Abstract

Objectives

Histiocytic disorders are pathologic expansions of myeloid cells in multiple organs, including the CNS. They share activation of the MAP kinase pathway due to either *BRAF*^{V600E} variant or other variants in the RAS-RAF-MEK-ERK pathway. The rarity and heterogeneity of the disease only enable therapy through pathophysiologic considerations.

Methods

We present 2 histiocytosis cases without *BRAF* sequence variants that affect the CNS, one with Erdheim-Chester disease and the other with an unspecified histiocytosis, and their diagnostic and therapeutic challenges.

Results

In both cases, comprehensive analysis of the RAS-RAF-MEK-ERK signaling pathway secured the diagnosis. Treatment with the MEK inhibitor cobimetinib brought the disease to a complete halt. However, side effects such as thrombosis and serous macular edema made it necessary to reduce cobimetinib dosage. Low-dose cobimetinib maintenance medication was successful in preventing recurrence of histiocytic disease.

Discussion

CNS involvement of histiocytic disorders can lead to detrimental neurologic symptoms. MEK inhibitors are effective treatment options for some of these patients. Since side effects are common, according to our cases we propose a low-dose treatment of 20 mg per day to balance treatment effects with side effects.

Classification of Evidence

This case report provides Class IV evidence. This is a single observational study without controls.

Introduction

Histiocytoses encompass several rare conditions that can be best described as inflammatory myeloid-derived neoplastic disorders.¹ They are characterized by a proliferation of myeloid cells, mainly tissue-resident macrophages or dendritic cells, presenting with an inflammatory infiltrate that is mostly responsible for the organ-specific lesions and symptoms. Of 5 distinguished groups of histiocytosis, the most prominent "L" group consists of Langerhans cell histiocytosis and xanthogranuloma syndrome, both mainly affecting children, and Erdheim-Chester (ECD)

syndrome.² ECD represents a non-Langerhans cell histiocytic disorder with multiorgan infiltration of CD68⁺CD1a⁻ histiocytes. In up to 90%, sclerosis of the long tubular bones occurs, often without symptoms. CNS involvement occurs in 30%–50% of cases and is the main predictor of a poor prognosis.³ Patients with CNS-associated symptoms most often suffer from central diabetes insipidus, ataxia, nerve palsy, or cephalgia.¹ Up to 25% of patients develop exophthalmos due to retrobulbar infiltrates. Altered RAS-RAF-MEK-ERK signaling because of somatic variant of the *BRAF* proto-oncogene at the codon V600 (*BRAF*^{V600E}) is the most common genetic alteration associated with the disease.⁴ Detection of the variant is important as treatment options with *BRAF* inhibitors such as vemurafenib are available.⁵ For those 50% of patients with wild-type *BRAF*, clear treatment options are missing. Because histiocytic disorders have been proposed to be ERK-dependent, treating patients with *BRAF* wild-type histiocytosis with the MEK1/MEK2 inhibitor cobimetinib has been suggested⁶ and in few cases performed⁷ (eFigure 1). In this study, we present 2 patients with L-type histiocytosis with prominent CNS involvement and complete and long-term response to cobimetinib treatment.

Case Presentations

Case 1

In 2016, a 51-year-old man suffered a traumatic knee injury. Right knee MRI showed symmetric sclerosis of the femur, consistent with asymptomatic ECD. Four years later, he experienced dysarthria and dizziness, followed by ataxia and fine motor dysfunction. An MRI scan in March 2020 showed subcortical T2 lesions in the right superior frontal gyrus, right peritrigonal region, left centrum semiovale, and left central region as well as cerebellar and subcortical contrast

enhancement. MRI of the spinal cord showed no abnormalities. However, osteolytic lesions were found in the 10th thoracic vertebra. CSF analysis was without any pathologic findings. A vertebral biopsy confirmed ECD diagnosis, revealing foamy CD68-positive macrophage accumulation (Figure 1) and wild-type *BRAF*. Oral administration of cobimetinib 60 mg/d for 21 days followed by a 7-day break was started in May 2020. Because of diarrhea, treatment was reduced to 40 mg cobimetinib per day. Neurologic symptoms stabilized with medication. In early 2021, the patient experienced blurred vision in the left eye and was diagnosed with a central retinal vein thrombosis of the left retinal vein and cystic macular edema of both eyes. Assuming the symptoms were treatment-related, cobimetinib was stopped. In the following months, there was progressive gait instability and new MRI lesions. This led to a second treatment course in July 2022, which was subsequently discontinued because of persistent diarrhea. Cobimetinib was resumed in July 2023 at 20 mg/d with 7 days off per month; neither symptom, MRI progression, nor side effects occurred as of November 2023 (Figure 1).

Case 2

In 2016, a 39-year-old woman experienced menstrual irregularities and weight gain. A brain MRI identified a tumor located at the infundibulum of the pituitary gland. CSF revealed lymphocytic pleocytosis (63 cells/ μ L) and positive oligoclonal bands selectively in the CSF (type 2) without other pathologic findings. In the biopsy of the infundibular mass, cellular morphology was suspicious for a histiocytic tumor presenting a strong CD68 positivity. Lesions contained CD3-positive T cells, CD20-positive B cells, as well as a strong gliosis with GFAP and S100 reactivity. Phosphorylation of STAT1 and STAT3 led to the differential diagnosis of neurosarcoidosis.⁸ A thoracal and abdominal CT scan as well as

T2 FLAIR sequence in transversal orientation (A) before treatment with cobimetinib in 04/2019 and (B) under therapy with cobimetinib in 06/2023. (C) Contrast-enhanced (CE) T1 sequence in transversal orientation in 04/2019. (D) Strong reduction of contrast enhancement in CE T1 sequence in transversal orientation in 06/2023. (E–G) Cerebral tissue of histiocytosis not otherwise specified obtained by brain biopsy. (E) Morphological evidence for histiocytes in hematoxylin-eosin (H&E) staining as well as immunohistochemical detection of (F) CD186 and (G) phosphorylated ERK (pERK) suggesting a strong induction of the end stage of the RAS-RAF-MEK-ERK signaling pathway.

an FDG-PET remained without suspicious findings for metastases or lymphadenopathy. As cerebral lesions progressed to the left parahippocampal gyrus and temporal lobe, lacking tumor characteristics, but with signs of inflammation in the CSF, the patient underwent infliximab treatment from April 2017 to September 2017. Owing to progression, treatment was changed to rituximab for 2 cycles. However, neither rituximab nor steroids or tofacitinib were able to halt enlargement of the inflammatory mass. Infiltration of the optic tracts and chiasm caused bitemporal hemianopsia. In addition, hyperintensities on T2-weighted images with contrast enhancement in T1 appeared in the inferior third ventricle, medial part of the left temporal lobe, subcortical area of the right frontal lobe, and right cerebellum (Figure 2). Histology from the transsphenoidal tumor resection in 2019 was, again, suggestive of histiocytosis without further specification. Targeted NGS did not reveal oncogenic sequence variants; however, a strong phosphorylation of ERK was detected, indicating activation of the end-stage RAS/MEK pathway (Figure 2). This made histiocytosis, not otherwise specified, without the *BRAF*^{V600E} variant the most likely diagnosis. Cobimetinib treatment in March 2021 led to the regression of MRI lesions and contrast enhancement within 3 months. However, in April 2021, the patient developed dyspnea attributed to pulmonary embolism, prompting a reduction in cobimetinib dosage from 60 mg to 40 mg per day. In follow-up examinations, macula edema and reduction of cardiac functions were recorded. After remission of the tumor lesions, no new neurologic symptoms occurred. However, bilateral hemianopsia and reduced vision in the left eye remained, presumably because of irreversible damage during transsphenoidal surgery. Because the patient showed no signs of disease activity, the cobimetinib dose was further reduced to 20 mg/d in March 2023. Follow-up

brain MRI, in June and finally in December 2023, revealed no contrast enhancement or enlargement of lesions (Figure 2). No side effects were recorded.

Discussion

Both cases of histiocytic disorders without *BRAF* sequence variants that affect the CNS exhibit remarkable treatment responses to the MEK inhibitor cobimetinib, even at reduced dosage.

Histiocytosis with affection of the CNS is rare. To facilitate treatment based on the underlying pathophysiology, a comprehensive evaluation is necessary, encompassing clinical assessment, imaging, and histologic analysis.⁹ MRI lesions, particularly subcortical lesions in ECD, can be misleading and nonspecific. However, in the first case, CNS symptoms were preceded by bone abnormalities suggestive of ECD and confirmed by biopsy of the affected vertebra. In the second case, the findings were less clear, requiring the consideration of alternative diagnoses such as neurosarcoidosis and neoplasm. A brain biopsy revealed dysregulation of the RAS-RAF-MEK-ERK pathway. Because both patients lacked the *BRAF*^{V600E} variant, the analysis of ERK phosphorylation was decisive for treatment decisions.

In both our cases, cobimetinib resulted in clinical stabilization and reduction in CNS infiltrates. This aligns with a prior study where patients with histiocytosis were effectively treated using a MEK 1/2 inhibitor, irrespective of their *BRAF*^{V600E} variant status.⁶ However, in both instances, suspected side effects such as thrombosis and cystoid macular edema prompted a temporary halt and subsequent dose reduction, as previously described during cobimetinib treatment.^{10,11} MEK inhibitors have been

approved for use in various cancers and tumor predisposition syndrome.¹²⁻¹⁴ Because of the rarity of histiocytic disorders, there are no trials aiming for dose dependency of BRAF or MEK inhibitors, but it is well known that most patients treated with BRAF inhibitors relapse when treatment is stopped.^{15,16}

In conclusion, in these 2 cases of histiocytosis involving the CNS, even low-dose cobimetinib effectively mitigated the pathologic activation of the RAS-RAF-MEK-ERK pathway. This was recorded with clinical and imaging outcomes. Given the observed adverse effects, a general dose reduction in histiocytosis is warranted. Thus, we suggest a treatment approach of histiocytic disorders lacking the *BRAF*^{V600E} variant with cobimetinib 60 mg/d until remission, followed by maintaining the response with a low dose of 20–40 mg/d.
