm^3 , $n=8$). **C:** SEM images of the collagen hydrogel before and after compression, highlighting a decrease in porosity with no modification of fiber morphology. **D:** confocal imaging of Hd DCH with 5% labelled Scl-Ab showing clusters and focal points well-distributed all over the DCH ($n=1$). **E:** Scl-Ab loading in DCHs as a function of Scl-Ab mass in the initial solution, suggesting that the maximum loading capacity is reached for a starting 2 mg.mL^{-1} concentration ($n=2$ gels/condition). **F:** Release kinetics profile of Scl-Ab from DCHs with two different loadings, showing a rapid release over the first *ca.* 10 hours ($n=3$ gels for 2 mg.mL^{-1} condition, 2 gels for 0.2 mg.mL^{-1} condition, no significant difference at each time for each condition).

Figure 2: Evaluation of bone repair in the presence of Sclerostin antibody-loaded dense collagen hydrogels. **A:** Representative three-dimensional images of bone defects created in mice calvaria, in four conditions: left empty, filled with acellular hydrogel and filled with acellular Scl-Ab loaded (initial concentration: Ld: 0.2 mg.mL^{-1} , Hd: 2 mg.mL^{-1}) hydrogels after 30 days (D30, light color) and 60 days (D60, deep color), revealing an almost complete closure at D60 for Hd DCH. **B-C:** BV/TV (**B**) and porosity (**C**) evolution at 0, 30 and 60 days showing a significant difference at day 60 between the Hd DCH condition ($n=14$) and the empty ($n=6$), DCH alone ($n=12$) and Ld DCH ($n=16$) conditions. **D:** Masson's trichrome staining of a whole defect (coronal orientation) and magnified inserts (scale bar: $200 \mu\text{m}$). Light blue: remaining DCH, acellular; Green blue: Bone structure with organized layer of collagen, including osteocytes and vascularization (empty condition not shown, available in FigS2). **E:** SHG of a whole defect (coronal orientation) and a magnified insert of the Hd DCH condition. White arrow: organized layers of collagen **F:** Von Kossa, ALP and TRAP staining of representative histological sections. Whole defect (coronal orientation) (Von Kossa staining, scale bar: $200 \mu\text{m}$) and magnified inserts (scale bar: $20 \mu\text{m}$) showing the presence of a functional bone with

1
2
3 mineralized tissue (Von Kossa staining), osteoblast activity (ALP, purple staining), and
4 osteoclast activity (TRAP, red staining). Red arrows: osteoblasts associated to osteoid matrix
5
6 (light purple on Von Kossa).

11 **Figure 3: Evaluation of bone repair in the presence of dense collagen hydrogels seeded with**
12 **mDPSCs, with or without Sclerostin antibody. A:** Representative three-dimensional images
13 of bone defects created in mice calvaria, in four conditions: filled with acellular Hd DCH and
14 filled with *mDPSCs*-seeded unloaded DCH, Ld DCH and Hd DCH after 30 days (D30, light color)
15 and 60 days (D60, deep color), revealing limited bone formation at D60 for all cellularized
16 hydrogels. **B-C:** BV/TV (**B**) and porosity (**C**) evolution at 0, 30 and 60 days showing a
17 significantly lower repair for cellularized hydrogels (n=12, 10 and 14 for *mDPSCs*, *mDPSCs*-Ld
18 DCH and *mDPSCs*-Hd DCH conditions, respectively) compared to the acellular Hd DCH
19 condition (n=12). **D:** Masson's trichrome staining of a whole defect (coronal orientation) and
20 magnified inserts (scale bar: 200 μm), showing the presence of a bony structure with
21 organized layers of collagen, including osteocytes and few intra vascularization (only visible in
22 the Hd DCH and *mDPSCs*-Ld DCH conditions). **E:** Von Kossa, ALP and TRAP staining of
23 representative histological sections. Whole defect (coronal orientation) (Von Kossa staining)
24 and magnified inserts (scale bar: 200 μm), showing the presence of a functional bone with
25 mineralized tissue (Von Kossa staining), osteoclast activity (TRAP, red staining) and osteoblast
26 activity (ALP, purple staining).

44 **Figure 4: In vitro characterization of dense collagen hydrogels seeded with Dental Pulp Stem**
45 **Cells and loaded with Sclerostin antibody. A:** Live/Dead images of *mDPSCs* within unloaded
46 DCH, Ld-DCH and Hd-DCH after 24 h of culture. Green and red colors are for alive and dead
47 cells, respectively. Scale bar: 2 mm. Magnified insets (x4, 500 μm *500 μm) showing
48 homogeneous repartition of the living and dead cells in all conditions. **B:** Cell death ratio, as
49 calculated from the Live/Dead assay, indicating no significant difference after 24 hours of
50 culture among all conditions. **C:** Extent of Alamar Blue reagent reduction showing no
51 significant difference after 28 days of culture among all conditions. **D:** Cumulative release of

9

10 **Figure 5: Comparison of bone repair in local or systemic dispensation of the Sclerostin**
11 **antibody.** A: Representative three-dimensional images of bone defects created in mice
12 calvaria, in two conditions: filled with acellular hydrogels loaded at high dose (Hd DCH) and
13 filled with acellular unloaded hydrogels combined with weekly Scl Ab IV injection (inj), after
14 30 days (D30, light color) and 60 days (D60, deep color) revealing nearly complete closure in
15 both conditions at 60 days. **B-C:** BV/TV (**B**) and porosity (**C**) evolution at 30 and 60 days showing
16 no significant difference between Hd DCH (n=16) and DCH + inj (n=12) conditions (Dotted line,
17 sham surgery). **D:** Masson's trichrome staining showing a whole defect (coronal orientation)
18 and magnified inserts (Scale bar: 200 μ m), showing the presence of a bony structure with
19 organized layers of collagen, including osteocytes and vascularization. **E:** Von Kossa, ALP and
20 TRAP staining of representative histological sections (Scale bar: 50 μ m), showing the presence
21 of a functional bone with mineralized tissue (Von Kossa staining), high osteoblast activity (ALP,
22 purple staining), and low osteoclast activity (TRAP, red staining). **F:** SHG of a whole defect
23 (coronal orientation) and a magnified insert of the Hd DCH and DCH + inj conditions. Fibrillar
24 collagen is enhanced in red (Scale bar: 200 μ m).
