

Supplementary Material

Integrated multiscale analysis reveals complex gender-specific changes in lymphocytes of smokers

Anne-Cécile Ribou, Florence Riera, Fabienne Durand, and Laurent Henry

Table S1: Raw hematological data.

Measurements of the number of white blood cells (WBC), lymphocytes (LYMP), monocytes (MONO), granulocytes (GR) and platelets (PLT), together with measures on erythron variables: number of red blood cells (RBC), hemoglobin (Hb), hematocrit (Hct), mean corpuscular volume (MCV), mean cell Hb (MCH), mean cell Hb concentration (MCHC), RBC distribution width (RDW), and WBC/PLT ratio (PRL) in 33 donors the day of the collection.

Table S3: Cells imaging of lymphocytes.

First peak of the distribution (FI-1_{max}), mean of the total fluorescence intensity (MFI), and the standard deviation (SD) of fluorescent markers for the plasma membranes (Nil Red, NR) and the mitochondria (rhodamine 123, R123) give functional information. The illuminated pixel, related to the morphological parameters, of fluorescent markers staining the cell membranes (NR) and staining the nucleus (Hoechst 33342, Ho342) allows to calculate the FI-1_{max}, mean and SD of cell and nucleus surface, respectively. We also calculated these three parameters (FI-1_{max}, mean and SD) for the ratio cell area/nucleus area, Cell/Nuc. To consider the heterogeneity of the population, two parameters were calculated: the percentage of large cells (% Cell > 350 pixels), the percentage of cell with a small nucleus relative the cell surface (% Cell/Nuc > 3). The analyses were performed one day after blood collection.

Cell imaging: the triple labelling protocols

To record parameters related to lymphocytes morphology (cell and nuclear sizes) and functional information (level of mitochondria energetic state and amount, and properties of the plasma membrane), videomicrofluorometry associated to multiple labelling has been used.

1. Apparatus

The fluorescence digital imaging microscopy system (Salmon, 1992; Vigo, 1991) consists of an inverted fluorescence microscope (IMT2, Olympus, Rungis, France) equipped with an epi-illuminator, a 40X objective (NA 0.75) (Leitz, Rueil-Malmaison) and a Silicon Intensified Target (SIT) camera from Lhesa (Saint Quentin, France) coupled to a Matrox MVP-AT digitizing card (Matrox, Dorval, Canada). The mercury lines of a high-pressure mercury lamp (100 W) at 365 nm and 435 nm were selected by dichroic mirrors to selectively excite Ho342 and R123 or NR. A computer-controlled filter holder automatically stepped a filter depending on the specific fluorescence of the dyes: no filter for Ho342;

an interference filter $\lambda_{\text{max}} = 525 \text{ nm}$, half bandwidth = 10 nm for R123; and an interference filter $\lambda_{\text{max}} = 610 \text{ nm}$, half bandwidth = 20 nm for NR. A specific data acquisition program, which included the background subtraction, the correction of non-linearity of the digitizer and the pixel-to-pixel heterogeneity of the camera gain, allowed quantitative measurements of the fluorescence intensities of the dyes.

2. Cell labelling

A stock solution of Ho342 (1 mM) from Aldrich (Saint Quentin Fallavier, France) and R123 (0,1 mM) from Sigma (Saint Quentin Fallavier, France) were prepared in phosphate buffer saline (PBS) from ICN (Orsay, France) and kept at -20°C while NR (1 mM) from Sigma (Saint Quentin Fallavier, France) was prepared in ethanol from Merck (Nogent-sur-Marne, France) and stored at 4°C . Ten μl of Ho342 were added to 1 ml (1 000 lymphocytes) of cells suspended and incubated for 2 h at 37°C . After the first hour of incubation, 115 μl of R123 were added to the cell suspension. The cells were then incubated for 57 mn simultaneously with the two probes before 15 μl of NR were added. After the remaining 3 mn, the cell suspension was centrifuged and rinsed three times with 1 ml of Hank's balanced salt solution (HBSS) from ICN (Orsay, France). The cells were again suspended in 1 ml of HBSS and from this 300 μl were plated in Sykes Moore chambers for observation and numerical image multiparametric analysis.

3. Numerical image analysis

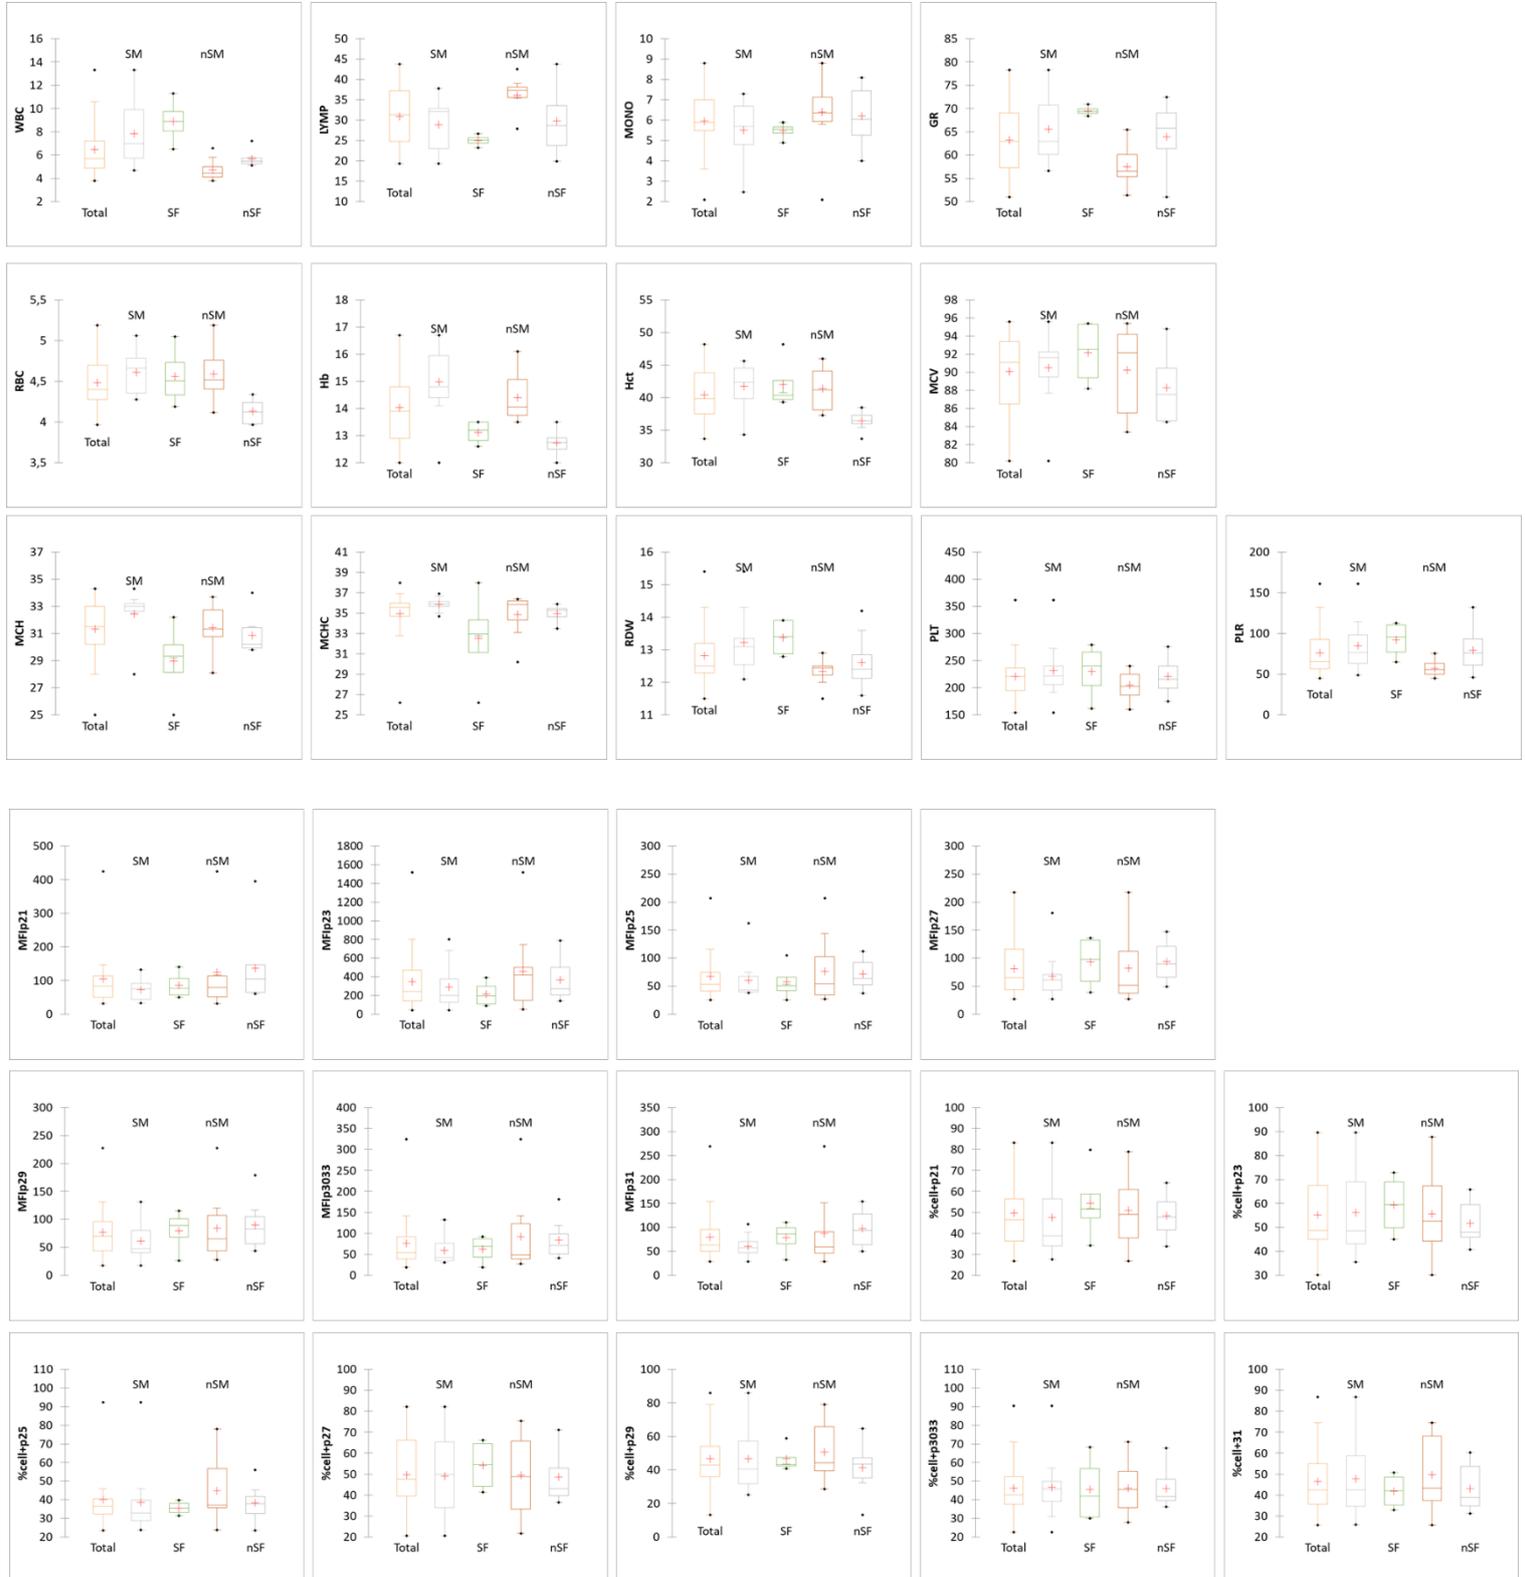

A protocol was developed to analyze the fluorescence of the three probes: Ho342-stained nuclei, NR-stained plasma membrane and R123-stained mitochondria. The NR fluorescence automatically provided the cell outline from an image segmentation using thresholding, followed by a cell contour smoothing from opening and closing sequences. NR fluorescence image of the cells was required as it allows the determination of the cell size from plasma membrane staining as well as determination of parameters related to the shape of the cells. Such parameters were necessary to exclude the data related to subcellular debris or cell clumps and gave an estimation of cell integrity. Because R123 fluorescence was heterogeneous as it is distributed in clusters, no segmentation was possible. The mask of each cell was then generated from NR fluorescence image and superimposed on the R123 fluorescence image of the corresponding cell, in order to delineate the cell contour in which the fluorescence of R123 was quantified after subtraction of the background corresponding to the fluorescence of the medium. Thresholding and contour smoothing by closing and opening sequences isolated the corresponding Ho342-stained nucleus. The fluorescence intensity parameters were normalized, using a reference standard, to compensate for mercury lamp fluctuations.

4. Parameters recording

The numerical image multiparametric analysis allows to evaluate cell and nucleus area and perimeter, shape factors, and fluorescence intensity parameters (total, mean and standard error) for Ho342, R123 and NR on about 200 cells. Then the properties of the lymphocyte populations were analyzed through cell population distribution histograms for each of the selected parameter. For each histogram we took the value of the maximum of the distribution ($FI-1_{\text{max}}$), the mean value (MTI) and the associated standard deviation (SD) in order to account for the distribution pattern as the lymphocyte population is heterogeneous. Due to their symmetry coefficient, not showing any significant variation, the nuclear labeling (Ho342 intensity and surface) were removed from this study.

Figure S1. Box plots of the 41 parameters. Donors were separated by gender and smoking status and compared with the total population. SM: smoking male, SF: smoking female, nSM: non-smoking male, nSF: non-smoking female. Cross (+): mean, ●: minimum/maximum. Marker abbreviations as shown in Table 2.

A. hematological data

B. Proteasome parameters.

C. Cells imaging of lymphocytes.

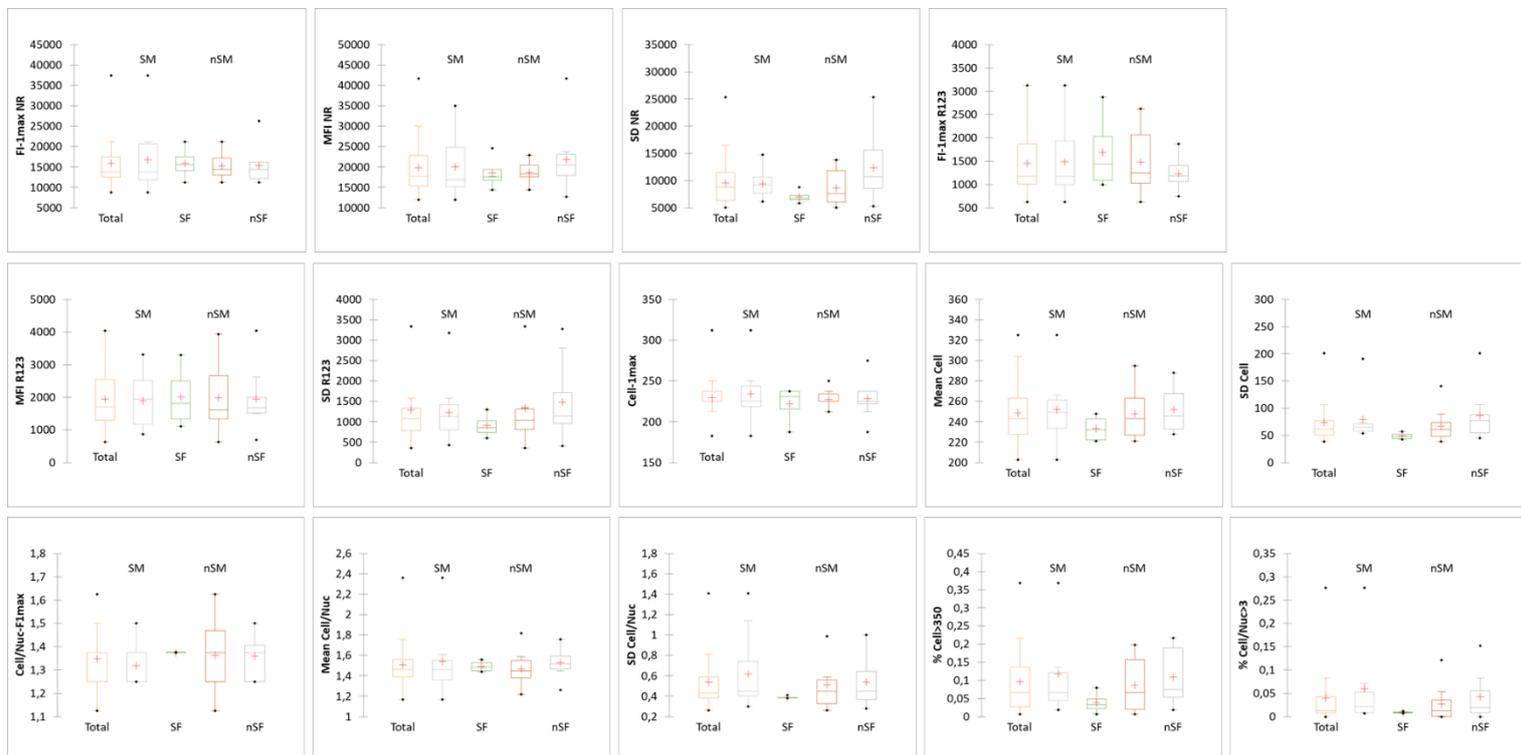

Table S4

Inter-population variations for the 41 parameters among the six sub-populations of donors, analyzed in pairs. Donors were grouped by smoking status (smokers vs. non-smokers separated or not (total population) according to sex), and gender (men vs. women according to their smoking habit). The mean and standard deviation (SD) for each sub-population are provided in Table 1. The comparison between two sub-populations is presented by (i) the variation, calculated using the equation $\% \text{ var} = (x-y)/\text{mean}(x,y)$, where x and y the parameters for smokers or males, and nonsmokers or females, respectively; and (ii) the adjusted p-value, calculated using the Benjamini & Hochberg false discovery correction procedure. Boldface indicates variation greater than 12%, and adjusted p-value less than 0.05.

Figure S2. DFA correlation circle of DFA performed with four groups for univariate and bivariate analyses.

DFA was performed to classified in four groups healthy donors ($n = 33$). DFA was run using “fixed class weight” option. The graphs present the correlation circle, parameters projection on the factor space (F1 and F2). (A) Proteasome and lymphocyte imaging data ($p = 28$), (D) Proteasome and CBC data ($p = 27$), (C) Lymphocyte imaging and CBC data ($p = 27$), (D) Only CBC data ($p = 13$). In these four DFAs, all the donors are correctly separated (training accuracy was 100%). We zoomed in to distinguished between parameters.

This representation can sometimes be used to identify groups characteristics according to parameters. No obvious information is gathered from these graphs, but all the CBC parameters, with the exception of PLT and MONO, are, for DFAs performed with hematogram data, the parameters closest to the circle, as expected according to the adjusted p-values presented in Table S4.

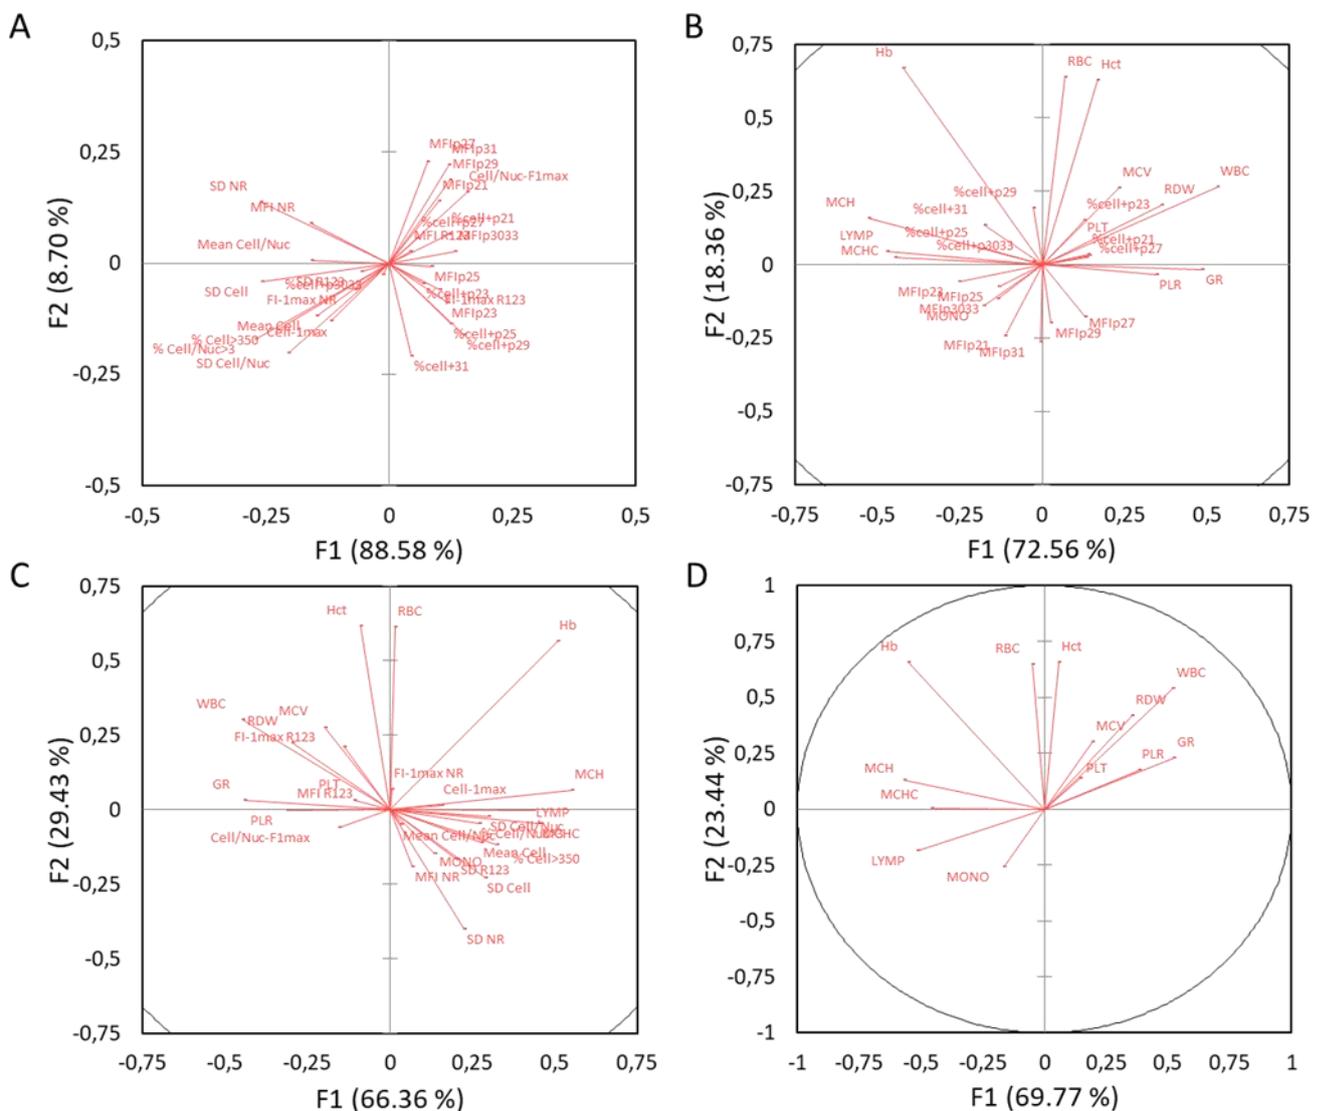

Figure S3. DFA classification into three sub-groups for univariate and bivariate analyses.

DFA was performed to classify healthy donors (n = 29) into three groups, excluding the four female smokers. Projection of donors on the two axes (F1 and F2), with confidence circles. SM: smoking male, nSM: non-smoking male, nSF: non-smoking female. (A) Lymphocyte-based approaches (imaging and cytometry) (p = 28), (D) Proteasome and CBC data (p = 27), (C) Lymphocyte imaging and CBC data (p = 27), (D) Only CBC data (p = 13).

For bivariable analyses, the training population showed 100% training accuracy and low validation accuracy (17%, 31% and 41%, for A, B and C, respectively). In contrast to the DFA performed on four groups, there are only two factorial axes, allowing the man to be separated according to their smoking habits. Hematological data alone (Figure D) give a training accuracy of 93% (validation accuracy 63%).

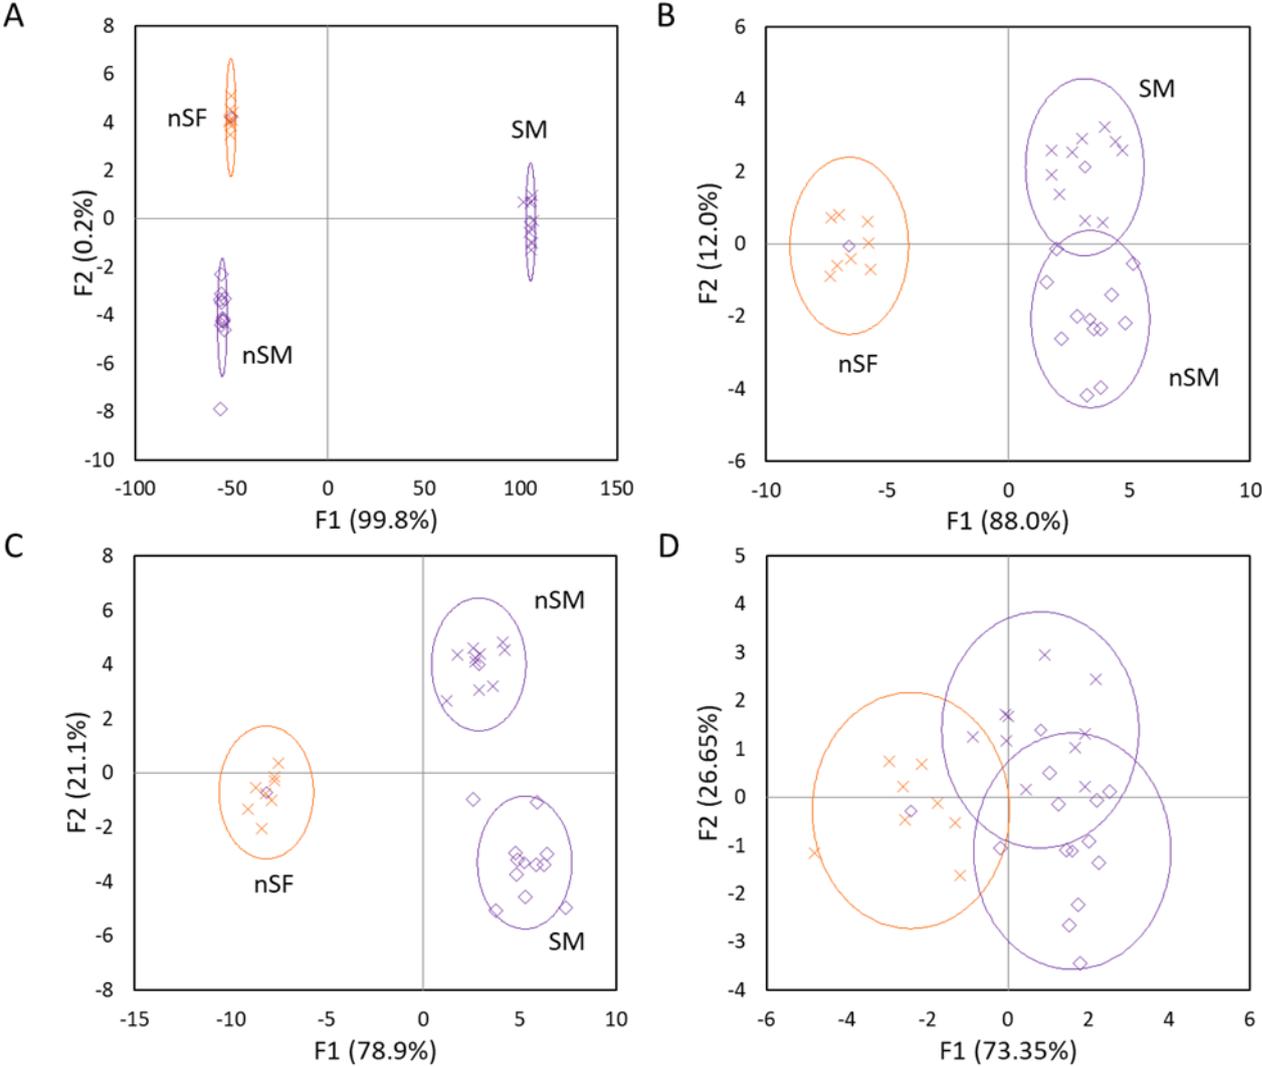

Table S5. Informative parameters selected from the three datasets by regression. Column 1: Ridge regression, Column 2: Lasso regression, Column 3: Elastic net regression with equal weight for Lasso and Ridge. The selected parameters were used in DFA with the donors divided in four and three groups (without female smokers). The results are presented as training accuracy (validation accuracy) in percentage.

Cell/Nuc-F1_{max} Mean Cell/Nuc SD Cell/Nuc % Cell>350 % Cell/Nuc>3		SD NR Cell/Nuc-F1_{max}		SD NR Cell/Nuc-F1_{max}	
MFip31		MFip31		MFip31	
RBC Hb Hct MCH MCHC RDW		Hb RDW		GR RBC Hb Hct RDW	

Ridge, Lasso and Elastic net regressions were tested by varying the partition until R^2 (coefficient of determination) was closest to 1 and MSE (mean square error) was minimized. R^2 indicated the goodness of fit of the model, while MSE reflected the model's predictive accuracy. The analysis involved 33 donors (four groups) and 29 donors (three groups). A compromise was chosen for Lasso regression with R^2 equal to 0.60 and MSE equal to 0.55 with a small lambda (0.02), resulting in the selection in of 5 parameters. Ridge regression, which was unaffected by partitioning, produced ten more adequate parameters with a lambda around 4 ($R^2 < 0.60$ and $MSE \approx 0.6$). Using Elastic Net regression, with equal weight for Lasso and Ridge, 7 parameters were identified, including one new parameter (GR), with a lambda around 0.2 ($R^2 = 0.62$ and $MSE = 0.5$). The differences observed when the four female smokers were removed were minimal. One donor, donor 16, was repeatedly misclassified. All parameters identified by these methods were already included in the final model, except for Cell/Nuc-F1_{max}.
