30 Abstract

31 Plant phytoliths, which represent the main pool of silica (Si) in the form of hydrous Si
32 oxide, are capable of providing valuable information on different aspect of environmental issues
33 including paleo-environmental reconstruction and agricultural sustainability. Phytoliths may
34 have different chemical composition which in turn affects their preservation in soils ad impacts
35 terrestrial cycle of the occluded elements including micro-nutrients and environmental
36 toxicants. Yet, in contrast to sizable work devoted to phytoliths formation, dissolution and
37 physico-chemical properties, the mechanisms that control total (major and trace) elemental
38 composition remains poorly known. Towards assessing full elemental composition of
39 phytoliths from different plants, here we measured 45 major and trace elements in 9 samples of
40 grasses collected in northern Eurasia during different seasons, 18 grasses from Siberian regions,
41 and 4 typical Si-concentrating plants (horsetail, larch, elm and tree fern).

42 In the European grasses, the variations of phytolith chemical composition among
43 species were highly superior to the variations across vegetative season. Compared to European
44 samples, Siberian grass phytoliths were impoverished in Ca and Sr, exhibited similar
45 concentrations of Li, B, Na, Mg, K, V, Zn, Ni, Mo, As, Ba, and U, and were strongly enriched
46 (x 100-1000) in lithogenic elements (trivalent and tetravalent hydrolysates), P, Mn, Fe and
47 divalent metals. Overall, the variations in elemental composition between different species of
48 the same region were lower compared to variations of the same species from distant regions.

49 The main factors controlling phytoliths elemental composition are the far-range
50 atmospheric (dust) transfer, climatic conditions (humidity), and, in a lesser degree, local
51 lithology and anthropogenic pollution. Despite significant, up to 3 orders of magnitude,
52 difference in TE composition of grass and other plant phytoliths, the dissolution rates of grass
53 phytoliths measured in this study were similar, within the experimental uncertainty, to those of
54 other plants studied in former works. Therefore, elemental composition of phytoliths has
55 relatively minor impact on their preservation in soils.

57 1. INTRODUCTION

58 High importance of the biogenic cycle of silicon in terrestrial environments has been
59 widely recognized (Meunier and al., 1999; Conley, 2002; Derry and al, 2005). Dissolved silicic
60 acid, trapped by plant roots, precipitates in aerial tissues cells as micrometric opal particles
61 called phytoliths (Neethirajan et al., 2009; Guerriero et al., 2016; Hodson et al., 2016). Studies
62 on phytoliths have shown applications in various environment fields linked to ecosystems
63 services (Meunier et al., 2022; Hussain et al., 2023). Phytoliths are released during organic
64 matter degradation in the litter horizon and can be dissolved, preserved and transferred to deeper
65 horizons, or evacuated by aerial or hydrographical ways (Bartoli, 1981; Piperno, 1988;
66 Kaczorek et al., 2019). The dissolved (water-labile) fraction constitutes a pool of Si that is easily
67 available for plants (Shaller et al., 2019). Silicon bioavailability is a topic of increasing interest
68 because of the positive impact of Si on sustainable agriculture (Liang et al., 2015). The fraction
69 that is preserved from dissolution can be used as a proxy for palaeoenvironments (Cabanès,
70 2020). Understanding the reactivity of phytolith is therefore essential for predicting the
71 behaviour of phytoliths in the environment.

72 Experimental studies on the dissolution rate of natural phytoliths demonstrated their
73 similarity to quartz and amorphous silica, with a minimum in acidic solutions and in increase
74 in dissolution rate with pH in neutral and alkaline solutions (Frayssé et al., 2006 a, b; 2009;
75 2010). However, while the reactivity of phytoliths is relatively well characterized, it is not so
76 for their elemental composition and the role that incorporated metals exert on phytoliths
77 dissolution behaviour. Besides Si, some major and trace elements can be trapped in phytoliths
78 (Hodson, 2015) but their effects of phytolith reactivity as well as their role in tracing soil and
79 plant type remain poorly assessed. Carbon trapped in phytoliths has been first measured by
80 Jones and Beavers (1963) which is widely used in the field of phytolith dating and carbon
81 sequestration (Santos et al., 2012; Li et al., 2013; Hodson, 2018). Nguyen et al (2015) showed

82 that potassium (K) incorporated into phytoliths might affect the fertility of soils. Aluminium
83 (Al) is also occluded in phytoliths but the effect of Al on phytolith reactivity is controversial
84 (Frayse et al., 2009; Li et al., 2014). Carnelli et al (2002) found that woody taxa contain higher
85 concentration of Al suggesting applications in paleo-vegetation studies. Metals such as Cu and
86 Zn have been shown to be encapsulated in phytoliths with consequences for their terrestrial
87 biogeochemical cycles (Nguyen et al., 2019; Tran et al., 2019). A few studies have tested the
88 hypothesis that the composition of multi-elements in phytoliths might be used for tracing of
89 environmental conditions (Cabanès, 2020; Hart, 2001; Li et al., 2020; Tan et al., 2022). Thus,
90 elemental composition of wheat and barley phytoliths has been reported to be strongly sensitive
91 to contaminations on the surface of the leaves and awns (Kameník et al., 2013; Wytténbach et
92 al., 2002; Kucera et al., 2007). In particular, Kameník et al. (2013) measured 30 major and trace
93 elements in barley's phytoliths and provided the relationship between phytoliths composition
94 and that of source plant materials demonstrating that phytoliths are significantly enriched in
95 terrigenous elements. Two studies characterized the distribution of multiple trace elements (Al,
96 Fe, Mn, Cu, Zn, Cr, Ni, Pb, As, Sn, Cd) in grass and shrub phytoliths within a mining
97 contamination context (Bujan et al., 2013; Delplace et al., 2020). The latter authors
98 demonstrated strong encapsulation in siliceous matrix of As, Cu, Mn, Pb and Zn, in contrast to
99 Cd, Sb and Sn which were prone to be concentrated in organic biomass. However, up to present
100 time, the variations of elemental composition of the same plant from different geographic
101 regions, non-affected by specific local pollution source, remain largely unknown. This does not
102 allow incorporating the role of phytoliths in overall biogeochemical cycle of trace element in
103 terrestrial plants. The first goal of the present study was a first-time assessment of large number
104 (about 50) of major and trace elements in phytoliths of typical grasses (Poaceae) of Northern
105 Eurasia, across seasons and geographical locations. We further compared the elemental
106 composition of grass phytoliths to that of other plants known to concentrate Si in their tissues

107 (horsetail, fern, larch, elm; Frayse et al., 2009). Via normalization to average earth crust
108 composition, we intended to assess elements that are preferentially enriched in phytoliths in
109 order to provide some insights into the biological (active or passive) concentration mechanisms.

110 Our second goal was to quantify the dissolution kinetics of previously unknown grass
111 phytoliths, and compare the rates with those already available for other plants. Here we intended
112 to relate the difference in elemental composition between different plants to phytoliths
113 reactivity (dissolution rates) in aqueous solutions. Taken together, the present study should
114 improve our capacity to use phytoliths for tracing TE migration in soil system and to relate the
115 phytoliths preservation ability in soil to their elemental composition.

116

117 **2. MATERIALS AND METHODS**

118 *2.1 Study sites and collected plants*

119 Five plant species growing on different soil, under various climatic conditions and
120 containing phytoliths have been investigated. The grass phytoliths belong to the same plant
121 family, *Poaceae* (formerly known as Graminae) are listed in the **Table 1**, and include wood
122 small-reed (*Calamagrostis epigejos*), rough small-reed (*Calamagrostis arundinacea*), reed-
123 mannagrass (*Glyceria maxima*), sweet vernal grass (*Anthoxanthum odoratum*) and common
124 reed (*Phragmites communis*). Included in this table also the climate parameters of the sampling
125 site, type of soil and its mineral substrate. The European grasses (samples E1 to E11) were
126 sampled in the boreal zone of Eastern Europe, between 1998 and 2003 during summer period
127 (June to August). This collection allowed testing 1) the variability of elemental composition
128 among several species (*P. communis*, *G. maxima*, *C. arundinacea* and *C. epigejos*), which were
129 sampled during the same period in the same place (West Dvina, July-August 1998); 2) the effect
130 of growth stage (beginning of June and end of June) for the same specie (*C. epigejos*) collected

131 in the same place, and 3) the variability of phytolith elemental composition of the same specie
132 (*C. epigejos*) collected across different regions.

133 The grasses from Siberia were obtained from Krylov's botanical collection of the Tomsk
134 State University and included *P. communis*, *C. arundinacea*, *C. epigejos*, *A. odoratum*, and *G.*
135 *maxima*. These samples were collected during July-August period, and included northern taiga,
136 forest-steppe and steppe biomes (between 51.4 °N and 62.0 °N) in the Krasnoyarsk, Omsk,
137 Tomsk, and Novosibirsk administrative regions, Baraba, Tuva, Buryatia, Altai, Yakutia (**Fig.**
138 **1, Table 1**). Grass phytoliths in this study are compared to phytoliths of horsetail (*Equisetum*
139 *arvense*), larch (*Larix gmelinii*), elm (*Ulmus laevis* Pall.), and tree fern (*Dicksonia squarrosa*)
140 that are known to concentrate Si in their biomass (Frayse et al., 2009).

141

142 2.2. Phytoliths extraction

143 All the manipulation were performed in a clean room class A10,000. Transferring solid,
144 solutions, and addition of chemicals was performed in the laminar hood box class A100. First,
145 dry plant material (10-20 g) was rinsed by Milli-Q ultrapure water, and then dried in an oven at
146 50°C. Afterwards, it was ground in an agate mill. Ashing of plant material was performed in a
147 porcelain crucible at 500°C for 8 hours. Note that calcination at 500 °C gives the best results
148 for phytolith extraction (e.g., Bujan, 2013). The ash (approximately 0.2 g) was then transferred
149 to polypropylene tubes, into which we added 10 mL of 10% ultra-pure bidistilled HCl to
150 dissolve all insoluble solid phase except silicon oxide. The content was heated in the water bath
151 at 70°C during 20 min, and then centrifuged at 3500 rpm for 5 min followed by decantation. To
152 remove the last traces of organic matter, we added 10 mL of ultra-pure 15% H₂O₂ and heated
153 the content in the water bath at 70°C during 20 min. Finally, the residual solid material was
154 rinsed with Milli-Q water via repetitive centrifugation at 3500 rpm during 20 min, and dried at
155 50°C during 48 hrs in an oven. The cleaned phytoliths were examined by scanning electron

156 microscopy (SEM) using a Jeol JSM840a, coupled with a SDD PGT Sahara EDS analyzer in
157 order to check the lack of contaminants and identify different morphotypes.

158 Phytoliths were extracted from plant material by dry ashing which is most efficient way
159 to remove organic matter (Parr et al., 2001a, b). These authors demonstrated that morphological
160 pattern of phytoliths (dimensions and curvatures) obtained via dry ashing (500 °C) and wet
161 (boiling) extractions are statistically identical. The dry ashing method of phytolith extraction
162 used in this study is not expected to produce any artefacts of preparation. Indeed, the electronic
163 microscopic observations of freshly extracted and reacted phytoliths did not reveal any heat-
164 generated smoothing and melting features on the surface. The X-ray diffraction analysis of our
165 phytoliths material did not demonstrate the presence of any crystalline phases. Moreover, a
166 thorough methodological work of Parr et al. (2001) demonstrated that phytoliths pattern
167 dimensions and curvatures preparations via dry (500°C) and wet (boiling) are statistically
168 identical and there is no detectable evidence of morphological impact as a result of these
169 methods. Recent results of Delplace et al. (2020) on grass phytoliths demonstrated a lack of
170 artefacts linked to organic matter presence in phytoliths which allows adequate assessment of
171 elemental composition of phytoliths prepared via dry ashing. At the same time, we do not
172 exclude some redistribution of metals (i.e., Zn) from the organic material to the silica, possibly
173 promoted by the release of structural water from amorphous opal throughout the heating
174 procedure at higher temperatures (i.e., at 700 °C; Sarret et al., 2022).

175 Further, we have to admit that there is no possibility of separating the phytoliths from
176 refractory silicate minerals which are insoluble in concentrated HCl at the stage of phytolith
177 extraction as described above. While these minerals are unlikely to be incorporated inside the
178 plant biomass, adventitious dust of atmospheric aerosols can be attached to the leaf surfaces
179 and not removed even after thorough water rinsing. Although the amount of these minerals is
180 negligible, given lack of their identification by XRD and SEM, they still are capable of

181 accommodating some trace elements which are unrelated to phytoliths per se. Use of refractory
182 elements without any physiological functions (Al, Ti, Zr), when interpreting the elemental
183 phytoliths after total acid leaching (see section 2.2 below), can help to resolve these possible
184 artefacts.

185

186 *2.3 Analytical methods*

187 For total Si content in the phytoliths, powdered sample (between 10 and 20 mg) was
188 entirely digested in 10 ml of 30% NaOH at 120°C during 2 h in closed Savillex Teflon vials,
189 then treated in ultrasonic bath for 2 h and heated again at 120°C overnight. The solution was
190 centrifuged and 1 ml of supernatant was then diluted in 10 ml of ultrapure deionized water and
191 acidified with bi-distilled HCl 10 N in a 1/1 (molar/molar) ratio. Total silica concentration in
192 phytoliths was measured using the molybdate blue method with High Resolution Digital
193 Colorimeter (Bran + Luebbe Auto-analyser III using control software AACE 6.03) with an
194 uncertainty better than 2% and a detection limit of 0.36 µM.

195 The mineralization of phytolith sample (between 15 and 30 mg) involved 0.5 ml of
196 Suprapur HF and 0.6 ml of bi-distilled 15 N HNO₃ which were added together in closed Teflon
197 vials in a class 10,000 clean room at the GET laboratory (Géoscience Environnement Toulouse,
198 France). The Teflon vials were heated on a hotplate located inside a polycarbonate chamber
199 (class A100 filtered air). International certified materials (2711a Montana II Soil standard or
200 LKSD sediment) were processed together with samples to account for accuracy of
201 measurements. Besides, the international geostandards of Apple Leaves SRM 1515 (from NIST,
202 USA), lichens BCR-CRM 482 (from BCR, Belgium), and Pine Needles SRM 1575a (from
203 NIST, USA) were used to check the efficiency of both the acid digestion protocol and the
204 analysis.

205 Major and trace elements concentrations in phytoliths were obtained via quadrupole
206 ICP-MS (inductively coupled plasma mass spectrometry, Thermo Scientific) at HSM
207 laboratory (HydroScience Montpellier, France) and GET Laboratory (Toulouse). To each
208 sample, ~3 µg/L of In and Re were added as internal standards. Four in-house external standards
209 were analysed every 10 samples. The uncertainty for TE measurement ranged from 5 % at 0.1–
210 100 µg/L to 10 % at 0.001–0.01 µg/L. The data tables present results for elements exhibiting a
211 good agreement between the certified or recommended values and our measurements (relative
212 difference expressed as $([X]_{\text{recommended or certified}} - [X]_{\text{measured}})/([X]_{\text{recommended or certified}} + [X]_{\text{measured}})/2$ * 100 lower than 10 %), or for cases where we obtain a good reproducibility
213 (relative standard deviation on our various measurements of standards lower than 10 %), even
214 if no certified or recommended data are available.

216 Blank tests indicated that the level of contamination induced by the acid digestion
217 procedure was negligible, < 2% of the sample element of interest. The international geostandard
218 SLRS-5 (Riverine Water Reference Material for Trace Metals certified by the National
219 Research Council of Canada) was used to check the validity and reproducibility of solution
220 analyses.

221

222 *2.4. Phytolith reactivity in aqueous solution*

223 Phytoliths dissolution rates were measured in batch reactors at 25°C in 0.01 M NaCl
224 solution. Phytoliths suspensions of 2.5 g/L were prepared in 100 mL polypropylene reactors
225 and dissolution rates were calculated by measuring dissolved silica concentration as a function
226 of time. The reactors were agitated on a Ping-Pong shaker (150 rpm). Typically, between 10
227 and 20 samplings were performed over elapsed time between 3 and 4 hrs. About 5 mL of
228 suspension was sampled under vigorous stirring, without changing the solid : solution ratio in

229 the reactor; the fluid was filtered through 0.22 μm acetate cellulose filter and stored in the
230 refrigerator pending spectrophotometric analysis of Si.

231 The dissolution rate of phytoliths (R , mol Si $\text{g}^{-1} \text{d}^{-1}$) was calculated from the slope of Si
232 concentration vs elapsed time ($d[\text{Si}]/dt$) following the equation:

$$233 \quad R = \frac{d[\text{Si}]}{dt} \times \frac{1}{m}$$

234 where m is the concentration of phytoliths in the reactor. Solution pH was measured using a
235 combination glass electrode (Mettler Toledo) calibrated with NIST buffers (pH 4.01, 6.86,
236 10.00 at 25°C), with an uncertainty of 0.01 pH units.

237

238 *2.5. Data treatment*

239 Statistical treatment of the data included mean values and their standard deviations (in
240 case of replicates and for calculating the mean concentrations of several species. Pairwise
241 (Pearson) correlations were used to assess the relationship between major and trace elements in
242 phytoliths, separately for European, Siberian grasses and other plants, as well as for the full set
243 of data. Further, a pairwise comparative analysis was run via non-parametric Mann-Whitney
244 test (U-test) to detect the differences in elemental composition of various species and the same
245 species from different locations, as well as between Si release rate from different phytoliths.
246 The level of significance was fixed at 0.05 (95% confidence level) to consider a result as
247 statistically notable. All plots were built using MS Excel 2016 and the Statistica-12 software
248 package (<http://www.statsoft.com>).

249

250 **3. RESULTS AND DISCUSSION**

251 *3.1 Phytolith morphology, total Si content in phytoliths and phytoliths's content in the*
252 *biomass*

253 The phytoliths preparation procedure employed in the present study yielded clean

254 particles of various size and forms without visible admixture of crystalline silicate minerals or
255 metal oxides, as also confirmed by EDX analyses of selected spots of the samples (**Fig. S1**).
256 The presence of organic residues could not be established by a thorough SEM examination.
257 Similar to former studies of phytoliths from soils (e.g., Kaczorek et al., 2019), several main
258 morphotypes were identified, such as globular, elongated, vascular, plain, porous, and
259 cratered/spongy. We could not detect clear difference in bulk chemical composition (Si, O, C,
260 Al, Fe, Ca) of phytoliths of different morphotypes via EDX probing (not shown). Although
261 some differences in elemental composition of different phytoliths could be present (e.g.,
262 Kaczorek et al., 2019), we used sizable amount of homogenized (pooled) phytolith particles
263 from each plant for total acid leaching. As such, we integrated several phytolith morphotypes
264 for each analysis and the obtained data for each species and each location can be considered as
265 integral values incorporating large number (> 20) of individual phytoliths.

266 Phytoliths content in the biomass ranged from 0.9 to 6.7% and 0.2 to 3.1% in European
267 and Siberian grasses, respectively (**Table 2**). This is similar to the values in trees (3.4 and 3.8
268 in larch and elm, respectively) but lower than that in typical Si-concentration plants such as fern
269 and horsetail (12 and 14 %, respectively). Other studies reported 1-3 % in dryland grasses and
270 up to 10-15% in some wetland plant species (Epstein, 1994), with a general range for plants of
271 < 0.1 to 10% Si in shoot dry matter (Epstein, 1999). Bujan (2013) reported the range of phytolith
272 content in Ericaceae leaves from 0.5 % in organic soils to 2.5 % in mine and serpentine soils.

273 The total Si concentration was quite similar in all phytoliths from Europe and ranged
274 from 1.26 to $1.52 \times 10^{-2} \text{ mol}_{\text{Si}} \cdot \text{g}^{-1}_{\text{phytoliths}}$. By considering an average of $(1.40 \pm 0.01) \times 10^{-2}$
275 $\text{mol}_{\text{Si}} \cdot \text{g}^{-1}_{\text{phytoliths}}$ for the $[\text{Si}]_{\text{total}}$ in phytoliths, this suggests 39.3 mass % of Si in phytoliths which
276 is in accord with Blecker et al. (2006) who estimated a value of 39.7% for Si content in
277 phytoliths of various plants. The phytoliths from Siberian plants exhibited much higher
278 variability of Si content (from 15.6 to 57.3 %), with an average value of 33.7 ± 10.1 %. Assuming

279 a phytolith formulae of $\text{SiO}_2 \times n\text{H}_2\text{O}$, this corresponds $n = 0.62$ to 1.28 (average 0.95), and
280 suggests, in accord with previous results (Frayse et al., 2009), that phytoliths of different plant
281 species have similar major composition.

282

283 *3.2. Phytoliths of European grasses: variations among species and across seasons and*
284 *sites.*

285 The variability of trace element (TE) composition of the same grass species from
286 different geographical (climate) zones were weakly pronounced, thus suggesting that element
287 concentration in phytoliths is their intrinsic, species-related property. Phytoliths chemical
288 compositions of different plant species sampled at the same time (July-August 1998) from the
289 same place (West Dvina, Russia) could be compared among samples E4, E7, E11 and E5
290 corresponding to *Phragmites communis*, *Glyceria maxima*, *Calamagrostis arundinacea* and
291 *Calamagrostis epigejos* (**Fig. S2**). One can note general similarity of elemental composition
292 with highest concentrations of Mg, Ca, Mn, Fe, Zn, Sr, Mo, Ba and U in all samples.

293 After normalization of phytolith composition to that of the upper crust (Rudnick et al.,
294 2004), an enrichment in Mg, Ca, and Sr appears (ratio phytoliths : crust > 1 , **Fig. S3**). The crust-
295 normalized rare earth elements (REE) patterns of phytoliths from different species are highly
296 variable with exceptional Eu enrichment of *C. epigejos* and *P. communis* and generally flat
297 pattern for other species (**Fig. S4**). Another comparison, for the same species sampled during
298 different vegetation period could be performed for samples E3 and E10 of *Calamagrostis*
299 *epigejos* from Yaroslavsk region (European Russia). There was no sizable difference in major
300 and trace element concentrations between these samples (**Fig. S5**).

301 Finally, the variations in elemental composition of phytoliths extracted from
302 *Calamagrostis epigeios* which was sampled during summer in different regions of Eastern
303 Europe, also demonstrated general similarity among sites, with highest concentration of Ca,

304 Mg, K, Sr, Ba, Fe, Mn, Zn, Ni, As, Mo and U (**Fig. S6**). An upper crust (UC) – normalized
305 pattern demonstrated slight enrichment of phytolith in Ca, and Sr and similarity of
306 concentrations in phytoliths and UC of Mg, Ga, As, and Mo (**Fig. S7**). All samples of
307 *Calamagrostis e.* exhibited an enrichment in HREE relative to LREE and a local Eu maximum
308 (**Fig. S8**).

309 Taken together, phytoliths of European grasses were rather similar among species
310 (**Table S1; Fig. 2A**), whereas, compared to UCC, their elemental pattern was similar in
311 concentrations of B, Na, Mg, Si, and Mo, strongly enriched in Ca, Se and Sr, and strongly (\times
312 10^3 - 10^4) depleted in lithogenic trivalent and tetravalent trace elements and divalent metals (**Fig.**
313 **2B**).

314

315 3.3. Elemental pattern of phytoliths from Siberian grasses

316 The phytoliths from Siberian grasses exhibited distinct difference in their elemental
317 composition from phytoliths of European Russia (**Fig. 3 and Fig. S9**). Siberian phytoliths were
318 strongly ($\times 10^2$ - 10^3) enriched in most lithogenic elements (Al, Ti, Cr, Y, Zr, Nb, REEs, Hf, Th)
319 but also macro- and micro-nutrients (P, Mn, Fe, Co, Ni, Cu, Zn, Rb), Cs and some trace
320 toxicants (Cd, Tl, Pb). At the same time, phytoliths from European grasses (*Phragmites*,
321 *Calamagrostis*) were sizably ($> \times 10$) enriched in Ca, Sr and Se, and exhibited comparable
322 concentrations of Li, B, Na, K, Mg, V, Zn, As, Mo, Ba and U.

323 Alike European samples, Siberian phytoliths had rather similar concentrations of all
324 major and trace elements across four studied species (**Fig. 3A**). The difference between species
325 was similar or inferior to the variation in elemental composition within the same species. The
326 latter typically achieved a factor of 2 to 3, although for phytoliths of *Calamagrostis epigejos*,
327 this difference for many elements reached a factor of 5 (**Table S2**). Although the upper crust –
328 normalized patterns of major and trace elements in Siberian phytoliths were globally similar

329 among different species (**Fig. 3B**), we noted that, compared to other species, phytoliths of
330 *Anthoxanthum* were distinctly enriched in essentially lithogenic low mobile elements such as
331 Ti, V, Cr, Fe, Co, Y, Zr, Nb, REEs, Hf, Ta, Th and U. We could not detect distinct differences
332 in elemental concentrations of phytoliths from different locations, having different soils and
333 highly contrasting climate (including most remote Yakutian sample S1 of the permafrost zone
334 and sample S18 from frozen peatlands of Western Siberia). Similar conclusion has been
335 achieved for samples of the same grass species collected during different years in neighbouring
336 settings (S10 and S4; S5 and S9 of Krasnoyarsk and Tomsk regions).

337 Much higher concentration of insoluble (low mobile, lithogenic) elements in Siberian
338 phytoliths could be partially linked to higher aridity of the climate, hotter vegetation period and
339 generally stronger evaporation, compared to the European part of Russia. These conditions are
340 likely to facilitate the retention of metals within the plants. At the same time, we have not
341 evidenced a correlation between given element concentration and mean annual precipitation
342 (MAP) ($p > 0.05$). For example, the samples collected from the sites of lowest MAP (300-350
343 mm y^{-1}), E6 in Europe and S2, S8, S14 and S16 in Siberia, did not exhibit particularly high
344 metal concentration, compared to phytoliths from other sites of two territories. An enrichment
345 of phytoliths from European grasses (*Phragmites*, *Calamagrostis*) in Ca and Sr could be linked
346 to dominantly carbonate rocks and sedimentary silicate as lithological substrate for soils
347 developed in this part of the Russian Platform, compared to the Siberian Platform and mountain
348 regions, where the dominant soils are developed on crystalline silicate rocks.

349

350 3.4. Comparison of phytoliths from grasses and other plants (*horsetail*, *larch*, *tree fern* 351 *and elm*)

352 Earlier works demonstrated that grass (bamboo) phytoliths are rich in K, Mg, Na and
353 Ca, whereas phytoliths from woody species are enriched in lithogenic elements (Al, Sc, Ti, V,

354 Cs, Fe, REE) because they contain higher proportions of aluminosilicates (Jones et al., 1966;
355 Carnelli et al., 2002; Kamenik et al., 2013). Results of the present study confirm these general
356 features while strongly extending the list of major and trace elements that exhibit different
357 behaviour in phytoliths from different grasses.

358 Combining both European and Siberian species (*C. epigejos*, *G. maxima*, *P. communis*,
359 *A. odoratum*, and *C. arundinacea*), the elemental composition of grass phytoliths (**Table 3**) can
360 be compared to that of other plants such as horsetail (*Equisetum arvense*), larch (*Larix*
361 *gmelinii*), elm (*Ulmus laevis* Pall.) and tree fern (*Dicksonia squarrosa*) as illustrated in **Fig. 4**.
362 Compared to phytoliths of *E. arvense*, *L. gmelinii*, *U. laevis* Pall., and *D. squarrosa* originated
363 from France, Siberia, Ukraine and New-Zealand, respectively, Eurasian grass phytoliths are
364 sizably enriched in Li, B, Na, Mg, Ca, Se and Sr. All other major and trace elements in grass
365 phytoliths exhibited concentrations that were within their variations among four other plant
366 species. Noteworthy that two plants that are known to concentrate Si most significantly
367 (horsetail and fern, having 14 and 12 % of phytoliths in their biomass, respectively) did not
368 exhibit any particulate elemental pattern compared to phytolith-poor grasses such as *P.*
369 *communis* (0.51 %, sample S15) or *A. odoratm* (0.16 %, sample S6) from Siberia.

370 The mean concentrations of B, Na, Si, P, Sr, Mo, Ag, Cd, and Sb in grass phytoliths are
371 comparable to those of the upper crust. At the same time, grass phytoliths are generally poor in
372 all lithogenic elements such as trivalent and tetravalent hydrolysates, divalent heavy metals, Ta,
373 Bi, W, U. Compared to phytoliths studied in other works, Eurasian grass phytoliths are
374 comparable in Mg and Ca concentrations to phytoliths of Ericaceae from Iberian Peninsula
375 (Bujan, 2013), but they are strongly, more than a factor of 10, impoverished in all metals (Al,
376 Fe, Mn, Cr, Ni, Zn, Cu, Pb) and As. There are several possible explanations for this difference.
377 First, Iberian metal belt is well-known for its high metal concentration in soils, hence the
378 capacity of Ericaceae's phytoliths to accumulate Fe, Mn, Cu, Zn, Pb and As at the level strongly

379 exceeding that observed in mine-free sites (Bujan, 2013). However, the phytoliths of Iberian
380 grasses sampled from unpolluted soils (serpentinite, quartzite, and peat) also demonstrated
381 more than an order of magnitude higher concentrations of all trace metals compared to Eurasian
382 grasses. A second possible explanation is specificity of heathers (Eriaceae) metabolism that are
383 capable to immobilize trace metals by Si in vacuoles of living cells or in the cell wall (e.g.,
384 Montes-Botella, 2001) therefore augmenting the tolerance of plants to metal pollutants (Rossini
385 et al., 2009, 2011). A third possibility is rather pristine environment of Eastern European and
386 Siberian sites where the grasses were collected. In the Russian Plain, the sites are remote from
387 any centers of local industrial or domestic pollution, and rather far from aerosol dust provinces.
388 The latter can deliver silicate material to the land surface, which then can be absorbed by plants.
389 Siberian sites are closer to local desert or semi-desert regions that are known to be sources of
390 solid aerosols (Kazakhstan, Mongolia), and this can explain an enrichment in many lithogenic
391 elements of the Siberian grasses relative to the European part of Russia. The influence of
392 atmospheric silicate deposition on the snow cover of southern regions of Western Siberia
393 leading to an enrichment in lithogenic elements is fairly well established from Siberian
394 snowpack studies (Shevchenko et al., 2017, 2020; Krickov et al., 2022).

395 The Sahara desert influence on Iberian sites of grass collections is much higher than the
396 impact of far-range atmospheric transfer from deserts of Central Eurasia on Siberian sites, given
397 the relative geographical distances. The industrial activity in the Iberian Peninsula is also much
398 lower than that in Siberia. Note that the sampling in Siberia was performed 50 to 70 years earlier
399 than that in Spain. As a result, many anthropogenically-impacted trace elements (Cu, Zn, Cr,
400 Ni, Pb and As) could originate from local atmospheric fallouts (industry, roads, domestic
401 emissions) and be pronounced in grasses from Spain. Enhanced uptake of trace element by
402 plants from contaminated soils may also become the dominant mechanism of phytolith
403 enrichment in trace pollutants. Thus, phytoliths of reeds growing in mining environments

404 (metal sulfide ores) of Southern Europe (e.g., Delplace et al., 2020) were strongly (> 10-100
405 times) enriched in Mn, Cu, Pb, Zn, As, Cd, Sb and Sn compared to grass phytoliths from pristine
406 environments analyzed in the present study. Alleviating the toxicity of such pollutants via
407 adsorption and coprecipitation with amorphous hydrated silica oxide, linked to intracellular
408 phytoliths production, is well known for various plants of the world (Turnau et al., 2007; Keller
409 et al., 2015; Rizwan et al., 2016; Delplace et al., 2020; Liu et al., 2022, 2023; Sarret et al.,
410 2022). However, we admit that a new contemporary sampling of Siberian grasses is necessary
411 to judge the level of anthropogenic pollution and its impact on chemical composition of grass
412 phytoliths.

413 Finally, alike for the local difference between European grasses growing in more humid
414 climate compared to Siberian grasses of dryer and hotter summer periods, the global difference
415 between Eurasian and Iberian phytoliths may reflect hot and dry climatic conditions of the
416 latter, given that the temperature and precipitation are among the primary factors that control
417 the size, localization and shape of phytoliths from common reed (e.g., Liu et al., 2016 a, b).
418 Under dry Iberian climate and lack of water during grass maturation period (end of summer),
419 the immobilization of even soluble metals inside the tissue and within the phytoliths may
420 become quite efficient. This hypothesis, however, requires further verification by both natural
421 observations and laboratory-scale experiments.

422 In addition to the source control described above, soil pH might be a non-negligible
423 factor of insoluble element enrichment in phytoliths. Thus, Hodson and Sangster (1999)
424 demonstrated that, for Al in conifers, free Al is mobilized in soils affected by acidic
425 precipitation; this Al is then taken up by plants and sequestered in phytoliths. However, we
426 could not evidence any relationship between soil water pH (estimated for the sampled sites from
427 soil typification) and insoluble element concentration in phytoliths (not shown). Therefore, it
428 remains unclear, to which degree the other trivalent and tetravalent elements, typically more

429 labile in acidic environments, are capable to follow the Al pathway through the atmospheric
430 precipitation, soil migration and plant phytolith accumulation.

431

432 *3.5. Elemental correlations in phytoliths and mechanisms of elemental uptake*

433 Pairwise (Pearson) correlation coefficients (**Table S3**) demonstrated two main groups
434 of major and trace elements, present in both Eurasian and Siberian phytoliths. Labile elements
435 (alkali and alkaline-earth metals), B, Mo, Se, but also Cu and Zn exhibited significant ($0.5 <$
436 $R_{\text{Pearson}} \leq 0.98$; $p < 0.01$) correlation with Na and Ca as major indicators of such soluble
437 elements. The second large group of inter-correlated components was constituted of lithogenic
438 elements and included trivalent (Al, Fe, Y, REEs), and tetravalent hydrolysates (Ti, Zr, Hf, Th),
439 Cr, V, Mn, Co, Nb, Tl, Bi, Pb. It is important to note that As correlated with both Fe and Al in
440 the Siberian phytoliths, whereas P correlated only with Al. We therefore hypothesize an
441 overwhelming role of Fe and Al hydroxides as carriers of many insoluble trace elements as well
442 as some major (P) and micro- (V, Co, Ni) nutrients in grass phytoliths. These TE^{3+} , TE^{4+} -
443 bearing oxy(hydr)oxides could be dispersed (occluded) within the bulk of the phytoliths rather
444 than being adsorbed the phytolith surface, given that the phytoliths were treated with HCl
445 during their extraction. This result corroborates former observations on phytoliths of barley that
446 were enriched in several lithogenic elements (i.e., Al, Sc, Ti, V, Cs, and Fe), reflecting
447 endogenous source of these elements (Carnelli et al., 2002).

448 We further believe that the two groups of inter-correlated elements described above
449 reflect two main sources of material that is deposited onto plant leaves via atmospheric transfer.
450 The two sources are known from atmospheric aerosols and snow precipitation studies in Siberia
451 (Shevchenko et al., 2017; Krickov et al., 2021, 2022): 1) carbonate mineral particles, providing
452 a signature of labile elements and 2) silicate and other refractory minerals, providing a signature

453 of lithogenic material. In addition, these two natural sources can be combined with atmospheric
454 dust from local anthropogenic pollution (Zn, Cd, Pb, As).

455 The main element constituting plant phytoliths, after Si and O, is Ca. The primary cell
456 wall contains around 35% of pectin, which is crosslinked by coordination with Ca ions (e.g.,
457 Perry and Keeling-Tucker, 1998). Presumably, during silica mineralization within the Ca-rich
458 cell wall region, sizable amount of Ca can be taken up by / coprecipitated with amorphous
459 hydrous Si oxide. Magnesium, Sr and Ba, also exhibiting high concentrations in phytoliths,
460 could participate, together with Ca, in pectin cross-linking assemblages and hence enrich the
461 forming Si phases. Sizable amount of Fe and Al in the phytoliths could be linked to strong
462 capacity of both cations to maintain silicic acid in solution up to its solubility limit (Perry and
463 Keeling-Tucker, 1998) thus playing some role in the genesis of the solid phase. Any information
464 on other trace cations, likely to be (passively) present within the sites of silica deposition and
465 can enter the phytoliths via co-precipitation with $\text{Si}(\text{OH})_4$ (s), is currently not available.
466 Elucidating these mechanisms requires specially designed in-vitro laboratory experiments.

467 Some trace elements, belonging to both 'labile' and 'insoluble' group of phytoliths'
468 constituents described above and serving as micro-nutrients for plants (B, Zn, Mn, Ni, Co, Mo,
469 Se) can enter the plant according to 'internal' metabolic requirements, regardless of availability
470 of external soil stock. After being carried within the plant tissues via protein and carbohydrate
471 components of the organic matrix associated with Si (e.g., Perry and Keeling-Tucker, 2000;
472 Perry and Fraser, 1991; Currie and Perry, 2007; Belton et al., 2004, 2012), they eventually can
473 be deposited within the cell interior in the form of coprecipitates with amorphous silica, which
474 happens within cellular fluids and sap solutions. At the same time, TE interaction with silicon
475 transporters involved in biosilicification in plants such as proline-rich proteins and siliplant_1
476 protein (e.g., Nawaz et al., 2019) remain virtually unknown. Strong control on TE fractionation
477 during phytolith formation may be exerted by cell wall polymers complexation with trace

478 cations and anions, given that the polymeric template controls the shape and size of colloidal
479 Si particles as it is known for horsetail (e.g., Sapei et al., 2007). Note that both trace cations and
480 oxyanions can strongly interact with proteins and silica moieties of cell walls of diatoms
481 (Gélabert et al., 2018), similarly to what may occur in sites of plant phytolith deposition.

482 During these interactions, soluble, labile alkalis, alkaline-earth metals and oxyanions
483 exhibit a distinctly different behavior from low soluble, low mobile trivalent and tetravalent
484 hydrolysates. Note that in this discussion of element affinity to phytoliths and relevant
485 mechanisms, we ignore the diversity of phytoliths morphotypes, which can reflect different
486 sites and modes of amorphous silicate deposition in plant cellular structure (e.g., Nawaz et al.,
487 2019). It is possible that phytoliths of different shape, water and Si content and density, being
488 formed in different parts of grass leaves, have different elemental composition. Phytolith
489 morphotype-specific analyses via high spatial resolution laser ablation or nano-SIMS
490 techniques would be necessary to verify this possibility.

491

492 3.6. Effect of metals (Fe, Al, Ca, Mg) on phytoliths dissolution kinetics

493 Dissolution kinetics of *Calamagrostis epigejos* from Europe could be tested only for the
494 five samples of this specie, for which we possessed sufficient amount of phytolith material for
495 multiple batch experiments (**Table 4**). Individual experimental results are illustrated in **Fig.**
496 **S10**. In order to assess the effect of major element (Ca, Mg, Fe, and Al) concentration in
497 phytoliths on Si release rate, we first compared the concentration level of these elements in
498 grass phytoliths studied in this work to that previously assessed in horsetail, fern, larch and elm
499 (e.g., Fraysse et al., 2009). A histogram of major elemental composition of various phytoliths
500 (**Fig. 5**) illustrates that grass phytoliths are 100-1000 and 10-100 times lower in Al and Fe
501 concentration, respectively, and strongly (x 100 for Ca, x 10 for Mg) enriched in alkaline-earth
502 elements compared to other phytoliths. However, despite these sizable differences in elemental

503 composition of various phytoliths, all of them exhibited similar (± 0.2 - $0.3 \log R$ unit, which is
504 within the experimental uncertainties) rates of Si release as shown in a plot of the $\log R_{\text{Si}}$ of
505 phytoliths as a function of aqueous solution pH (**Fig. 6**). This finding is also consistent with
506 similarity (within $\pm 0.35 \log R$ unit) of silicate mineral dissolution rates in the circumneutral pH
507 range as recently reported by Hermanska et al. (2023). In agreement with latter authors, we
508 suggest that observed similarity in dissolution rates is due to the fact that these minerals, but
509 also hydrous amorphous silica, are controlled by the breaking of the same, tetrahedral Si-O,
510 bridging bonds. At these circum-neutral pH conditions, there is a limited exchange of divalent
511 and trivalent cations (c.f. Oelkers, 2001; Oelkers et al., 2009) that are likely present within the
512 amorphous hydrous silica. Therefore, because there is no sizable impact of breaking the bonds
513 between metal and oxygen which are adjacent to Si-O bonds, the overall dissolution rates of
514 phytoliths containing different proportion of Ca, Na, Fe and Al are weakly dependent on major
515 elemental composition. It is of note that various soils also exhibit similar Si release rate in the
516 circum-neutral solutions (Lim et al., 2023) which stems from the similarity of bond-breaking
517 mechanisms for silicate minerals as described above.

518 A global significance of this result is that phytoliths' reactivity in aqueous solution, and
519 hence, their preservation in soil horizons are weakly dependent on the concentration of major
520 and trace element occluded within these phytoliths. This may justify the use of phytoliths for
521 various paleo-reconstructions, as well as for tracing the external input of pollutants, plant
522 metabolic requirements and detoxification mechanisms in case of anthropogenically-affected
523 settings. At the same time, phytoliths are capable of Al adsorption (Bartoli 1985) and some
524 studies have shown that soil phytoliths are more resistant to dissolution compared to fresh
525 phytoliths (Liu et al., 2023). Such a resistance is commonly linked to chemisorbed Al (Van
526 Cappelen et al., 2002). It is possible that similar mechanism can operate for surface-adsorbed
527 Fe oxy(hydr)oxide as it is known for biogenic silica in marine sediments (Ward et al., 2022).

528 Therefore, some metals are capable of impacting the reactivity of phytoliths depending on
529 whether they are incorporated into the mineral structure or remain on their surface.

530

531 **4. CONCLUSIONS**

532 In this study we assessed the factors that control multi-elemental composition of grass
533 phytoliths, via measuring 56 major and trace elements in phytoliths extracted from grasses
534 (poaceae) growing in Eastern European (Russian Plain) and Central and Southern Siberia. In
535 the European part of Eurasia, different grass species from the same region exhibited very similar
536 elemental composition of phytoliths. We observed rather insignificant impact of local climate,
537 soil substrate and time of sampling during vegetative period on trace element concentration in
538 European grass phytoliths. We also showed distinct differences in elemental composition of
539 grasses sampled in European part of Russia and Siberia. In particular, phytoliths of European
540 grasses from generally milder and wetter climate exhibited more than 10 times higher
541 concentration of some labile elements (Ca, Sr and Se), compared to phytoliths from strongly
542 continental climate of Siberia, whereas comparable concentrations of Li, B, Na, K, Mg, V, Zn,
543 As, Mo, Ba and U were obtained for phytoliths from both locations. The phytoliths of Siberian
544 grasses were strongly ($\times 10-100$) enriched in lithogenic, low mobile elements and some heavy
545 metals. We tentatively explain these differences by the differences in humidity regime and
546 intensity of atmospheric silicate mineral dust deposits, linked to distance to the desert provinces
547 of solid aerosols generation. In contrast, the local anthropogenic pollution and lithological
548 aspect of parent rocks / soils played a sub-ordinary role. Considering all Eurasian grass
549 phytoliths together, the concentration values of B, Na, Si, P, Sr, Mo, Ag, Cd, and Sb were
550 comparable to those of upper crust. At the same time, grass phytoliths are generally poor in all
551 lithogenic elements such as trivalent and tetravalent hydrolysates, divalent heavy metals, Ta,
552 Bi, W, U. The upper crust-normalized composition of European grass phytoliths demonstrated

553 their sizable enrichment in macro and micronutrients and labile elements such as B, Na, Ca, Sr,
554 Se, Mo, and U and strong depletion in lithogenic elements (Al, Ti, Y, Zr, Nb, Sn, Cs, REE, Hf,
555 Pb, Ta, W, Tl, and Th) relative to the phytoliths of horsetail, fern, elm and larch. Overall,
556 grasses exhibited distinctly different elemental composition compared to horsetail, fern, elm
557 and larch.

558 A pairwise correlation analysis demonstrated two group of elements – (1) labile, soluble
559 alkali, alkaline-earth metals and oxyanions and (2) lithogenic low mobile trivalent and
560 tetravalent trace elements, heavy metals and toxicants. Despite significant, by 1 to 2 orders of
561 magnitude difference in major element (Ca, Mg, Fe, Al) concentration in phytoliths from grass
562 and those from other Si-concentrating plants studied previously (horsetail, fern, elm, larch), the
563 dissolution rates of all phytoliths in circum-neutral aqueous solutions are identical within the
564 experimental uncertainty. Our laboratory experiments confirm the use of phytoliths as
565 environmental proxies and indicate that the preservation of phytoliths in soils is unrelated to
566 phytolith elemental composition. Further work on mechanisms of trace element concentration
567 by plant phytoliths via measuring element distribution coefficients between sap solution and
568 precipitated amorphous silica should allow distinguishing different group of major and trace
569 elements depending on their speciation in cellular fluids.

570

571 **Acknowledgements**

572 The European grass samples used in this study were collected by late Nina K. Kisileva. OP

816 **Table 1 B: Siberian grasses**

N°	Name	Typical environment	Sampling date	Location	MAP, mm	MAAT, °C	Soil type (WRB 2022)	Soil parent material
S1	<i>P. communis</i>	Floodplain in a sharply continental climate	08/5/1974	Yakutia, 7 km SW from Yakutsk	216	-9.0	Dystric Fluvisol	Alluvial deposits
S2	<i>C. epigejos</i>	Dry steppe in continental climate	08/12/1927	Northern Baraba, village Mitrofanovka	333	1.2	Calcic Mollic Solonetz	Layered loess-like silt and loam deposits
S3	<i>C. arundinacea</i>	Barrier-rain temperate continental forests	08/29/1956	Kemerskaya region, Leninsk-Kuznetsky district	673	2.0	Albic Luvisol (Ochric)	Loess-like cover clay deposits
S4	<i>G. maxima</i>	Continental deciduous forests	07/16/1969	Tomskaya region, Zyryansky distr., d. Cherdaty, lake Charochkino	520	1.0	Greyzemic Phaeozem	Loess-like loam deposits
S5	<i>C. arundinacea</i>	Continental light coniferous forests	08/25/1959	Krasnoyarsk region, Natl. Park Stolby, riparian zone of spring	483	1.2	Mollic Gleysol	Alluvial deposits
S6	<i>A. odoratum</i>	Mountain continental taiga	08/10/1936	Krasnoyarsk region, watershed divide of Kazyr and Kizir	600	-1.0	Skeletal Cambisol (Ochric)	Colluvium felsic metamorphic and igneous rocks
S7	<i>G. maxima</i>	Barrier-rain temperate continental forests	07/8/1928	Altai, villages Troitskaya and Kebezen	778	1.1	Albic Luvisol	Loess-like clays on colluvium of shale and sandstone
S8	<i>C. epigejos</i>	Continental steppe	07/23/1931	NW Altai, Rubtsovsky distr., d. Berezovka and Ermelikha	331	2.7	Calcic Chernozem	Carbonate loess
S9	<i>C. epigejos</i>	Continental forest-steppe	07/27/1939	Krasnoyarsk region, Rybinsk district, d. Krasnoyarovka	450	-0.4	Luvic Phaeozem (Albic)	Clayey and heavy loamy gravelly colluvial deposits
S10	<i>G. maxima</i>	Continental lowland southern taiga	07/27/1970	Tomskaya region, Kolpashevsky dist., Ob's River floodplain, d. Pavlovka	489	-0.4	Orthofluvic Fluvisol (Aric)	Alluvial silt-clay deposits
S11	<i>A. odoratum</i>	Continental light coniferous and small-leaved forests	07/14/1966	Tomskaya region, Tomsk, d. Anikino	544	0.9	Luvic Phaeozem (Albic)	Cover loess-like loams.
S12	<i>A. odoratum</i>	Sharply continental mountain boreal taiga	08/9/1959	Buryatia, Natl. Park Barguzinsky, rivers Talamysh and Malaya	450	-2.0	Leptic Regosol (Ochric)	Colluvium from felsic metamorphic and igneous rocks and shales
S13	<i>G. maxima</i>	Continental steppe	07/8/1969	Omskaya region, Nazyvaevsky dist., d. Iskra	398	2.0	Gleyic Chernozem	Lacustrine alluvial deposits
S14	<i>P. communis</i>	Continental mountain boreal taiga	07/29/1975	Tuva, Piy-Khemsy dist, Uyukski ridge, d. Saigara	305	-1.4	Skeletal Regosol (Ochric)	Shale colluvium
S15	<i>P. communis</i>	Continental lowland southern taiga	08/1/1958	Tomskaya region, Molchanovsky dist., pos. Suiga	470	0.4	Brunic Arenosol (Aric)	Aeolian sand deposits
S16	<i>A. odoratum</i>	Mountain forest-tundra	07/22/1975	Tuva, Todzhinsky dist., lake Karabalyk	350	-4.4	Brunic Regosol	Sandy colluvium of basic metamorphic and igneous rocks and sandstones
S17	<i>C. arundinacea</i>	Continental light coniferous and small-leaved forests	07/28/1972	Novosibirsk region, d. Kisilevka	485	1.3	Luvic Greyzemic Phaeozem	Loess-like clays
S18	<i>C. epigejos</i>	Continental forest-tundra in a zone of discontinuous permafrost	08/2/2014	Khanymey station of INTERACT, Nojabrsk region	520	-3.4	Histic Fluvisol	Lake sediments

818 **Table 2.** Mass content of the phytoliths in the grass biomass and total Si concentration in
 819 phytoliths

820 **A:** Phytoliths of grasses from Eastern Europe

Sample	Phytoliths content in biomass, %	% mass Si in phytoliths
E1 <i>C. epigejos</i>	2.0	38,9
2. <i>C. epigejos</i>	4.6	42,6
3. <i>C. epigejos</i>	0.9	35,3
4. <i>P. communis</i>	0.9	40,3
5. <i>C. epigejos</i>	1.8	39,2
6. <i>C. epigejos</i>	3.4	39,5
7. <i>G. maxima</i>	0.9	37,8
9. <i>C. epigejos</i>	2.9	42,0
10. <i>C. epigejos</i>	3.4	35,8
11. <i>C. arundinacea</i>	6.7	39,8

821

822 **B:** Phytoliths of grasses from Siberia

Sample N°	Phytoliths content in biomass, %	% mass Si
S1	1.15	38.8
S2	1.88	42.6
S3	1.33	33.0
S4	1.84	24.8
S5	2.45	32.2
S6	0.16	32.8
S7	2.40	32.3
S8	2.60	32.1
S9	2.62	50.8
S10	1.11	32.7
S11	0.70	15.6
S12	1.19	22.9
S13	1.82	57.3
S14	1.23	34.6
S15	0.51	29.3
S16	0.52	23.0
S17	3.09	28.5
S18	0.44	43.3

Figure 4. Upper Continental Crust-normalized pattern of grass phytolith (mean of European and Siberian) elemental composition compare to that of other Si-concentrating plants (horsetail, fern, larch and elm).

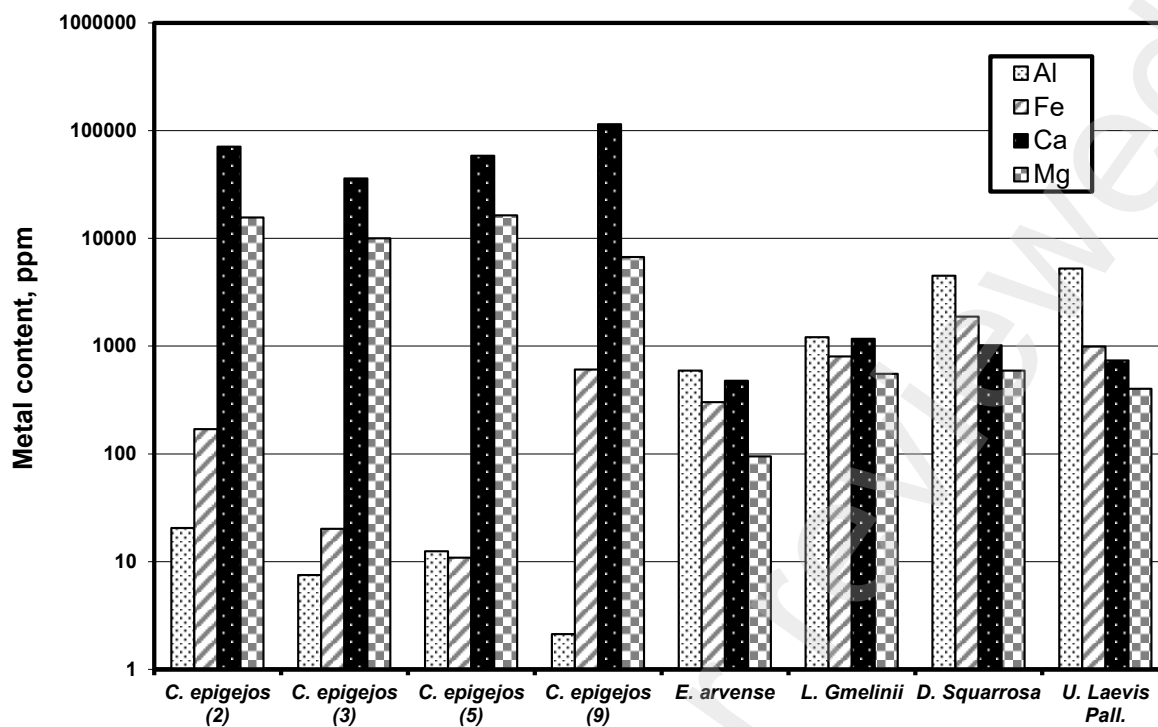

Figure 5. Al, Fe, Ca and Mg contents (ppm) in phytoliths used in present (*C. epigejos*, samples 2, 3, 5 and 9) and previous study (*E. arvense*, *L. gmelinii*, *D. squarrosa* and *U. Laevis* Pall.; Fraysse et al., 2009) of dissolution kinetics.

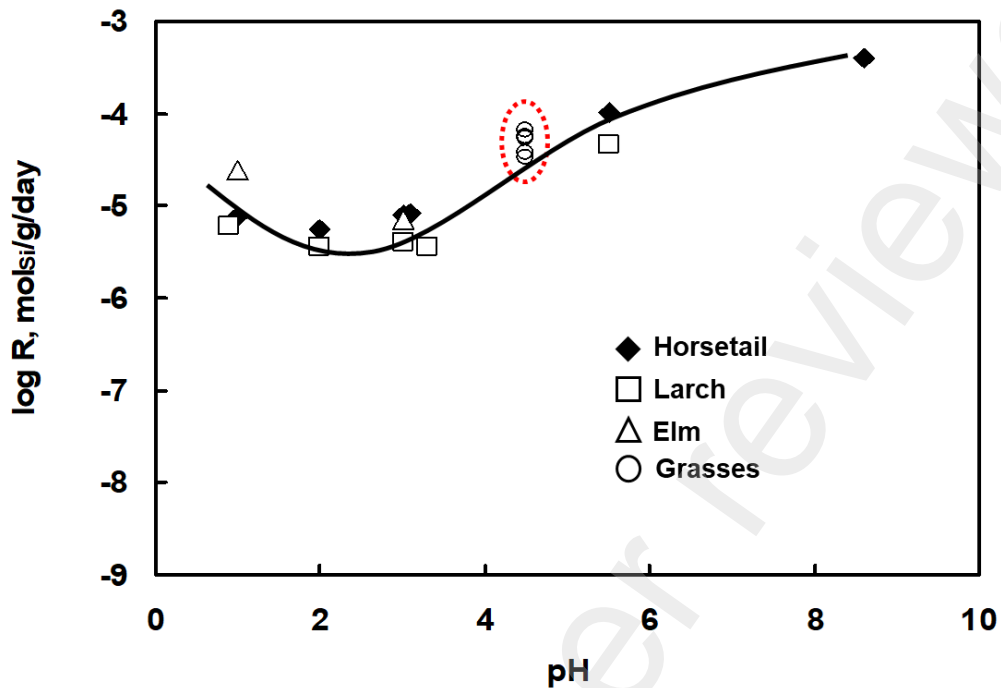

Figure 6. Dissolution rates of *Calamagrostis epigejos* (open circles, encircled by red contour) phytoliths at 25°C as a function of pH, compared to phytoliths from larch (squares), horsetail (solid diamonds), elm (triangles). The solid line is generic phytolith rate dependence on pH, based on previous studies with bamboo phytoliths (Frayse et al., 2009).
