Abstract: Flowable electrodes, a versatile alternative to traditional solid electrodes for electrochemical applications, face challenges of high viscosity and carbon content, limiting flow and device performances. This study introduces colloidal suspensions of thin multiwall carbon nanotubes (MWCNTs) with diameters of 10-15 nm as electrode materials. These thin nanotubes, stabilized in water with surfactant, form percolated networks, exhibiting high conductivity (50 ms/cm) and stability at a low carbon content (below 2 wt%). Colloidal clustering is enhanced by weak depletion attractive interactions. The resulting suspensions display a yield stress and a shear thinning behavior with a low consistency index. They can easily flow at a nearly constant shear over a broad range of shear rates. They remain electrically conductive under shear making them promising for flow electrochemical applications. This work suggests that the use of depletion induced MWVNT aggregates addresses crucial issues in flow electrochemical applications, such as membrane fragility, operating energy, and pressure. These conductive colloidal suspensions offer thereby potential advancements in device performance and lifespan.

Keywords: carbon nanotubes; conductivity; flow electrochemistry, depletion

1. Introduction

Flowable electrodes are emerging as a versatile and promising alternative to traditional solid electrodes in various electrochemical applications, including flow capacitors [1-3] and water capacitive desalination [4-6]. Flow capacitors enjoy several promising features such as cost effectiveness and high energy storage capabilities. More critically, flow electrochemical technologies offer the possibility to decouple energy and power ratings. The energy scales with the volume of the reservoirs, whereas the charge transfer depends on the structure and stacks of the device. These features make flow capacitors and flow batteries particularly suited for storage of intermittent renewable energies. Flowable electrodes are also promising to address an environmental concern that is the global water resource shortage [7]. So-called flow capacitive deionization of water using carbon slurry was already introduced in 2013 [8], and has been the topic of extensive research since then [9-11]. Moreover, flow capacitive water desalination has been shown to be potentially more effective by implementing energy recovery during continuous deionization process [12].

In these applications, which are based on related physico-chemical mechanisms, carbon micro- or nano-particles [13] are suspended in an electrolyte medium, often containing formulating agents [14, 15]. At elevated concentrations, the colloidal particles create an electrically conductive network [16]. Upon application of a given voltage, ions from the volume of the electrolyte adsorb to the particle surface during the charging stage. Conversely, electrical charges are delivered to a current collector in the discharge mode. In contrast to their solid counterparts, flowable electrodes offer numerous ad-

48 vantages, such as a high surface area accessible from the entire electrolyte volume, en-
49 hanced mass transport, and ease of replacement. Flowable electrodes in these applica-
50 tions generally contain a high amount of carbon particles to ensure electrical conductiv-
51 ity. High concentration yields viscoelastic suspensions, with a slurry like texture, im-
52 peding easy flow. They necessitate high pressure and energy to be pumped. More criti-
53 cally, a high concentration of carbon particles can result in plug formation or membrane
54 rupture, limiting the performance and lifespan of devices [17]. This can become critical
55 when using ion exchange membranes, which are costly components of energy storage or
56 deionization devices.

57 To overcome these limitations, an approach consists of developing flowable elec-
58 trodes with reduced carbon content. Reducing carbon content holds the potential for
59 improving device stability, prolonging lifespan, and enhancing energetic efficiency. The
60 first challenge towards this objective involves optimizing the rheological performance of
61 carbon dispersions. Maintaining the dispersion's ability to flow is crucial. The second
62 challenge is to formulate flowable dispersions that still exhibit sufficient electronic con-
63 ductivity and electrochemical capacitance. Generally, as reviewed in references 3 and 18
64 [3, 18], carbon-based slurries made of carbon black particles display conductivities below
65 a few mS/cm, for carbon contents on the order of 10wt% or more. Moreover, the conduc-
66 tivity of such slurries decreases sometimes substantially in flow conditions.

67 A way of maintaining conductivity over a wide shear rate range is to realize a fluid
68 that can accommodate high shear rates with limited viscous dissipation. This is particu-
69 larly the case of threshold fluids with low plastic viscosity or, more precisely, with a low
70 consistency index and a high yield stress. Their equation of state is $\sigma = \sigma_s + A\dot{\gamma}^n$, where
71 A is the consistency index, σ_s the yield stress, σ the applied shear stress, $\dot{\gamma}$ the shear
72 rate and n the flow index [19]. In the limit of low A , the applied stress is maintained
73 around the yield stress. The apparent viscosity, defined as $\eta_{app} = \frac{\sigma}{\dot{\gamma}} = \frac{\sigma_s}{\dot{\gamma}} + A\dot{\gamma}^{n-1} \approx \frac{\sigma_s}{\dot{\gamma}}$,
74 varies with the shear rate to the power -1. Flow in such fluids generally occurs through
75 minute structural variations, characterized by fractures that continuously form and heal,
76 especially as the fluid flows in close proximity to its yield stress. Such a behavior is usu-
77 ally observed at low shear rates in yield stress fluids with high carbon contents [3, 20, 21].
78 Realizing such flow conditions over a broad range of shear rates and at low carbon con-
79 tents remains challenging.

80 Carbon nanotubes appear as natural candidates to meet the above challenges. In-
81 deed, carbon nanotubes display a low percolation threshold at equilibrium because of
82 their high aspect ratio, L/d , where d and L are the diameter and length of the nanotubes,
83 respectively [22]. They hold therefore the potential for making conductive suspensions at
84 low carbon content. Actually, such particles have been used as additives, mixed with
85 other carbon particles, to improve capacitive water desalination performances [23-25].
86 Nanotubes contribute to generate connectivity between the carbon particles. They have
87 also been used as sole conductive species in aqueous electrodes with remarkable proper-
88 ties [18, 26, 27]. In these earlier studies, electronic conductivities at equilibrium reached
89 values between 5 to 10 ms/cm for carbon contents between 2.5 to 10 wt% typically. These
90 remarkable properties result from the high conductivity of carbon nanotubes and from
91 their high aspect ratio. Nevertheless, nanotubes used in these studies have a diameter of
92 50-80 nm and a length of 10 μ m. Stabilization of such particles remains quite difficult be-
93 cause of their large size and tendency to settle. In addition, the large size of the particles
94 results in a more limited specific surface area and electrochemical capacitance compared
95 to smaller colloidal nanoparticles.

96 Following the investigation of carbon nanotube-based flowable electrodes, we re-
97 port in the present work the realization of electrodes made of suspensions of thin multi-
98 wall carbon nanotubes (MWCNTs) with a diameter of 10-15nm. These thinner nano-
99 tubes do not settle, and can be more easily dispersed than large multiwall nanotubes. The
100 nanotubes are stabilized in water with surfactant. Addition of excess surfactant is used to
101 promote the formation of percolated networks in response to weak depletion attractive
102 interactions [28]. These structures are shown to display high conductivity and high sta-

103 bility along with decent electrochemical capacitance. Typically, the best dispersions in-
104 vestigated in the present work display an electronic conductivity of 50ms/cm for a carbon
105 content below 2wt%. The viscosity of these suspensions does not exceed 2Pa.s for a shear
106 rate of 5s⁻¹. This original combination of high electronic conductivity and low plastic
107 viscosity makes the present suspensions promising for flow electrochemical applications
108 where membrane fragility, operating energy and pressure are key issues.
109

110 2. Materials and methods

111 Two types of commercial Multiwall carbon nanotubes have been used, namely
112 Graphistrength C100 materials from Arkema and NC 700 materials from Nanocyl. These
113 nanotubes are produced by a chemical vapor deposition process and contain small frac-
114 tions of metal catalysts. They are used as received without further purifications. Both
115 materials have diameters in the 10-15nm range. Their length exceeds several microns
116 in their raw state.

117 The carbon nanotubes are added to distilled water and stabilized with surfactant
118 molecules. US4498 from US Research Nanomaterials is presently used. The exact molec-
119 ular structure of the surfactant is unknown, but the compound is provided by US Re-
120 search Nanomaterials as a non-ionic surfactant suited for the stabilization of carbon
121 nanotubes in water. This surfactant contains aromatic groups with good affinity towards
122 carbon nanotubes. Mother suspensions are prepared by mixing 1wt% of MWCNTs and
123 2wt% of US4498 in distilled water for Arkema samples, and 0.5wt% of MWCNTs and
124 2wt% of US4498 for Nanocyl samples. The suspensions are homogenized by tip soni-
125 cation for 30 minutes. They are obtained using a Branson homogenizer, Sonifier model
126 S-250A associated to a 13-mm step disruptor horn and a 3-mm tapered microtip, oper-
127 ating at a 20-kHz frequency. The suspensions are found to be free of aggregates after such
128 treatment. Tip sonication induces disentanglement and scission of the nanotubes [29, 30].
129 The latter display a typical length in the range of 500nm-1 μ m. Transmission electron mi-
130 crographs of isolated MWCNTs after sonication are shown in Figure 1.

131
132 **Figure 1.** Transmission electron micrographs of individual Arkema (a) and Nanocyl (b) MWCNT
133 after sonication. Scale 100nm.

134 The mother suspensions are then further concentrated by dialysis. This is realized by
135 placing the suspensions in Spectra/Por dialysis membrane bags with a 6-8 kD molecular
136 weight cut-off. This cut-off allows the transport of water and surfactant molecules, but
137 the membranes retain MWCNTs. The dialysis bags are placed in contact with a Spec-
138 tra/gel absorbing hydrogel. Water and surfactant molecules are adsorbed by the gel, and
139 the concentration of MWCNTs in the dialysis bag increases with time. The concentration
140 of surfactant also increases nearly similarly because of its much lower diffusion com-
141 pared to that of water molecules. Using aqueous solutions of surfactant, we have actually
142 verified that the transport of surfactant across the membrane is negligible on the time
143 scale of the present experiments. Typically, the surfactant concentration is found to in-

144 crease almost linearly with the reduction of volume of the solution. The ratio of surfac-
145 tant to MWCNTs can therefore be considered as constant when the total concentration of
146 dried materials increases. Varying the time of dialysis allows different concentrations of
147 MWCNTs to be achieved. The amount of dried materials, including surfactant and
148 MWCNTs, contained in the suspensions is measured by dry extract experiments. The
149 weight fraction of MWCNTs is deduced from the known initial ratio of surfactant to
150 MWCNT. The most concentrated samples investigated in the present work have a
151 MWCNT weight fraction above 4wt% obtained after 6 hours of dialysis.

152 The phase behavior of the samples is assessed by optical microscopy using a Leica
153 DM2500 microscope.

154 Conductivity of the samples at equilibrium is measured using a Radiometer CDC749
155 conductivity cell connected to a Keithley 2000 multimeter. A constant voltage of 0.5V is
156 applied between the electrodes of the cell, and the current is measured as a function of
157 time. The current decreases until it reaches a stationary value, typically after a few
158 minutes. The stationary current corresponds to the contribution of electronic conductivity
159 of the samples, without the contribution of ionic conductivity [31].

160 Conductivity in shear flow is measured using a Couette cell (Caplim Rheophysique
161 West 3400) as detailed in [3]. In the present work, conductivity is measured in the radial
162 direction of the Couette cell with two concentric circular electrodes. The conductivity
163 corresponds to the conduction in the shear plane, perpendicular to the flow direction.

164 The rheological properties are characterized by an AR1000 controlled stress
165 rheometer from TA Instrument. A ramp of shear rate is applied from 200 s^{-1} to 0.1 s^{-1} , with
166 5 points per decade. Each shear rate is maintained during 30 seconds and the viscosity is
167 measured by averaging the measurements over the last 5 seconds. The temperature is set
168 with a Peltier system at 20° C .

169 The electrochemical capacitance of the suspensions is measured in a two-electrodes
170 symmetric cell configuration. The setup is described in detail in [3]. The liquid electrodes
171 have the same volume and are separated from each other by using an anion exchange
172 membrane (SnakeSkin®Dialysis Tubing 1000 MWCO). Cyclic voltammetry is performed
173 using an Autolab PGSTAT204 Metrohm potentiostat/galvanostat.

174 3. Results and discussion

175 Optical micrographs of MWCNTs suspensions are shown in Figure 2 for Arkema
176 samples and in Figure 3 for Nanocyl samples. It is observed in both cases that aggregates
177 tend to form with increasing the concentration of MWCNTs and surfactant in the sus-
178 pensions. This aggregation behavior is ascribed to depletion attraction between the
179 nanotubes due to the presence of surfactant micelles [28, 32]. Depletion attraction is weak
180 [33], and results in loose aggregates that do not settle with time. The aggregates remain in
181 constant equilibrium with dispersed and individualized nanotubes.

197
198 The results of electronic conductivity measurements at equilibrium are shown in Figure 4. A typical percolation type behavior is observed. The conductivity increases by several orders of magnitude at the percolation threshold. These thresholds are about 1 and 1.5 wt% for Nanocyl and Arkema materials, respectively. Particularly high conductivity values are obtained for concentrations above 2 wt% for both materials, approaching 100ms/cm. Note that the small difference in percolation thresholds observed for Nanocyl and Arkema materials can be explained by the slightly greater aspect ratio of Nanocyl materials compared to Arkema systems. This is consistent with optical microscope images reported in Fig. 2 and 3 where Nanocyl tend to form a sample-spanning network of aggregates at a lower weight fraction.

206
207
208
209
210 Rheological properties of samples with different weight fractions are shown in Figure 5. The presence of MWCNTs results in a clear shear thinning behavior of the suspensions. The viscosity decreases as a function of shear rate by three orders of magnitude, with an exponent close to -1, revealing thereby a yield stress fluid behavior. A distinctive feature of these suspensions is their low carbon content and very low consistency index, ensuring that the stress remains near a constant value across a broad range of shear rate. A likely representation of the flow involves the formation of a small number of weak regions that are the locus of rearrangements-fractures that constantly form and heal.

211
212 This behavior results in interesting effective viscosity properties. The suspensions containing 1.8wt% of Nanocyl material, which are highly conductive, display an effective

213
214
215
216

viscosity of 1.2 Pa.s for a shear rate of 5 s⁻¹. Even highly concentrated Arkema suspensions with 4.5 wt% of MWCNT still display a limited viscosity of only 6.4 Pa.s at a shear rate of 5 s⁻¹. The present results therefore confirm that the use of thin MWCNTs enables the realization of highly conductive suspensions with reasonably low apparent viscosity.

In order to confirm the potential interest of the present suspensions for flow electrochemical applications, it remains critical to check their conductivity under shear. Results of conductance measurements in a Couette cell [3] are shown in Figure 6 for Arkema and Nanocyl materials. The conductance, $1/R$, is plotted as a function of shear rate, where R is the resistance measured between the concentric circular electrodes. It is observed that the conductance decreases very slightly for all the investigated MWCNT suspensions. This slight decrease can result from small fractures that allows flow of the material. The fact that conductivity does not vanish with shear shows that the structural changes in nanotube suspensions remain limited. This is consistent with the description given above of a yield stress fluid with a low consistency index. The material resist against fluidization and disruption of conductive pathways up to shear rates of several hundreds of s⁻¹, even for solid contents as low as 1 wt%.

239

Results of cyclic voltammetry experiments [34] are shown in Figure 7. The current I was measured when the voltage V was varied from -0.5V to 0.5V at a scan rate ($\frac{dV}{dt}$) of 50mV/s. The specific gravimetric capacitance C_{sp} is then deduced by normalizing the current measured for $V=0$ by the weight m of carbon material contained in the volume of the cell. The cell volume in the present setup is 0.24 cm³ per electrode [3].

$$C_{sp} = \frac{2I}{m \cdot \left(\frac{dV}{dt}\right)}$$

The Arkema suspension containing 4.5wt% of MWCNT, and the Nanocyl suspension containing 1.8wt% of MWCNT respectively display specific gravimetric capacitance of 2F/g and 6.5F/g. These values are not particularly high but comparable to those measured for low viscosity carbon black suspensions at similar scan rates [3].

Figure 7. Cyclic voltammetry of suspensions containing 4.5 wt% of Arkema MWCNT and 1.8 wt% of Nanocyl MWCNTs.

5. Conclusion

In conclusion, this study presents a novel approach to address challenges associated with flowable electrodes in electrochemical applications by introducing colloidal suspensions of thin multiwall carbon nanotubes (MWCNTs). The suspensions are stabilized in water with a non-ionic surfactant, and are further concentrated through a dialysis process. The used surfactant molecules contain aromatic groups that promote their adsorption at the interface of the nanotubes. The suspensions are homogenized by tip sonication prior concentration by dialysis. Characterizations of electrical properties demonstrate a percolation-type behavior in electronic conductivity with a strong increase above a critical concentration of carbon nanotubes. Additionally, the suspensions display a shear-thinning behavior in rheological properties, and a stable conductance under shear conditions. Clustering of nanotubes is enhanced and conductivity improved because of weak depletion attractive interactions between the nanotubes. The depletion attraction is attributed to the presence of a large excess of surfactant micelles. Shear induces small structural variations of the depletion-induced aggregates through constant minute structural rearrangements. These reversible rearrangements allow maintaining flow at a nearly constant stress of a globally persistent percolated and conductive network. Optimal suspensions display high conductivity on the order of 50 ms/cm at a low carbon content, below 2 wt%. Cyclic voltammetry experiments reveal specific gravimetric capacitance values comparable to low viscosity carbon black suspensions. This work contributes therefore to advancing the field of flowable electrodes, offering a potential solution to the challenges associated with high viscosity and carbon content. The use of thin MWCNTs in colloidal suspensions presents a promising approach for further developments in flow electrochemical applications, emphasizing the importance of balancing electronic conductivity and viscosity for improved device performance and longevity. Future research directions should focus on enhancing energy storage capabilities. At present, using a low carbon content is naturally an intrinsic limitation for achieving high gravimetric capacitance. This limitation can be somehow mitigated using thin carbon nanotubes, but still remains

276 an obstacle. A promising perspective would consist in using pseudo-capacitive flow
277 electrodes by introducing red-ox active species, such as quinone derivatives, in the for-
278 mulations. This approach has already been proved to be efficient at increasing perfor-
279 mances of flow electrochemical systems [35-39].
