ABSTRACT

Context. Direct imaging (DI) campaigns are uniquely suited to probing the outer regions around young stars and looking for giant exoplanet and brown dwarf companions, hence providing key complementary information to radial velocity (RV) and transit searches for the purpose of demographic studies. However, the critical 5-20 au region, where most giant planets are thought to form, remains poorly explored, lying in-between RV and DI capabilities.

Aims. Significant gains in detection performances can be attained at no instrumental cost by means of advanced post-processing techniques. In the context of the COBREX project, we have assembled the largest collection of archival DI observations to date in order to undertake a large and uniform re-analysis. In particular, this paper details the re-analysis of 400 stars from the GPIES survey operated at GPI@Gemini South.

Methods. Following the pre-reduction of raw frames, GPI data cubes were processed by means of the PACO algorithm. Candidates were identified and vetted based on multi-epoch proper motion analysis – whenever possible – and by means of a suitable color-magnitude diagram. The conversion of detection limits into detectability maps allowed for an estimate of unbiased occurrence frequencies of giant planets and brown dwarfs.

Results. Deeper detection limits were derived compared to the literature, with up to a twofold gain in minimum detectable mass compared to previous GPI-based publications. Although no new substellar companion was confirmed, we identified two interesting planet candidates awaiting follow-up observations. We derive an occurrence rate of $1.7^{+0.9}_{-0.7}\%$ for $5 M_{\text{Jup}} < m < 13 M_{\text{Jup}}$ planets in $10 \text{ au} < a < 100 \text{ au}$, that raises to $2.2^{+1.0}_{-0.8}\%$ when including substellar objects up to $80 M_{\text{Jup}}$. Our results are in line with the literature, but come with lower uncertainties thanks to the enhanced detection sensitivity. We confirm the finding, hinted at by previous studies, of a larger occurrence of giant planets around BA hosts compared to FGK stars; moreover, we tentatively observe a smaller occurrence of brown dwarf companions around BA stars, although larger samples are needed to shed light on this point.

Conclusions. While waiting for the wealth of data expected from future instrument and facilities, valuable information can still be extracted from existing data. In this regard, a complete re-analysis of SPHERE and GPI data is expected to provide the most precise demographic constraints ever provided by imaging.

Key words. Planets and satellites: detection – Planets and satellites: gaseous planets – brown dwarfs – Planetary systems – Techniques: high angular resolution

1. Introduction

1 Bolstered by more than 5000 confirmed detections to date, the
2 exoplanet field has become mature enough to accompany the
3 still thriving detection-oriented endeavor with follow-up stud-
4 ies aimed at shedding light on key questions related to the ori-
5 gin, the prevalence, and the architecture of planetary systems.
6 By unveiling statistical trends in the measured physical, orbital
7 and star-related properties of the exoplanet population, exoplanet
8 demographics seeks to connect theory and observation, in order
9 to fully understanding the physical processes underlying planet
10 formation (Biazzo et al. 2022).
11

The census of known exoplanets currently spans about four
magnitudes in mass and in semi-major axis¹. No single detection
method is adequate to probe such a large extent of the parame-
ter space: it is through the combination of the different meth-
ods, each optimized for detection inside a specific niche, that
the large-scale picture can be unveiled and reconstructed (see,
e.g., Gratton et al. 2023, 2024). However, obtaining a complete
and unbiased blend from heterogeneous ingredients is hindered
by factors such as inconsistent detection criteria, completeness
and false positive assessment, uncertainty quantification, neglect
of underlying selection or observational biases (Gaudi et al.

¹ Empirically estimated based on the Extrasolar Planet Encyclopaedia:
<http://www.exoplanet.eu/>.

2021). Whenever two different methods can be simultaneously employed, their complementarity allows better characterizing individual objects (see, e.g., Gandolfi et al. 2017; Bonnefoy et al. 2018; Bourrier et al. 2018; Lacedelli et al. 2021; Kuzuhara et al. 2022; Philipot et al. 2023, Lagrange et al. under review) and strengthening the statistical trends emerging in each of the methods (Rogers 2015; Santerne et al. 2016). In the cases where different techniques probe instead different separations within the same system, the joint analysis opens up exquisite dynamical and formation studies (see, e.g., Covino et al. 2013; Bryan et al. 2016; Zhu & Wu 2018).

Radial velocity (RV) surveys have provided invaluable constraints on the physical and orbital properties of giant planets up to ~ 5 au (Wolthoff et al. 2022; Rosenthal et al. 2024). Yet, the reliability of RV trends for larger separations has been questioned (Lagrange et al. 2023), and the predicted yields for direct imaging (DI) surveys based on extrapolations of RV results have been shown to be too optimistic (see, e.g., Cumming et al. 2008; Dulz et al. 2020). On the other hand, direct imaging (DI) is mostly sensitive to young giant planets in wide ($a \gtrsim 20$ au) orbits, providing access to the scarcely studied outskirts of planetary systems. Starting from 2004 (Chauvin et al. 2004), direct imaging has discovered ~ 30 planets ($M < 13M_{\text{Jup}}$) (Zurlo 2024), including iconic systems like the disk-enshrouded PDS 70 (Keppler et al. 2018), the ~ 20 -Myr-old β Pictoris (Lagrange et al. 2009), 51 Eridani (Macintosh et al. 2015), AF Leporis (Mesa et al. 2023; De Rosa et al. 2023; Franson et al. 2023), and the four-planet HR 8799 (Marois et al. 2008). These detections are the main outcome of large blind surveys targeting tens (e.g. MASSIVE, Lannier et al. 2016; SEEDS, Uyama et al. 2017; LEECH, Stone et al. 2018) or hundreds of stars (e.g. NICI-PCF, Liu et al. 2010; IDPS, Galicher et al. 2016; ISPY-NACO, Launhardt et al. 2020). The forefront of DI surveys, enabled by the exquisite performances of imagers and integral field spectrographs, coupled with extreme AO systems mounted on 8-m-class telescopes, is currently represented by the 400-star SHINE (Chauvin et al. 2017) and the 600-star GPIES (Nielsen et al. 2019) surveys.

By constraining the overall frequency and the properties of wide-separation giant planets, DI studies are expected to enable a thorough comparison with concurrent formation models (see, e.g., Bowler 2016; Vigan et al. 2021); orbital properties, for instance, shed light upon their formation and dynamical evolution (Bowler et al. 2020); the dependence of frequency on stellar mass provides clues about the initial state of the disk and the formation mechanisms at play (Nielsen et al. 2019; Janson et al. 2021). However, despite years of extensive searches, it is still not clear whether the main formation channel for the observed wide-orbit population be core accretion (CA; Pollack et al. 1996; Mordasini et al. 2009), the bottom-up process responsible for the formation of planets in the Solar System, or rather a top-down star-like scenario like gravitational instability (GI; Boss 1997; Vorobyov 2013). While an interplay between the two scenarios is deemed to be favored by empirical parametric models (Reggiani et al. 2016; Vigan et al. 2021) and direct comparison with synthetic planet populations (Vigan et al. 2021) alike, understanding in an unambiguous way how each known companion was formed is still beyond reach. The large uncertainties still existing in the interpretation of the observed picture can be attributed, at least partially, to the fact that the critical 5-20 au region, where most giant planets are thought to form, remains poorly explored being exactly in-between current RV and DI capabilities.

Under given observing conditions, the final performances attainable by a high-contrast imaging observation are dictated

both by instrumental (e.g., the telescope, the science instrument, the performance of adaptive optics and coronagraphs) and post-processing components (the algorithms applied to science images to decrease the level of systematic and random noise) (Galicher & Mazoyer 2024). Depending on observing conditions, stellar brightness and angular separation, state-of-the-art instruments such as the Spectro-Polarimetric High-Contrast Exoplanet Research (SPHERE; Beuzit et al. 2019) and the Gemini Planet Imager (GPI; Macintosh et al. 2014) typically achieve raw planet-to-star contrasts as low as $10^{-3} - 10^{-5}$ (Poyneer et al. 2016; Courtney-Barrer et al. 2023). On the instrumental side, 30-m-class telescopes and space-borne coronagraphic instruments are expected to bring about a major leap forward for the field in the next decade (see, e.g., Kasdin et al. 2020; Kasper et al. 2021), whereas upgrades of existing instruments such as SPHERE+ (Boccaletti et al. 2022) and GPI 2.0 (Chilcote et al. 2018) are going to represent the forefront in the medium term; on the reduction side, advanced post-processing algorithms have been already shown to increase the contrast by as much as two orders of magnitudes compared to pre-reduced data. Therefore, the developments of more powerful reduction techniques can greatly increase detection capabilities working on observations that already exist (see, e.g., Currie et al. 2023).

In the framework of the COupling data and techniques for BReakthroughs in EXoplanetary systems exploration (COBREX) project, we collected more than a thousand archival SPHERE and GPI observations, assembling the largest exoplanetary direct imaging survey to date, with the aim of re-reducing them in a uniform and self-consistent way. The results of the full re-reduction of the SHINE survey are illustrated in Chomez et al. (2024). In this work, we present the re-reduction of 400 stars coming from GPIES. Despite being the largest DI observational campaign to date, just two new substellar objects were discovered during the survey: one planet (51 Eri b, Macintosh et al. 2015) and one brown dwarf (HR 2562 B, Konopacky et al. 2016). A statistical analysis of the first 300 stars was performed by Nielsen et al. (2019, hereafter N19). By combining the two surveys, it will be possible to obtain the tightest constraints to date on the occurrence of wide-orbit giant planets, hence providing an ideal test-bed to scrutinize planet formation models.

This paper is organized as follows: after laying out the selection criteria for the sample and the corresponding observations (Section 2.2), and uniformly deriving the stellar parameters of interest (Section 2.3), we describe in detail the process of data reduction (Section 2.4). Section 3 presents the results of the analysis, namely companion candidates and completeness maps. The derived occurrence rates are presented and discussed in Section 3.4. A thorough comparison with the literature is the subject of Section 4. Finally, in Section 5, we summarize the results of this work.

2. Data

2.1. Raw data collection

The observations considered in this work were collected between 2013 and 2020 by means of GPI at the Gemini South telescope. GPI is an integral-field spectrograph (IFS) with low spectral resolution (~ 50 ; Maire et al. 2014), operating in the wavelength range $[0.97-2.40] \mu\text{m}$. As the vast majority of GPI observations were gathered in the H band ($[1.5-1.8] \mu\text{m}$) (Ruffio et al. 2017) – other bands being mostly used for characterization purposes – we decided to restrict our query to H-band observations.

We downloaded therefore all H-band raw frames from GPI that are publicly available on the Gemini archive² (~30000 frames)³. We neglected observational sequences with 5 or less frames (typically corresponding to $\lesssim 5$ -min exposure times), and observations of stars only taken for calibration purposes (easily identifiable through their program ID). The reason behind this choice is twofold: on the one hand, the known multiplicity of these stars is expected to detrimentally affect the performances attainable by post-processing; on the other hand, selection criteria for these stars are different from those of science targets, thus inducing a bias when interested in statistical considerations.

The preliminary sample obtained in this way (hereafter GPI database) is composed of 852 sequences for 655 stars. Most of the observations (715/852) within the database were collected in the course of GPIES, and additional 10 sequences are describable as follow-up observations of interesting stars from the campaign. Intertwined to GPIES observations, the remaining 127 sequences were gathered over the lifetime of the instrument as part of other scientific programs. The following Section 2.2 will elucidate how the final stellar sample was assembled, and the criteria that a sequence had to meet in order to be included in the corresponding sample of observations.

2.2. Sample definition

Like any other direct imaging search to date, GPIES was constructed by looking for young stars in the solar neighborhood; the reason lies in the fact that recently formed exoplanets and brown dwarfs are brighter and hotter than mature objects of the same mass due to residual formation heat, yielding a significantly more favorable planet-to-star contrast in near infrared bands. In particular, the stellar sample was assembled by merging lists of members of young moving groups from the literature (de Zeeuw et al. 1999; Zuckerman et al. 2001, 2011) with close (<100 pc) stars selected for large X-ray emission. Echelle spectra were obtained for ~ 2000 stars to further identify additional young stars based on lithium abundance and chromospheric activity (see Section 2.3 for details). After removing apparent binaries with angular separation $\in [0.02'', 3'']$ and $\Delta\text{mag} < 5$ (both before and during the campaign), and accounting for some new association members, a sample of 602 stars was finally obtained (Nielsen et al. 2019).

Due to the decommissioning of GPI – currently undertaking major upgrades to become GPI 2.0 (Chilcote et al. 2020) – in early 2020, the GPIES survey was never completed (~ 10% of the stars lack observations). It is thus vital to ascertain whether the sample of observed stars be an unbiased extraction of the full sample. An automated target-picker was employed to suggest the best targets for every telescope night, as a function of both observing conditions and stellar age/distance (McBride et al. 2011); however, we verified through a Kolmogorov-Smirnov test ($\alpha = 0.05$) that the age and distance distributions of the first 300 stars (those from N19) are compatible with those of the full sample of observed stars ($p_{\text{age}} \approx 1$, $p_{\text{dist}} = 0.051$). Additionally, stars with known companions were not prioritized in their first-epoch observation (Nielsen et al. 2019). We can thus confidently maintain that the available GPIES observations are not affected by

² <https://www.cadc-ccda.hia-ihp.nrcnrc.gc.ca/en/gemini/> and <https://archive.gemini.edu/>

³ We could not retrieve science commissioning data from 2014 from the old Gemini website (Macintosh et al. 2014). However, the targeted stars were only known hosts of exoplanets or disks (HR 8799, HR 4796, HD95806) that were later re-observed during GPIES.

selection biases, making the sample suitable for statistical studies.

The definition of the final sample was based on a combination of observational constraints and physical constraints on stellar properties. As regards the former aspect, a minimum amount of parallactic angle rotation $\Delta\text{PA} \sim 10^\circ$ is required to enable efficiently using angular differential imaging (ADI) during post-processing (Marois et al. 2006): we conservatively adopt a minimum rotation of 12° in order to exploit angular differential imaging (ADI) during post-processing⁴. A single observation with extremely bad seeing was removed. With respect to the latter, we only retained stars for which youth can be established with reasonable confidence (see Section 2.3).

Given our ignorance about the selection criteria adopted for stars from non-GPIES programs, we decided not to consider them for the purpose of this paper. However, we retained non-GPIES observations of GPIES stars as valuable follow-up epochs for promising point-source candidates. The final sample employed throughout this work consists of 400 stars (515 sequences).

2.3. Stellar parameters

The knowledge of stellar ages is pivotal to a meaningful interpretation of direct imaging campaigns, as a large degeneracy exists between age and mass – let alone additional parameters like metallicity or a planet’s formation history – for substellar objects for which only photometric data are available (see, e.g., Spiegel & Burrows 2012).

Our primary age diagnostics is provided by kinematic membership to young associations and moving groups (hereafter YMGs). Starting from Gaia DR3 (hereafter Gaia; Gaia Collaboration et al. 2023) data, we used BANYAN Σ (Gagné et al. 2018b) to classify a star as a member of a YMG if the associated membership probability $p > 90\%$. A second indicator was represented by the ages obtained by N19: we stress that the underlying data are not public and the derived ages, not equipped with error bars, are only available for the 300 stars presented in that study. Finally, the ages for 21 additional stars – that are not members of YMG nor targets of N19 – could be recovered after cross-matching our sample with SHINE (Desidera et al. 2024), whose thorough analysis builds upon a manifold variety of indicators (isochrones, YMG membership, activity, lithium abundance). For ages based on N19, that come with no associated uncertainty, we adopt a constant fractional uncertainty of 25%, empirically tuned to match the typical fractional uncertainty for SHINE stars.

Individual stellar parameters for each star were obtained by means of MADYS⁵ (v1.2, Squicciarini & Bonavita 2022), a tool for (sub)stellar parameter determination based on the comparison between photometric measurements and isochrone grids derived from theoretical (sub)stellar models. Assuming the ages described above, photometry from Gaia DR3 and 2MASS (Skrutskie et al. 2006) – corrected by extinction by integrating the 3D map by Leike et al. (2020) along the line of sight – was compared to the last version of non-rotating, solar-metallicity PARSEC isochrones (Nguyen et al. 2022).

The distance, age and spectral type of the 400 stars are shown in Figure 1. The full collection of the derived properties is sum-

⁴ The distribution of ΔPA across the database shows a bump for $\Delta\text{PA} > 12^\circ$. Whereas just 12 sequences have $10^\circ < \Delta\text{PA} \leq 12^\circ$, 49 observations are found inside the $12^\circ < \Delta\text{PA} \leq 14^\circ$ bin.

⁵ <https://github.com/vsquicciarini/madys>

Fig. 1: Age of the final stellar sample as a function of distance. The color scale labels different spectral types. Kernel density estimates for the distribution of the two properties are provided on top and to the right of the main plot.

259 marized in Table A, while the ages adopted for YMGs are provided in Table A.2.
260

261 2.4. Data reduction

262 2.4.1. Preliminary steps

263 The pre-reduction of raw GPI data is performed in two steps: the
264 goal of the first step is to build a 3D data cube (x, y, λ) starting
265 from the 2D image acquired in the detector plane; the collection
266 of the derived data cubes is then stacked into a final 4D data cube
267 (x, y, λ, t).

268 As routinely done for GPI data, we employed the version
269 1.6.0 of the GPI Data Reduction Pipeline (hereafter DRP; Perrin
270 et al. 2014, 2016; Wang et al. 2018) to handle the first part of
271 the pre-reduction. After subtracting a dark frame, bad pixels in
272 the image are substituted by interpolated values. The mapping
273 of the ~ 37000 small spectra created on the detector by GPI's
274 lenslet array to the corresponding spaxels of the 3D data cube is
275 determined by means of master wavelength calibrations based on
276 Xenon or Argon lamps, conveniently corrected for mechanical
277 offsets induced by flexure (Wolff et al. 2014). The signal of each
278 spectrum can be thus extracted and stored into the corresponding
279 spaxel (Draper et al. 2014). Subsequent steps correct for small
280 distortions effects of the field of view and for halos induced by
281 residual atmospheric turbulence.

282 Thanks to a square grid embedded within the pattern of
283 the apodizer, a diffraction pattern of *satellite spots* (hereafter
284 *satspots*) – attenuated images of the star – is created in the image.
285 The four first-order *satspots*, symmetrically situated at $\sim 20\lambda/D$
286 from the star, serve three different purposes: 1) to recenter the
287 frames, by locating the position of the occulted star; 2) to cali-
288 brate the flux level of each pixel in the science image; 3) to build
289 a model of the off-axis point spread function (PSF)⁶ (Wang et al.
290 2014). The final operations of the DRP deal with the astrometric
291 and photometric characterization of the *satellite spots*, fitted by
292 a Gaussian PSF template.

⁶ Unlike SPHERE, no PSF exposure is taken before and/or after the scientific observation in GPI.

293 The second step of the pre-reduction deals with stacking up
294 and recentering frames to build the final 4D data cube. In addition
295 to the data cube, three files are created: 1) a 4D PSF; 2)
296 a wavelength vector; 3) a parallactic angle vector, that indicates
297 the rotation of the field of view during the sequence. Indeed, GPI
298 observations are operated in a pupil-stabilized mode, i.e. with no
299 derotator, so as to allow using ADI-based post-processing algo-
300 rithms (see, e.g., Ruffio et al. 2017).

301 This stage is achieved using PYKLIP (Wang et al. 2015a).
302 Compared to the 2.6 version, we introduced slight modifica-
303 tions⁷ to create output files formatted in a SPHERE-like way as
304 regards the data format, the PSF, and data cube flux, and the FOV
305 orientation (East to the left). In this way, we ensured the har-
306 monization of the future SPHERE+GPI sample while smooth-
307 ing the I/O integration with the post-processing algorithm (Sec-
308 tion 2.4.2). In addition to computing the image center through
309 *satspot* pattern, PYKLIP estimates *satspot* flux in a more precise
310 way than the DRP, a crucial step for photometric characteriza-
311 tion purposes, and empirically recomputes the wavelength vec-
312 tor based on the *satspot*-to-center separation (which scales with
313 λ). We visually checked the goodness of the result for all our im-
314 ages; whenever a specific *satspot* was – due to intrinsic dimness
315 or systematic problems – not properly fitted, inducing centering
316 offsets in one or more frames, we used a specific option of PYKLIP
317 to ignore it during recentering.

318 As already mentioned, *satellite spots* are faint images of the
319 target star; the flux ratio between a *satspot* and the star, or grid
320 ratio, was determined by Wang et al. (2014) to be $\Delta m = 9.4 \pm 0.1$
321 mag through on-sky observations. The $\sim 10\%$ uncertainty on the
322 grid ratio turns out to be one of the main factors in the total error
323 budget of GPI spectrophotometry.

324 We performed several tests to quantify the reliability of the
325 wavelength solution, the image centering and the photometric
326 calibration of the PSF. The accuracy of the DRP wavelength solu-
327 tion was estimated by Wolff et al. (2014) to be 0.032% in H-
328 band, well below the 1% accuracy needed to achieve a spectral
329 characterization uncertainty $< 5\%$. As regards the wavelength
330 precision, we collected for every sequence the *satspot* positions
331 estimated by the DRP, computed separations from PYKLIP's frame
332 centers, $\xi(\lambda, t, s)$, then averaged over the temporal axis t and the
333 *satspot* axis s to obtain $\hat{\xi}(\lambda)$. We computed the ratio $\eta = \xi(\lambda)/\lambda$
334 for every sequence, a value that ought to be constant. The 50th,
335 16th and 84th percentiles of the distribution across the sequences
336 yields $\langle \eta \rangle = 37.921_{-0.046}^{+0.056}$ px/ μm , corresponding to a precision
337 of 0.15%.

338 As regards centering precision, propagation of random un-
339 certainties in PYKLIP yields a centering precision along one axis
340 $\sigma_{c,x} = 0.04$ px (that is, ~ 0.06 px in 2D), comparable to the one
341 reported in Wang et al. (2014). However, we identified a system-
342 atic deviation of the *satspot* pattern shape from a square (which is
343 an underlying assumption of PYKLIP's centering algorithm): the
344 difference between the centers computed from doublets of op-
345 posite *satspots* ($x_{c,13}, y_{c,13}$) and ($x_{c,24}, y_{c,24}$), stable over time, is
346 $\Delta S = \sqrt{(x_{c,13} - x_{c,24})^2 + (y_{c,13} - y_{c,24})^2} = 0.39 \pm 0.04$ px. We
347 consider the true center to be distributed according to a uniform
348 distribution between ($x_{c,13}, y_{c,13}$) and ($x_{c,24}, y_{c,24}$). The final cen-
349 tering error σ_c is therefore:

$$\sigma_c = \sqrt{\left(\frac{\Delta S}{\sqrt{12}}\right)^2 + 4 \cdot (\sigma_{c,x})^2} \approx 0.15 \text{ px} \sim 2 \text{ mas.} \quad (1)$$

⁷ url of GitHub repository, to be added upon acceptance

350 This value was consistently employed when propagating astro-
351 metric uncertainties of detected sources.

352 Finally, we adopted a platescale of 14.161 ± 0.021 mas px⁻¹
353 (De Rosa et al. 2020a), assuming it to be stable over time (Tran
354 et al. 2016). With respect to the north offset angle, we used a
355 time-varying value following the prescriptions indicated in Table
356 4 from De Rosa et al. (2020a).

357 2.4.2. Post processing – PACO

358 Pre-reduced datasets were processed in the COBREX Data
359 Center, an improved version of the High-Contrast Data Cen-
360 ter (HC-DC⁸, formerly SPHERE Data Center, Delorme et al.
361 2017). Prompted by the promising preliminary results presented
362 in Chomez et al. (2023), we decided to process our archive
363 by means of the PATCH-COVariance algorithm (PACO; Flasseur
364 et al. 2018) in its robust angular and spectral differential imaging
365 (ASDI) mode (Flasseur et al. 2020a,b).

366 PACO is a post-processing algorithm that employs ASDI to
367 model the spatial and temporal fluctuations of the image back-
368 ground inside small patches through a combination of weighted
369 multivariate (i.e., accounting for the spatio-spectral correlations
370 of the speckles field) Gaussian components. Extensive testing
371 proved that the resulting SNR map is distributed as a normal-
372 ized Gaussian $\mathcal{N}(0, 1)$, hence naturally providing a statistically
373 grounded detection map upon which $> 5\sigma$ detections can be
374 identified at a controlled false alarm rate (e.g., at 5σ significance
375 level). The algorithm was shown to be photometrically accurate
376 and robust to false positives, and to outperform reduction meth-
377 ods that are routinely employed for SPHERE (Chomez et al.
378 2023). For these reasons, PACO was appointed by the SHINE
379 consortium as the main reduction algorithm for the final analysis
380 of the whole survey (Chomez et al. 2024).

381 In addition to this, the ASDI mode of PACO uses vectors
382 of spectral weights (hereafter spectral priors) to maximize the
383 detection capability of candidate sources exhibiting physically
384 representative substellar spectra. As detailed in Chomez et al.
385 (2023), for every star we generated 20 such priors starting from
386 exoplanet spectra from the ExoREM library (Charnay et al.
387 2019) ($T_{\text{eff}} \in [400, 2000]$ K) and suitable stellar spectra from
388 the BT-Nextgen AGSS2009 library (Allard et al. 2011).

389 As in Chomez et al. (2023), extensive injection tests were
390 performed on GPI datasets in order to ensure the reliability of 5σ
391 detection limits, an output provided by PACO after the reduction
392 (Flasseur et al. 2020a). After randomly picking a sample of 10
393 sequences, 12 synthetic sources were evenly injected in each ob-
394 servation’s FOV; the mean flux of each source was set equal to
395 the 5σ detection limits estimated by PACO at the corresponding
396 coordinates. The whole process was repeated three times, vary-
397 ing the input spectrum – a flat contrast spectrum, a T-type spec-
398 trum and an L-type spectrum⁹ – of injected sources, yielding a
399 total 360 injected sources. The median SNR of the recovered
400 sources is 5.1, with little variation with spectral type, confirm-
401 ing the statistical reliability of the contrast and detection confidence
402 estimated by PACO and underlying the statistical analysis.

403 Figure 2 shows the final performances attained by the PACO
404 reduction as 5σ detection limits. It is possible to notice that the
405 usage of physically-motivated spectral priors does indeed en-

Fig. 2: 5σ detection limits obtained with PACO. Individual curves are plotted in gray. The median curve is plotted as a light blue solid line, the dashed lines representing the 16% and 84% percentiles of the curve distribution. The orange and green solid lines indicate the median detection limits assuming a T-type and an L-type spectral prior, respectively. The gray box marks the inner working angle of the coronagraphic mask.

406 enhance detection capabilities. However, in order to easily allow
407 for comparisons with reductions performed using different algo-
408 rithms, we conservatively adopt in the following analysis a flat
409 spectral prior, that is a combination of spectral channels assum-
410 ing that any source has the same spectral energy distribution as
411 its star; this is equivalent to standard SDI-based algorithms.

412 2.4.3. Post processing – cADI

413 One of the underlying assumptions behind PACO is that the
414 spatial and temporal fluctuations of noise inside patches are
415 much stronger than the additional contribution given by phys-
416 ical sources happening to cross the patch itself during the expo-
417 sure (Flasseur et al. 2018). The assumption breaks down when
418 a bright source, such as a stellar companion, is present. In other
419 words, the algorithm is optimized to detect faint sources but can
420 severely subtract, or even cancel, very bright sources in the de-
421 rived SNR map. In order to complete the census of sources at
422 the bright end, we developed a custom routine based on classi-
423 cal angular differential imaging (cADI; Marois et al. 2006) and
424 performed a uniform reduction of the archive. After computing
425 the pixel-wise median frame of the exposure sequence, the rou-
426 tine subtracts it from every frame, then de-rotates the frames and
427 sums them up both temporally and along wavelength. The 4D
428 PSF is stacked along the temporal axis to build a 3D (x, y, λ)
429 PSF, which is then fitted by a 2D Gaussian model. The reduced
430 map is finally normalized by the peak of the PSF model so as
431 to translate it in contrast units. Detections are automatically per-
432 formed on the derived map by computing the variance across
433 annuli, centered on the target star, of width equal to 1 px, and
434 finding the pixels of the map beyond a certain threshold level
435 κ (expressed in noise standard-deviation units). In a subsequent
436 step, a more precise characterization by fitting the PSF model
437 provides the astrometry and photometry of each source.

438 Because of the simplicity of the noise-reduction approach,
439 the SNR distribution in any annulus of a given contrast maps
440 usually shows large deviations from Gaussianity. On the one

⁸ <https://sphere.osug.fr/spip.php?rubrique16&lang=en>

⁹ Input contrast spectra, created using the same procedure as spec-
tral priors, are arbitrarily defined using the following parameters:
($T_{\text{eff}}, \log g, Z/Z_{\odot}, \text{CO}$) = (1000 K, 4.0, 1.0, 0.5) for the T type and
($T_{\text{eff}}, \log g, Z/Z_{\odot}, \text{CO}$) = (1900 K, 3.0, 10.0, 0.6) for the L type.

Fig. 3: Comparison between PACO and cADI performances. Sources only detected by PACO are shown as blue circles, while sources only seen through cADI are indicated as red diamonds. Common sources are plotted as blue squares with a red edge.

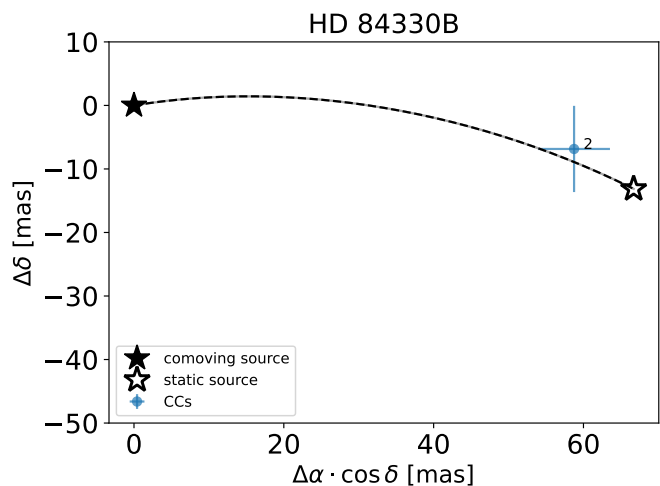

Fig. 4: Example of proper motion diagram. The astrometric displacement of the candidate around HD 84330B between the first and the second epoch is compatible with a background source with null motion (empty star). A bound object would have been in a position close to that marked by the filled star and within the boundaries allowed by a Keplerian motion.

441 side, this issue implies that high thresholds ($\kappa \gtrsim 20$) had to be
442 adopted to ensure the stability of the detection step; on the other
443 side, the poor robustness against outliers intrinsically prevents
444 one from precisely defining a statistically grounded detection
445 threshold.

446 Visual inspection of all the maps ensured the reliability of
447 the detections; given the above-mentioned caveats and the neg-
448 lect of a correction for signal self-subtraction, the derived pho-
449 tometry will only be used to characterize the stellar companions
450 presented in Section D.

451 3. Results

452 3.1. Exoplanet candidates

453 The PACO reduction of our sample yielded 91 detected sources.
454 This number does not include a few false positives that could
455 be recognized and removed (see Section 3.2). 11 additional
456 sources were detected through cADI. 62 sources are detected by
457 both methods, ensuring the overlap of the respective dynamical
458 ranges. Figure 3 shows the sources detected by the two meth-
459 ods. Astrometric and photometric details for all the candidates
460 are provided in Table C.1.

461 Candidate companions in DI observations are always seen as
462 unresolved point-like sources, and no information on their dis-
463 tance can be discerned from a single observation; in other words,
464 it is not clear a priori if a source is physically bound to the tar-
465 get star or is instead a distant background star that happens to
466 be projected close to the target. If two or more epochs are avail-
467 able, the differential motion between the foreground target star
468 (and the objects bound to it) and faraway background stars can
469 be disentangled (Figure 4).

470 Whenever more than one observation was available in our
471 sample, or if additional epochs from SPHERE could be recov-
472 ered, it was possible to ascertain the proper motion of the candi-
473 dates: 57 sources from the PACO reduction and 2 sources only
474 detected with cADI were ruled out as background contaminants
475 in this way.

476 If only a single observation was available, or if detection lim-
477 its allowed for detection in just one epoch, we adopted an alter-

native vetting criterion that exploits color-magnitude diagrams 478
(CMDs) to identify sources showing similar colors to known 479
imaged planets and to set them apart from background sources. 480
It might be argued that, given the availability of contrast spec- 481
tra, a spectrum-based classification could be employed; how- 482
ever, we argue that such a method would be highly sensitive to 483
both random uncertainties and the ignorance about the amount 484
of interstellar extinction to be adopted for background-star spec- 485
tra. Conversely, the photometric method based on CMDs has 486
already been shown to be highly reliable for absolute magni- 487
tudes $H \gtrsim 15$ mag, using an unprecedented sample of ~ 2000 of 488
confirmed astrophysical background sources found in SPHERE 489
data (Chomez et al. 2024). This usage of the CMD has been in- 490
troduced by the SHINE consortium (Chauvin et al. 2017) and 491
its construction is fully detailed in Bonnefoy et al. (2018). This 492
tool has already been used to efficiently classify some of the 493
sources detected in the first part of the SHINE survey (Langlois 494
et al. 2021). As a first step, the H-band spectrum of each tar- 495
get star was estimated by means of synthetic stellar spectra from 496
the BT-Nextgen AGSS2009 library¹⁰ (Allard et al. 2011), ade- 497
quately degraded to match the spectral resolution of GPI. The 498
best-matching synthetic spectrum was identified as the closest 499
in effective temperature; the latter was empirically estimated as 500
the median value across all literature measurements found in 501
VizieR (Ochsenbein et al. 2000). Contrast spectra from candi- 502
date sources detected with PACO¹¹ could thus be turned into 503
physical spectra by multiplying them by their corresponding pri- 504
maries spectra. We convolved these spectra with SPHERE H2 505
and H3 filters to derive synthetic H2 and H3 photometry for 506
all our candidates; in other words, GPI spectroscopy was turned 507
into SPHERE-like photometry both to exploit the CMD vetting 508

¹⁰ The library, available at <http://svo2.cab.inta-csic.es/theory/newov2/index.php?models=bt-nextgen-agss2009>, is defined by the following astrophysical parameters: $\log g[\text{cm s}^{-2}] = 4.5$, $\log Z/Z_{\odot} = 0$, alpha enhancement = 0.

¹¹ The status of all cADI candidates but one could be confirmed through dynamical arguments; the remaining one is too bright to allow for the CMD test.

Fig. 5: CMD of the companion candidates detected in this work. Overplotted to known substellar objects (white squares), background stars are represented as yellow stars if identified through proper motion analysis, or as blue circles if recognized via their color. Ambiguous sources are marked as red crosses. The exclusion area (gray) is defined by the two dashed lines. The two promising candidates (from left to right: C1 (HD 24072), C2 (HIP 78663)) are indicated as red dots.

method and to enable future comparisons between the results from the two instruments. The convolution was possible thanks to the broad extent of GPI's H band, whose wavelength window covers both SPHERE narrow-band H filters.

In this way, it was possible to place every PACO candidate in a $(H_2 - H_3, H_2)$ CMD (Figure 5). We used confirmed background objects from the SHINE survey – that offers a larger sample statistics thanks to the wide $11'' \times 11''$ field of view of IRDIS (Dohlen et al. 2008) – to build an "exclusion zone", defined as the region of the CMD that encompasses all the points within 5σ from the mean colors of background sources as a function of their absolute magnitude. As in SHINE publications, the exclusion zone was set to begin at $H_2 = 16$ mag, as the existence of some planets (e.g., HR 8799 b) with $H_2 \sim 15$ mag and $H_2 - H_3 \sim 0$ mag renders the method unreliable at brighter magnitudes (Langlois et al. 2021, Chomez et al. 2024). We labeled as "companion candidates" the sources lying along the T track or having additional indications hinting towards a bound nature, and as "ambiguous" the sources in the region $H_2 < 16$ mag and $H_2 - H_3 \sim 0$.

Excluding already known substellar companions, all but nine sources can be confidently ruled out as background contaminants. Seven of these are classified as ambiguous according to

our vetting scheme, and will not be hereafter discussed. The nature of the two remaining promising candidates – whose photometry and age is consistent with $5-8 M_{\text{Jup}}$ objects – is currently unclear. The candidate around HIP 78663 is located in a position of the CMD where the colors of bound companions overlay those of background stars; however, we classify it as a promising candidate because of a tentative $\sim 3.5\sigma$ detection in the shallower second epoch possibly hinting at common proper motion. As regards the candidate around HD 24072, in addition to the hypothesis of a bound nature, the following scenarios might be envisaged to explain its position along the young-object track:

1. a free-floating planet or brown dwarf, belonging to the same association as the target and hence possessing similar colors to substellar companion while not exhibiting a large variation of the distance modulus;
2. a statistical false positive (see Section 3.2). A spectral dependence of the photocenter of a false positive might happen to mimic, during the characterization step of PACO, blue spectra similar to those of real substellar companions lying along the T track.

Spurious detections in direct imaging have previously arisen due to extended objects (proto-planetary and debris disks) that were poorly subtracted (see, e.g., Sallum et al. 2015 and confutation by Currie et al. 2019), but we exclude this possibility given the lack of infrared excess in WISE (Wright et al. 2010) bands.

We finally notice that the HD 24072 system also comprises a low-mass star, closer to the primary than the planet candidate (see Section D); under the assumption of face-on circular orbits, we empirically verified, based on the results by Musielak et al. (2005), that the candidate would be far enough from the substellar companion to be dynamically stable.

Our reanalysis redetected all substellar companions (7 planets, 3 brown dwarfs) that we expected to find on the basis of the literature (Figure 6). Some of these companions – notably, HR 8799 c, d, and e – have just one epoch in our observing sample; consistently with the decision tree described above, we would have been able to confirm them as bound objects through proper motion test, employing additional available SPHERE or GPI epochs.

We report in Table 1 details about the astrometry and the photometry of these 10 substellar companions. Given the extensive characterization of these objects already undertaken in the literature, we deem a re-derivation of masses and semi-major axes – the main input needed for the statistical analysis of Section 3.4 – to be outside of the scope of this paper; instead, we decided to recover the most accurate values from dedicated literature works.

In addition to substellar companions, we detected 6 sources whose high luminosity points towards a stellar nature. We were able to confirm 5 of them as physically bound thanks to 1) a proper motion strongly disagreeing with background stars, and 2) astrometric wobbles indicated by the Gaia astrometric solution of the corresponding primaries; the remaining binary candidate to HD 74341B, with no second epoch and too bright to employ the CMD test, awaits confirmation. Details are provided in Section D.

3.2. False positives

As mentioned in Section 3.1, the roster of PACO candidates does not include a few detections identified as false positives, induced either 1) by real astrophysical or optical features, or 2) by statistical fluctuations of the SNR map. The former category includes residuals of the first Airy ring around very bright sources

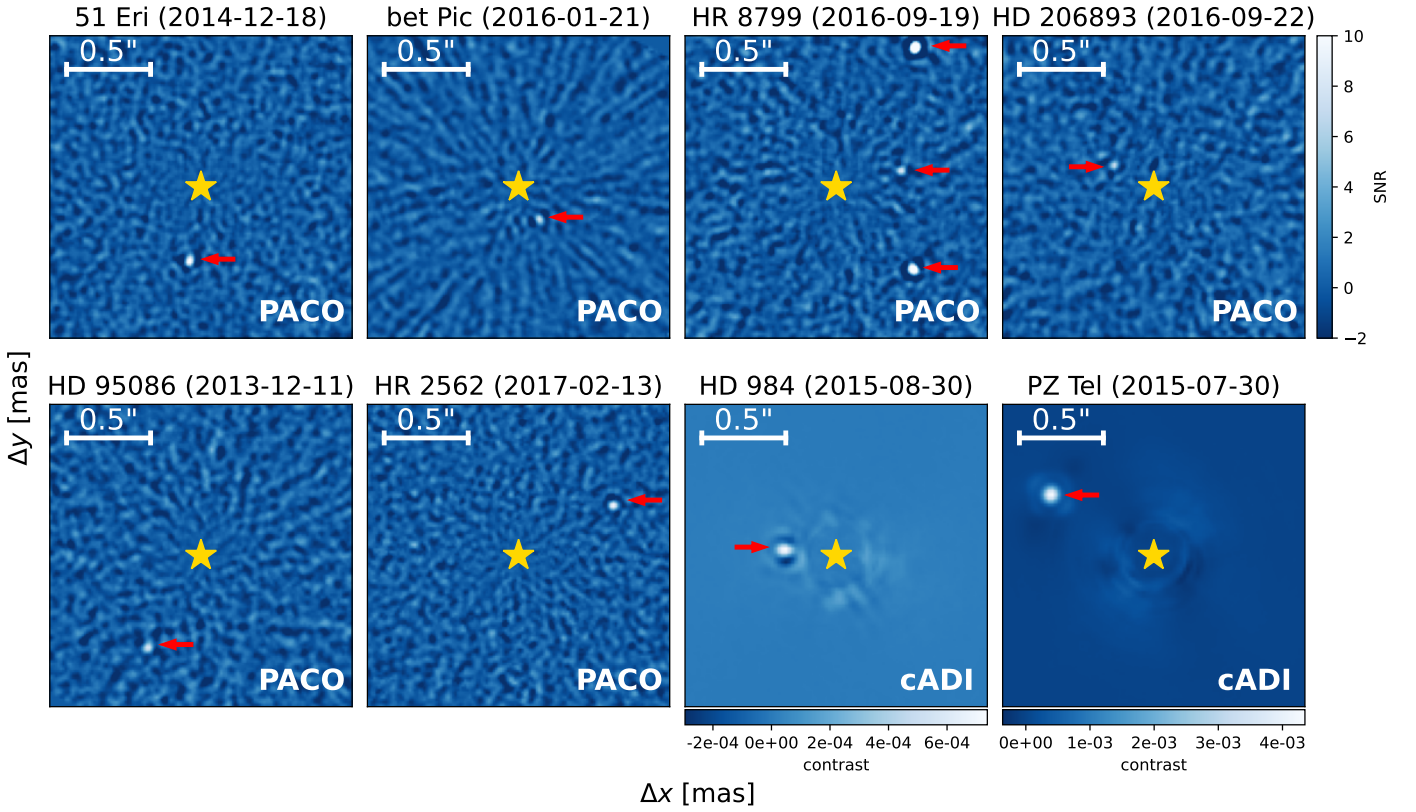

Fig. 6: PACO or cADI detection maps for the substellar companions detected in the survey (indicated by arrows). PACO maps are to be read as SNR maps, sharing a common colorbar. Individual colorbars are shown below the two cADI maps.

Table 1: Detected substellar companions to stars in the sample.

(2024); 5: De Rosa et al. (2020b); 6: Lacour et al. (2021); 7: Nielsen et al. (2019); 8: Rameau et al. (2016); 9: Zhang et al. (2023); 10: Franson et al. (2022); 11: Franson & Bowler (2023). The column named "subsample" indicates whether the parent star belongs to the FGK or the BA subsample (see Sec. 3.4).

593 (2 cases) and disk residuals (10 cases); the latter (8 cases) is con-
594 stituted by unusually bright residuals that had no counterpart in

additional GPI or SPHERE observations with better or similar
detection limits. 595
596

597 With respect to the latter case, we tried to estimate the number
598 of false positives expected to arise from statistical fluctuations.
599 We recall that the distribution of pixel intensities in PACO SNR maps is a normalized Gaussian $\mathcal{N}(0, 1)$. In this
600 case, a 5σ threshold corresponds to a false alarm probability
601 $p_{5\sigma} = 2.9 \cdot 10^{-7}$. Given the number of pixels in GPI's FOV,
602 $N_{px} = 185^2$ and the number of effectively independent spectral
603 priors, N_p , that we empirically estimate as $N_p \approx 4^{12}$, using a
604 binomial distribution, we expect ~ 20 false positives across the
605 entire survey (see Chomez et al. 2023). This number is larger
606 than the number of statistical false positives that could be identified
607 through second-epoch observations; hence, we expect that
608 some sources labeled as CMD background sources also belong
609 to the category.

611 3.3. Completeness

612 The completeness of our survey was quantified in the following
613 way. As a first step, we azimuthally averaged the 2D detection
614 maps provided by PACO, obtaining 1D contrast curves (detection
615 limits at 5σ).

616 Pending a final confirmation of the nature of the two promising
617 candidate companions, the detection limits of the corresponding
618 observations were adjusted accordingly to ensure the statistic
619 reliability of the corresponding observations. The same was done
620 for the seven datasets containing ambiguous sources. In particular,
621 the mean contrast of each candidate was employed as a floor value
622 in the corresponding 2D 5σ map. In other words, we pretend to
623 have shallower observations so that a source as bright as the
624 candidate can be at most a marginal 5σ detection. These maps
625 were then collapsed to 1D as described above.

626 The 1D curves obtained in this way were converted into mass
627 limits through MADYS, adopting the stellar parameters discussed
628 in Section 2.3. The mass-luminosity relation is based on the
629 ATMO evolutionary models (hereafter ATMO; Phillips et al.
630 2020; Chabrier et al. 2023)¹³. Chemical disequilibrium is
631 expected to critically affect the atmospheric features of cool T-type
632 and Y-type objects (see, e.g. Leggett et al. 2015, 2017; Miles
633 et al. 2020; Baxter et al. 2021); given that 1) the corresponding
634 temperature range is within the reach of our analysis (see
635 Figure 5), and 2) the effect is particularly strong in H-band
636 observations such as those under consideration, we decided to
637 employ the grid assuming weak chemical disequilibrium (ATMO-NEQ-
638 W) instead of chemical equilibrium (ATMO-CEQ). We explored
639 in Appendix E the effect of this assumption, comparing the
640 results with those obtained under chemical equilibrium and strong
641 disequilibrium (ATMO-NEQ-S)¹⁴. In addition to this, the impact
642 of model selection and age uncertainty was quantified.

643 Starting from mass limits, the completeness could be estimated
644 through Exo-DMC¹⁵ (Bonavita 2020). Within each cell of a
645 2D grid in the (mass, sma) plane, the detectability of $N = 1000$
646 companions to every star, whose orbital parameters are drawn
647 in a Monte Carlo fashion, is computed by comparison with 5σ

Fig. 7: Survey completeness as a function of companion mass and semi-major axis, computed using the ATMO-NEQ-W models. Red stars indicate known substellar companions (see Table 1).

Table 2: Input parameters used for Exo-DMC.

parameter	description
no. of steps in sma	500
no. of steps in mass	200
no. of draws per cell	1000
semi-major axis	log-uniform in [0.1, 1000] au
companion mass	log-uniform in [0.1, 100] M_{Jup}
inclination	$\cos i$ uniform in $[-1, 1]$
eccentricity	$ \mathcal{N}(0, 0.9) $
longitude of node	uniform in $[0, 2\pi]$
longitude of periastron	uniform in $[0, 2\pi]$
fraction of period	uniform in $[0, 1]$

mass limits as a function of the projected separation. We provide
in Table 2 an overview of the adopted parameters.

648 The final map is computed by taking the average of all the
649 individual maps. When multiple epochs for a given star are available,
650 the largest value for the detectability is selected for every
651 cell. The results are shown in Figure 7. We notice that the peak
652 sensitivity of the survey is about 88%: we interpret such a low
653 value as the combination of three factors: 1) the small field of
654 view of the instrument; 2) the moderate distance spread across
655 the sample; 3) the fact that, working in semi-major axis and not
656 in projected separation, a fraction of planets with given a might
657 be undetectable because of projection effects.

658 We are now able to directly compare our detection capabilities
659 with those of N19, so as to justify a posteriori the idea of
660 a reanalysis of those archival data. In order to avoid any possible
661 systematic difference, a new map was computed only using
662 the observations considered therein; moreover, instead of using
663 Exo-DMC, we closely reproduced the original method, including
664 the same values for distances, ages and substellar evolutionary
665 model. The comparison, shown in Figure 8, indicates that
666 the PACO-based reanalysis allows for a significant performance
667 gain at all separations, which can be up to twofold in terms of
668 detectable mass at given completeness.

¹² The correlation between SNR maps under any two spectral priors is larger than zero. By "number of effectively independent spectral priors" we mean the ratio $N_{positives,20priors}/N_{positives,1prior}$, estimated through extensive testing.

¹³ Using the most recent version, that features a new equation of state for dense hydrogen-helium mixtures: <https://noctis.erc-atmo.eu/fsdownload/zyU96xA60/philips2020>.

¹⁴ The amount of vertical mixing in disequilibrium models is parametrized through the eddy diffusion coefficient K_{ZZ} . Constraining K_{ZZ} is a long-standing issue (see discussion in Phillips et al. 2020).

671 3.4. Planet occurrence rates

672 Deriving unbiased occurrence frequencies of exoplanets is one
673 of the main goals of large blind surveys, and in turn a crucial
674 input to draw comparisons with formation models. Provided a
675 large enough sample, it is additionally possible to investigate the
676 dependence of these frequencies on host properties such as mass
677 and metallicity, highlighting the key role of the parent star in
678 shaping its planetary system.

679 We begin our investigation by focusing on the occurrence
680 frequency f for the entire stellar population represented by the
681 GPIES sample. Extracting this quantity from the fact of having
682 observed N companions given a certain survey completeness is
683 a typical inversion problem that can be treated within a Bayesian
684 framework.

685 We employ a formalism that is similar to that used in previ-
686 ous direct imaging studies (see, e.g. Lafrenière et al. 2007; Lan-
687 nier et al. 2016). Given a certain area \mathcal{A} in the (sma, mass) plane
688 defined by $a_{\min} < a < a_{\max}$ and $m_{\min} < m < m_{\max}$, let us de-
689 fine p_i the mean probability to see a companion around the i -th
690 star lying within \mathcal{A} . Based on our completeness analysis (Sec-
691 tion 3.3), p_i can be estimated as the mean detection probability
692 in \mathcal{A} across the entire survey, that is the mean value in \mathcal{A} of the
693 completeness map shown in Figure 7.

694 The probability $p_{\text{det},i}$ to detect a companion in \mathcal{A} around the
695 i -th star is the product of the detection probability and the under-
696 lying occurrence frequency f : $p_{\text{det},i} = p_i \cdot f$. The connection with
697 the observed planet sample is mediated by d , a vector whose i element
698 represents the number of companions detected within \mathcal{A}
699 around the i -th star.

700 The likelihood of the observed data as a function of the f can
701 be estimated as the product of individual Bernoulli events, one
702 per star:

$$L(\{d_i\}|f) = \prod_{i=1}^N (1 - p_{\text{det},i})^{1-d_i} \times (p_{\text{det},i})^{d_i} \quad (2)$$

The probability density function of f , that is the occurrence
703 frequency of companions in \mathcal{A} given the data can be finally esti-
704 mated through Bayes' theorem:
705

$$P(f|\{d_i\}) = \frac{L(\{d_i\}|f)P(f)}{\int_0^1 L(\{d_i\}|f)P(f)df} \quad (3)$$

as the posterior distribution emerging from the interplay
706 between a suitable prior distribution $P(f)$ and the likelihood
707 $L(\{d_i\}|f)$. We adopt two distinct priors: a uniform prior and a
708 Jeffreys prior. The uniform prior:
709

$$P(f) \propto 1, \quad \forall f \in [0, 1] \quad (4)$$

despite not incorporating any observational information, is
710 not uninformative, as it assumes much larger weights for large
711 values of f compared to what is expected from observations.
712 Nevertheless, the simplicity of this prior makes it widely adopted
713 in the literature: we decided to employ it in order to allow for
714 comparison with published results.
715

A Jeffreys prior has the twofold advantage of being non-
716 informative and counterbalancing the bias that favors $f \sim 0.5$.
717 In the case of Bernoulli events, the Jeffreys prior for the param-
718 eter f is simply:
719

$$P(f) = \frac{1}{\sqrt{f \cdot (1-f)}} \quad (5)$$

We adopt the latter prior distribution, that has the advantage
720 of being non-informative, as our standard choice in the following
721 analysis.
722

A particularly delicate point is represented by the choice of
723 \mathcal{A} : on the one hand, selecting a too narrow range would result in
724 a critical amplification of fluctuations from small number statis-
725 tics; on the other hand, including regions where $\langle p_i \rangle \sim 0$
726 would require a significant amount of extrapolation due to the
727 lack of data and, consequently, induce a flattening of the poste-
728 rior distribution over the prior. An additional factor to take into
729 account is the dependence of the results on both age uncertainty
730 and model selection, becoming more severe as the lower mass
731 limit is decreased (Appendix E). We decided to consider, as our
732 nominal case, a lower mass limit of $5M_{\text{Jup}}$ and a semi-major axis
733 range $10 \text{ au} < a < 100 \text{ au}$ as a compromise between these
734 concurrent factors; the upper mass limit will be set to either
735 $13 M_{\text{Jup}}$ or $80 M_{\text{Jup}}$ depending on whether brown dwarf com-
736 panions are considered or not. We derive occurrence frequencies
737 of $1.7^{+0.9}_{-0.7}\%$ when $\mathcal{A} = [5, 13] M_{\text{Jup}} \times [10, 100] \text{ au}$, and $2.2^{+1.0}_{-0.8}\%$
738 when $\mathcal{A} = [5, 80] M_{\text{Jup}} \times [10, 100] \text{ au}$, with f represented by
739 the median of the posterior and the error bars defined from the
740 [16%, 84%] percentiles. In order to allow a straightforward com-
741 parison with previous results from the literature (Section 4), we
742 also present additional occurrences starting from different defi-
743 nitions of \mathcal{A} (Table 3). We notice that no significant difference is
744 derived from the prior choice, confirming that our careful choice
745 for \mathcal{A} did minimize the impact of the prior; the errorbars, as
746 expected, are smaller in Jeffreys case compared to the uniform
747 case. In addition to this, no significant deviation arises for this
748

Table 3: Occurrence rates for different definitions of the (mass, sma) range \mathcal{A} and for the two choices for the prior distribution (U : uniform; J : Jeffreys). ^a: 95% upper limit.

\mathcal{A} $M_{\text{Jup}} \times \text{au}$	SpT	f_U %	f_J %

[13, 80] \times [5, 100]	FGK	$2.3^{+1.4}_{-1.0}$	$2.0^{+1.3}_{-0.9}$

749 choice of \mathcal{A} as an effect of the theoretical assumptions and obser-
750 vational uncertainties, ensuring the robustness of our results
751 (Appendix E).

752 We consider host star metallicity not to be a factor of par-
753 ticular concern, as the metallicity of young star-forming regions
754 in the solar neighborhood is typically solar with limited spread
755 (D’Orazi et al. 2011; Biazzo et al. 2012; Baratella et al. 2020;
756 Magrini et al. 2023). Conversely, as done in Nielsen et al. (2019)
757 and Vigan et al. (2021), we explicitly investigate the dependence
758 of the occurrence frequency on stellar mass. We divided our sam-
759 ple in three bins of stellar masses, obtaining the BA subsample
760 ($M > 1.5M_{\odot}$, 160 stars), the FGK subsample ($0.5 < M \leq 1.5M_{\odot}$,
761 235 stars), and the M subsample ($M \leq 0.5M_{\odot}$, 5 stars). Given its
762 small size, the M star sample was discarded.

763 Both the aggregated results and the mass-dependent ones are
764 plotted in Fig 9. Occurrence frequencies for different values of
765 \mathcal{A} are provided for reference in Table 3; moreover, a digitized
766 version of completeness maps is also made available¹⁶ so as to
767 allow interested readers to extract additional results based on dif-
768 ferent definitions of \mathcal{A} .

769 4. Discussion

770 Thanks to the analysis performed in Section 3.4, it is now possi-
771 ble to directly compare the results emerging from our PACO
772 re-reduction of GPI data to previous literature works.

773 Figure 10 presents a juxtaposition of our results with the
774 frequencies derived from the first 300 stars of GPIES (Nielsen
775 et al. 2019) and the first 150 stars of SHINE (SHINE F150; Vi-
776 gan et al. 2021). Moreover, the results emerging from the meta-
777 analysis of 384 imaged stars by Bowler (2016) are shown, al-
778 though we stress that they are, by design, less protected against
779 selection biases due to the heterogeneous underlying sample. A
780 general finding is that our results are fully compatible with liter-
781 ature estimates, but they are typically more precise. In particular,
782 the comparison with N19 clearly indicates that the new analysis
783 places the tightest constraints to date on giant planet occurrence
784 based on GPI data, with a gain in precision being a direct conse-
785 quence of the large gain in completeness (Figure 8). The smaller

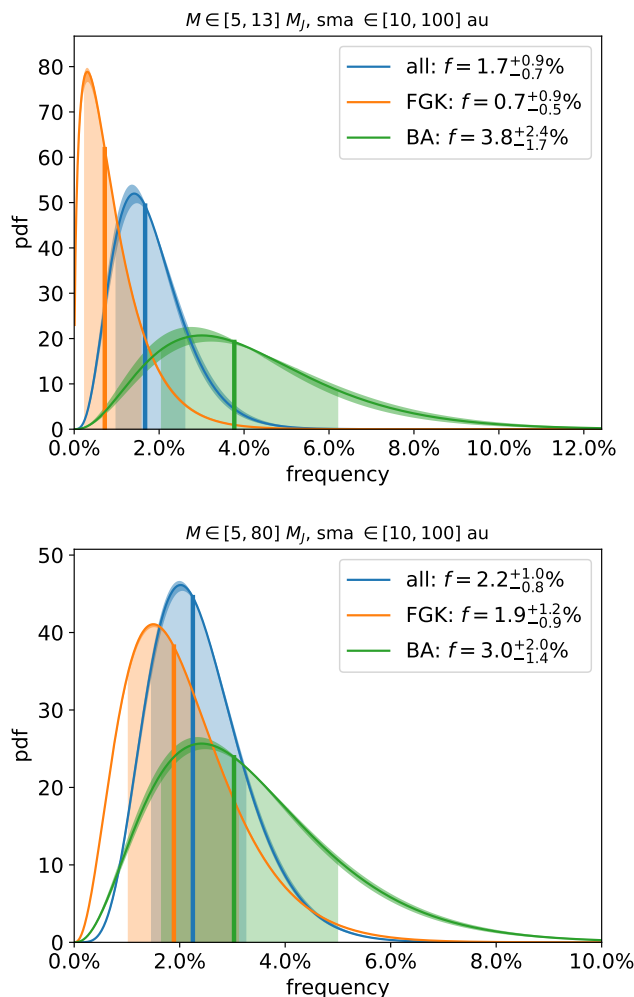

Fig. 9: Occurrence frequency of GP (upper panel) and GP+BD (lower panel) from the re-analysis of the 400-star GPIES sample presented in this work. Aggregated results are shown in blue, whereas results for the BA and the FGK subsample are plotted in green and orange, respectively. The colored area encompasses the [16th, 84th] of the posterior distribution.

786 frequency of companions is an effect of the increased complete-
787 ness with no new confirmed detection. As regards SHINE F150,
788 the much larger field of view of IRDIS (11" x 11", compared to
789 the 2.7" x 2.7" FOV of GPI) ensures a much more complete cov-
790 erage of the semi-major axis range of interest and thus larger
791 room for planet detection, compensating the twofold advantage
792 of our study in terms of sample size and reduction performances:
793 as a result, the precision of the derived occurrence rates is simi-
794 lar. In this regard, the full analysis of SHINE data with PACO
795 (Chomez et al. 2024), which combines all the advantages of the
796 two analyses, is expected to provide an invaluable contribution
797 to demographic studies of wide-orbit exoplanets.

798 In view of the profound consequences with respect to planet
799 formation scenarios, it is extremely interesting to assess the
800 dependence of the observed occurrence rates on stellar mass.
801 As in N19, we employed a threshold value of $M = 1.5M_{\odot}$
802 to distinguish a BA subsample and a FGK subsample. That
803 study claimed that a significant (3.4σ) tension between BA
804 and FGK planet rates (f_{BA} and f_{FGK} , respectively) exists for
805 $\mathcal{A} = [2, 13] M_{\text{Jup}} \times [3, 100] \text{ au} := \mathcal{A}_1$, with planets being more

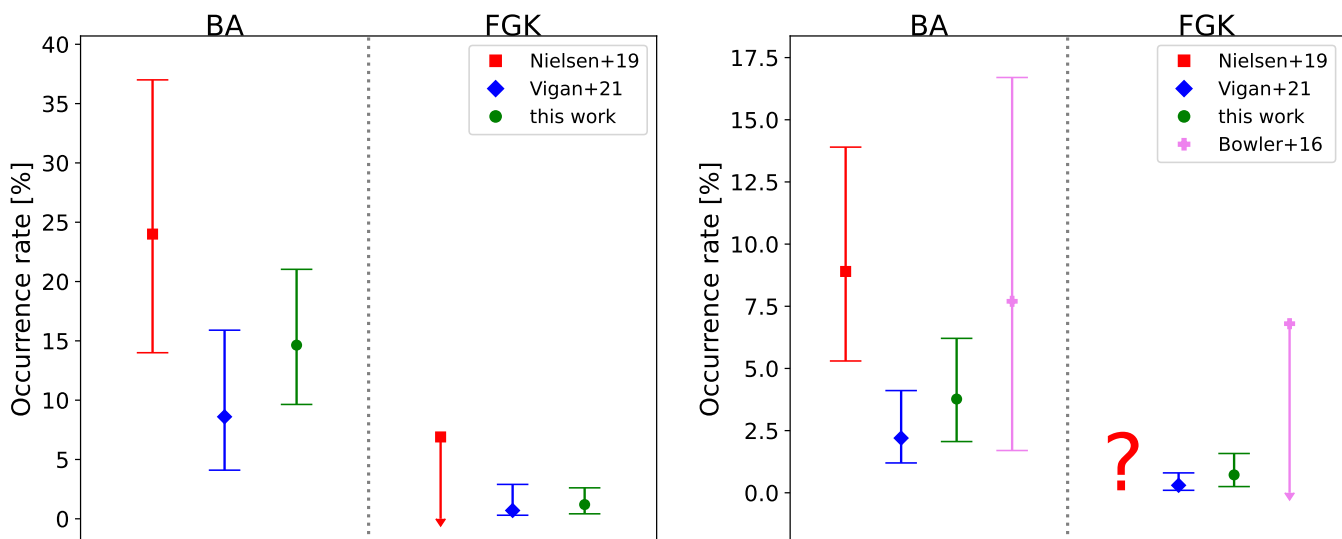

Fig. 10: Comparison of the occurrence rates (left panel: $\mathcal{A} = [2, 13] M_{\text{Jup}} \times [3, 100]$ au; right panel: $\mathcal{A} = [5, 13] M_{\text{Jup}} \times [10, 100]$ au) of giant planets with previous analyses by Bowler (2016), Nielsen et al. (2019) and Vigan et al. (2021). The left and the right half of each panel are relative to BA and FGK stars, respectively. Estimates indicated by arrows are to be read as 95% upper limits, while error bars on point estimates are defined as to encompass the 68% C.I.. Question marks indicate missing data points.

806 common around BA hosts; while six companions were detected
 807 inside \mathcal{A}_1 in the BA subsample, no companion was identified in
 808 the FGK subsample. However, we expect the result to be weak-
 809 ened by the re-evaluation of the mass of HR 2562 b (Zhang
 810 et al. 2023), a companion to an FGK star now firmly placed into
 811 the planetary-mass domain. In order to verify whether this is the
 812 case, we drew, in a Monte Carlo fashion, values from the poste-
 813 rior distributions of f_{BA} and f_{FGK} under \mathcal{A}_1 . The values from the
 814 latter distribution are larger than those drawn from the former
 815 in 0.1% of the cases, implying a 3.3 σ tension between the two
 816 distributions. Hence, our analysis confirms the finding by N19.

817 With respect to brown dwarf companions, no statistically signifi-
 818 cant difference in the observed rates was found by N19 be-
 819 tween BA and FGK hosts. The observation is in line with the
 820 results of previous analyses showing compatible rates across a
 821 wide range of stella types (see, e.g., Nielsen et al. 2013; Bowler
 822 et al. 2015; Lannier et al. 2016; Bowler & Nielsen 2018). Based
 823 on our analysis, a tentative (1.7 σ) tension between the two rates
 824 is found for $\mathcal{A} = [13, 80] M_{\text{Jup}} \times [5, 100]$ au, with an interest-
 825 ing inversion compared to the planetary case: in other words,
 826 giant planets appear to be more common around BA host, while
 827 brown dwarf companions tentatively appear to be more common
 828 around FGK hosts.

829 Although the BD trend is not statistically significant, an inter-
 830 esting analogy might be drawn with the behavior of the two
 831 empirical distributions of substellar companions introduced by
 832 Vigan et al. (2021) in the context of SHINE. A planet-like and
 833 a star-like distribution of companions – both being the product
 834 of a log-normal distribution for semimajor axis and a power-law
 835 for companion-to-star mass ratios – were simultaneously fitted
 836 to the substellar companion population, divided in three bins of
 837 mass (BA, FGK, M). Similarly to our planetary rates, the me-
 838 dian values of the planet-like posterior are larger than those of
 839 the star-like posterior for BA hosts, and smaller for FGK hosts.
 840 It might be argued that a strict distinction between giant planets
 841 and brown dwarfs based on the deuterium burning limit is not
 842 adequate to capture the complexity of the different formation
 843 mechanisms (CA and GI) involved (Chabrier et al. 2014), and

that studying together the entire population is the key to identify
 population trends (see, e.g., Gratton et al. 2024); while this is cer-
 tainly true, first-order, population-wise differences in some pa-
 rameter, arguing for different underlying formation channels, can
 sometimes be discerned using rough mass boundaries (Bowler
 et al. 2020).

In view of the low occurrence rates, the large extent of host
 star masses, the interplay of different formation channels and the
 impact of input assumptions, we deem it necessary to defer a
 thorough study of the distribution of companion properties to our
 future joint SPHERE+GPI analysis: thanks to its larger sample
 size, this sample is expected to bring about much tighter con-
 straints on the properties of the companion population, offering
 in turn the possibility to compare them both to empirical distri-
 butions and to synthetic populations of companions produced by
 formation models.

5. Conclusions

We have presented in this work the results of a complete re-
 reduction of 400 stars from the GPIES survey, one of the largest
 planet-hunting DI endeavors to date, by means of an advanced
 post-processing algorithm named PACO. The key results of this
 work are the following:

- the detection capabilities of the survey were greatly en-
 866 hanced by means of our novel post-processing technique,
 867 reaching up to a twofold gain in terms of detectable mass
 868 at given completeness; 869
- out of 102 detected sources, 2 were identified as promising
 870 companion candidates awaiting follow-up confirmation; 871
- thanks to the deeper detection limits provided by PACO, it
 872 was possible to place some of the deepest constraints ever
 873 provided by direct imaging on the occurrence of wide-orbit
 874 giant planets. We derive an occurrence rate of $1.7^{+1.0}_{-0.7}\%$ for
 875 $5 M_{\text{Jup}} < m < 13 M_{\text{Jup}}$ planets in $10 \text{ au} < a < 100 \text{ au}$,
 876 increasing to $2.3^{+1.0}_{-0.8}\%$ when including substellar companions
 877 up to $80 M_{\text{Jup}}$; 878

- 879 – we verified that the above-mentioned results are robust
880 against the effect of age uncertainty, model selection, and
881 disequilibrium chemistry;
- 882 – as in previous studies, we observe (3.3σ C.L.) a larger oc-
883 currence rate of giant planets around BA hosts compared to
884 FGK stars;
- 885 – we tentatively (1.7σ C.L.) identify an inversion of this trend
886 when considering brown dwarf companions, with FGK stars
887 possibly hosting more such companion than their BA coun-
888 terparts.

889 In a forthcoming study, we plan to combine the archives of
890 SPHERE and GPI data, leading to a threefold sample size com-
891 pared to this work. By applying the same reduction and analysis
892 methods presented here, it will be possible to assess a whole
893 series of stimulating questions related to the origin, the preva-
894 lence and the properties of wide-orbit planets. In addition to this,
895 these endeavors will enable a decisive step towards the coveted
896 combination of demographic constraints derived through differ-
897 ent detection techniques, delivering in turn key inputs for planet
898 formation models suited to a wide variety of host stars.

Appendix D: Stellar companions

In addition to the brown dwarfs HD 984 B and PZ Tel B, the ADI reduction identified 7 bright companion candidates (two of them detected twice in two different epochs). Proper motion analysis allowed us to identify one of them (namely, the one seen next to HIP 61087) as a background object and one as a bound companion (around HIP 74696). For the remaining objects, for which only one observation was available in our sample, we searched for archival detections in the literature. It turns out that all the candidates but one (around HD 74341B) had been already imaged in the course of past campaigns, but just one (around HIP 38160) had already been confirmed as a comoving object through follow-up observations (Rameau et al. 2013). Therefore, we performed the proper motion analysis for all the systems, using the astrometric measurements reported in Table D.1.

The proper motion test confirmed that the 5 sources with two epochs exhibit a significantly different motion compared to static background objects, with large displacements related to orbital motion (Figure D.1).

In order to clarify the status of HD 74341 B, to further corroborate the bound nature of the other objects and, finally, to test the reliability of the derived photometric masses, we ran the GaiaPMEX tool (Kiefer et al. 2024) to see if the astrometry of the primary from Gaia and/or Hipparcos showed hints of wobbles indicative of the presence of an unseen companion. GaiaPMEX comes equipped with a model of the Renormalized Unit Weight Error (ruwe; see Lindegren et al. 2021) and of the Gaia-Hipparcos proper motion anomaly (PMA; see Kervella et al. 2019, 2022) distribution expected for a single star as a function of stellar magnitude and colors. The evaluation of whether astrometric information is consistent with an unseen companion is performed in the following way. After defining a log-uniform grid of companion masses $M_c \in [0.1, 3000]M_{\text{Jup}}$ and semi-major axes $a \in [0.01, 1000]$ au with 30×30 bins, the program draws, within each bin, 100 $(\log M_c, \log a)$ -doublets from a uniform distribution. As regards the other orbital parameters, they are randomly extracted from the distributions described in Table D.2. We employ stellar parallaxes from Gaia DR3, while stellar masses are recovered from our analysis described in Section 2.3.

At each node of the mass–sma grid, distributions of the ruwe and/or PMA are determined given the target and its hypothetical orbiting companion, and compared to the actual ruwe and/or PMA; the derivation of confidence regions for possible companion masses and semi-major axes can be finally obtained through Bayesian inversion.

Clear astrometric detections were found for all the targets but HD 74341B (Figure D.2), due to the absence of the star in the Hipparcos catalog; due to the much shorter timespan of the astrometric measurements underlying the ruwe (~ 3 yr, compared with the ~ 24 yr of the PMA), the sensitivity of the ruwe at the relatively large separation of the companion candidate is virtually null.

We find good agreement between the photometric and the dynamical masses for three stellar companions (those around HIP 74696, HD 24072, and HIP 26369). As regards the companions to HIP 67199 and HIP 38160, which are the ones located at the shortest separations from the star, we confirm their bound nature but we find largely underestimated masses, despite the expedient to use no-ADI instead of cADI¹⁷. We attribute the

discrepancy to the fact that these sources lie at the edge of the coronagraph, where the transmission is much lower than elsewhere across the field of view.

¹⁷ The no-ADI algorithm can be thought as a cADI but with no median-subtraction step. The advantage of the method is to avoid self-subtraction of signal from the source, a problem becoming more severe

at shorter separations; on the other hand, this is obtained at the price of much poorer detection limits.

Table D.1: Stellar companions identified in the sample with their astrometric and photometric properties. In addition to GPI measurements, literature astrometry is reported too.

Fig. D.1: Proper motion test for the five stellar companion candidates with multiple epochs. As in Figure 4, a filled star indicates the displacement expected for a bound source with no relative motion to the star, whereas an empty star marks the location of a static background source. Second epochs are labeled by a '2', third epochs by a '3'. The large deviations from the filled star are likely caused by orbital motion.

Fig. D.2: Upper panel: flux maps (in contrast units) showing the stellar companion candidates detected with cADI. Lower panel: GaiaPMEX (sma, mass) maps, with contours outlining the area corresponding to the 68% and 95% confidence level. Photometric masses (dots) or lower limits (arrows) are overplotted for comparison. The HD 74341B map should be interpreted as a nondetection, the white area being incompatible with the absence of a signal.

Table D.2: Physical and orbital parameters used in Gai aPMEX.

Parameter	type	bounds or law
$\log M_c$	uniform	$\log M_c \pm \Delta \log M_c$
$\log a$	uniform	$\log a \pm \Delta \log a$
e	uniform	0–0.9
ω	uniform	0– π
Ω	uniform	0– 2π
ϕ	uniform	0–1
I_c	$\sin I_c$ uniform	0– $\pi/2$
ϖ	normal	$\mathcal{N}(\varpi, \sigma_{\varpi}^2)$
M_{\star}	normal	$\mathcal{N}(M_{\star}, \sigma_{M_{\star}}^2)$

Notes. e : eccentricity; ω : periastron longitude; Ω : longitude of ascending node; ϕ : phase; I_c : inclination; ϖ : parallax; M_{\star} : stellar mass.

Appendix E: Effect of input assumptions on occurrence rates

We explored the dependence of the results derived in Section 3 on several input assumptions: the uncertainty on stellar age, the choice of the substellar evolutionary model, the degree of disequilibrium chemistry of planet atmospheres. In principle, all of them are expected to induce systematic deviations in the luminosity-mass relation, possibly impacting the reliability of the derived occurrence rates.

As a first step, we evaluated the impact of model selection by repeating the computations from Table 3 using the AMES-Cond models (Baraffe et al. 2003) and the Sonora Bobcat models (Marley et al. 2021). AMES-Cond models ignore the effect of dust opacity and are therefore more appropriate for objects with $T_{\text{eff}} \lesssim 1300$ K compared to fully dusty models such as the AMES-Dusty models (Baraffe et al. 2003). The derived completeness maps are shown on the left side of Figure E.1; the differences between completeness values are plotted on the right side. In this regard, we stress that, given that it is the mean detection probability across the (mass, sma) area \mathcal{A} that enters into Eq. 2, absolute differences are a more accurate proxy than relative differences when evaluating the impact of completeness maps variations on the derived frequency posteriors. Inspection of Figure E.1 clearly indicates that the discrepancies are the widest in the mass range $[1, 5] M_{\text{Jup}}$, and rapidly decrease at larger masses: this can be seen as a consequence of the stronger cooling rate of less massive objects, combined with the larger theoretical uncertainties at lower masses.

As a consequence of this observation, we expect the lower mass value selected to define \mathcal{A} , M_{low} to have a large impact on the accuracy of the results. We quantified this effect by computing occurrence rates under the three models for $M_{\text{low}} = [1, 2, 3, 4, 5] M_{\text{Jup}}$. As expected, the problem exacerbates for lower values of M_{low} (Figure E.2). This test justifies our conservative choice for \mathcal{A} (Sec. 3.4).

Afterwards, we investigated the dependence of the results on the assumption of chemical equilibrium: in particular, we used two suites of ATMO models that assume 1) chemical equilibrium (ATMO-CEQ) or 2) strong chemical disequilibrium (ATMO-NEQ-S), that is, a different relation for the vertical mixing coefficient (Phillips et al. 2020). Given a certain H-band magnitude, the fractional mass difference, computed as a function of age and ATMO-NEQ-W mass ($m \in [1, 10] M_{\text{Jup}}$), can be as large as 30% compared to the chemical equilibrium case. The variation is larger at lower masses and larger ages, that is, at lower effective temperatures. The derived completeness maps, analogous to Figure E.1, are shown in Figure E.3. Given our careful choice of mass boundaries, it is possible to argue that completeness values within \mathcal{A} are dominated by projection effects rather than detection limits. Hence, we expect the occurrence rates to be fully consistent with those of the original analysis.

Finally, we provide similar completeness maps to quantify the dependence on age uncertainty: Figure E.4 shows the variation of the maps when assuming lower and upper values for stellar ages.

All the occurrence rates derived in this Section are visually compared in Figure E.5. It is evident that any doublet of estimates is compatible within the errors, making the estimates presented in this work robust against systematic effects.

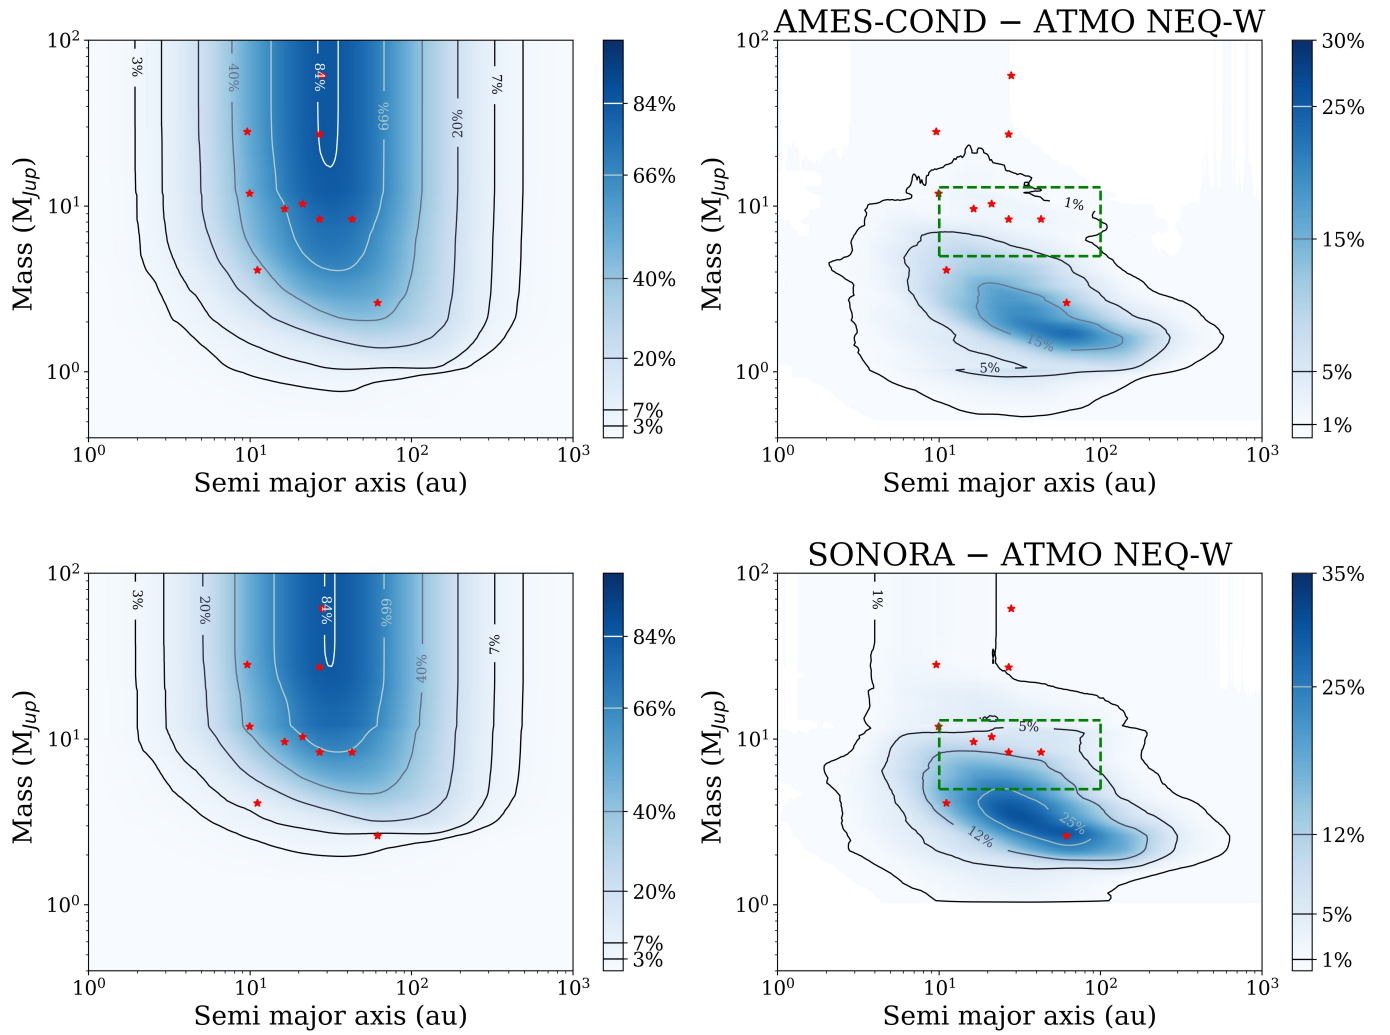

Fig. E.1: Effect of model selection on survey completeness: maps assuming the Ames-COND model (top row) and the Sonora model (bottom row). Left panels show completeness maps, while right panels indicate the difference relative to the map used for the analysis. The green dashed box indicates our nominal choice of \mathcal{A} .

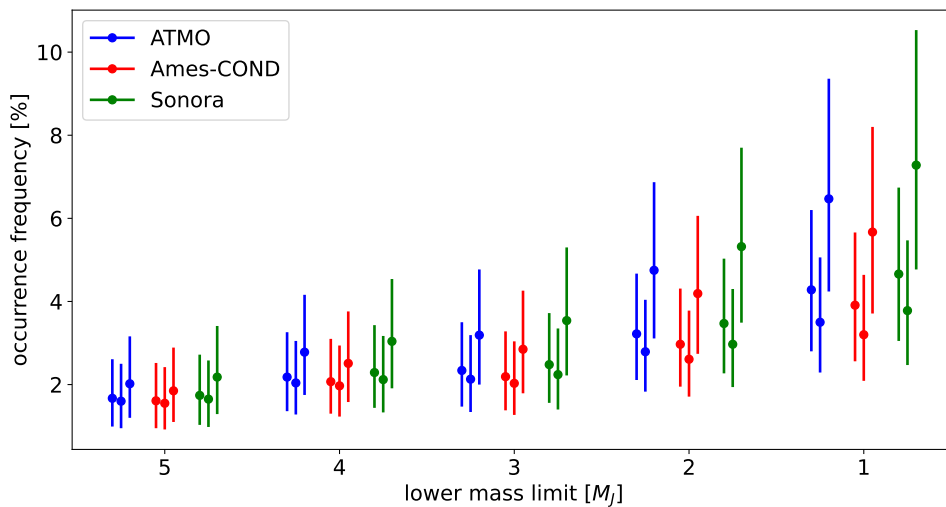

Fig. E.2: Trend of the uncertainties in the derived occurrence rates with M_{low} . Each model – shown as a triplet (nominal ages, lower ages, upper ages) – is plotted in a different color. Horizontal offsets have been applied to each line for the sake of visualization.

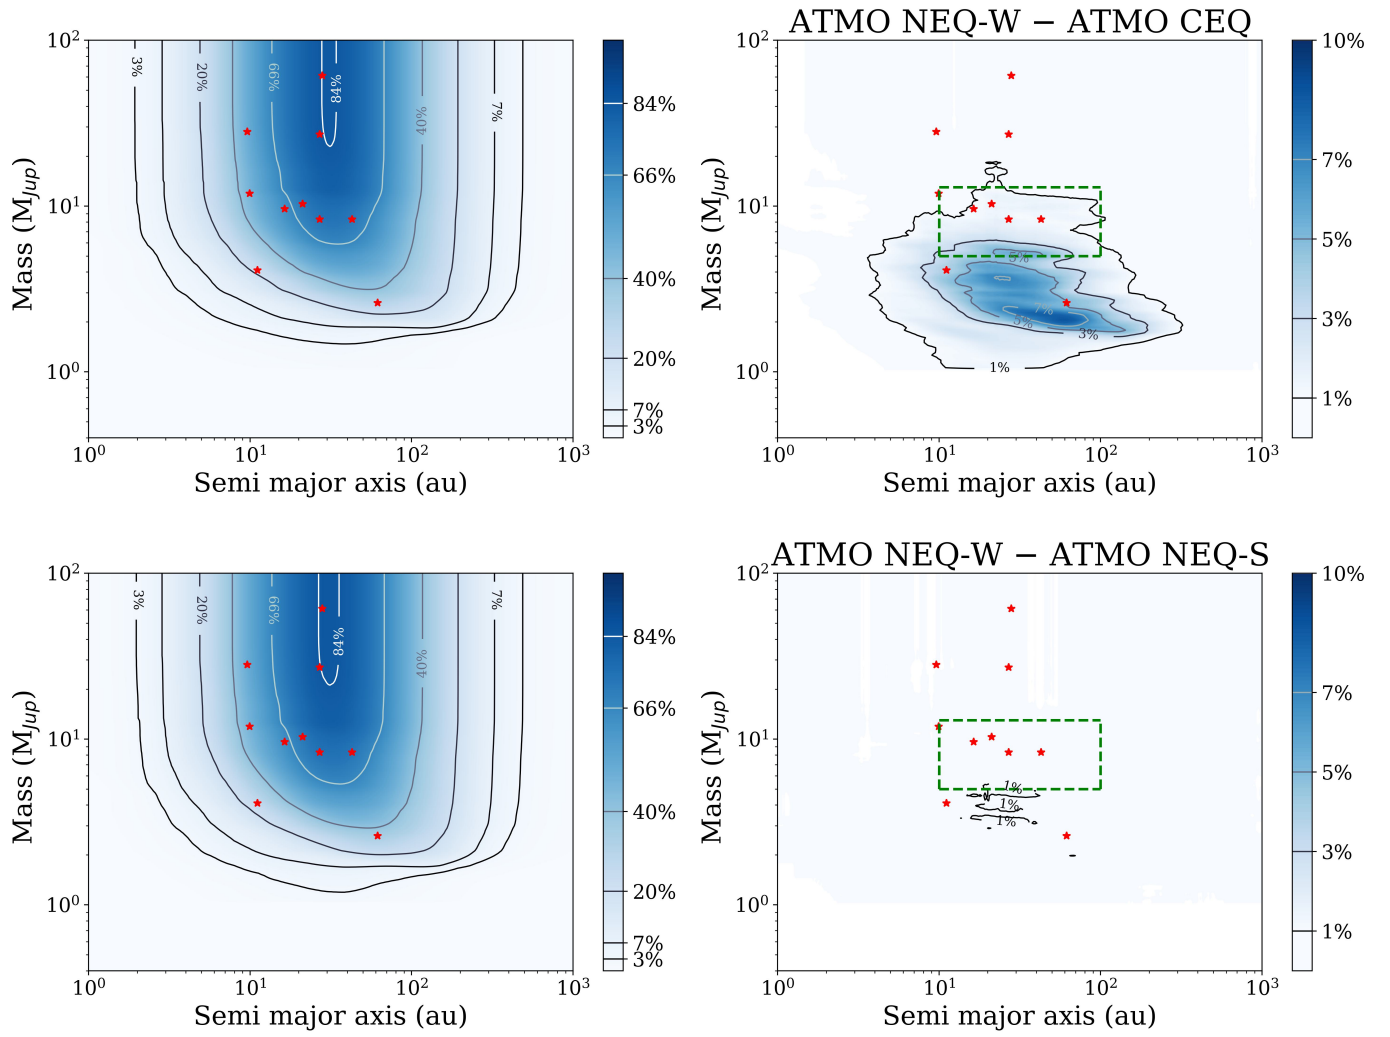

Fig. E.3: Effect of non-equilibrium chemistry on survey completeness: maps using the ATMO models assuming equilibrium chemistry (top row) and strong disequilibrium chemistry (bottom row). Left panels show completeness maps, while right panels indicate the difference relative to the map used for the analysis. The green dashed box indicates our nominal choice of \mathcal{A} .

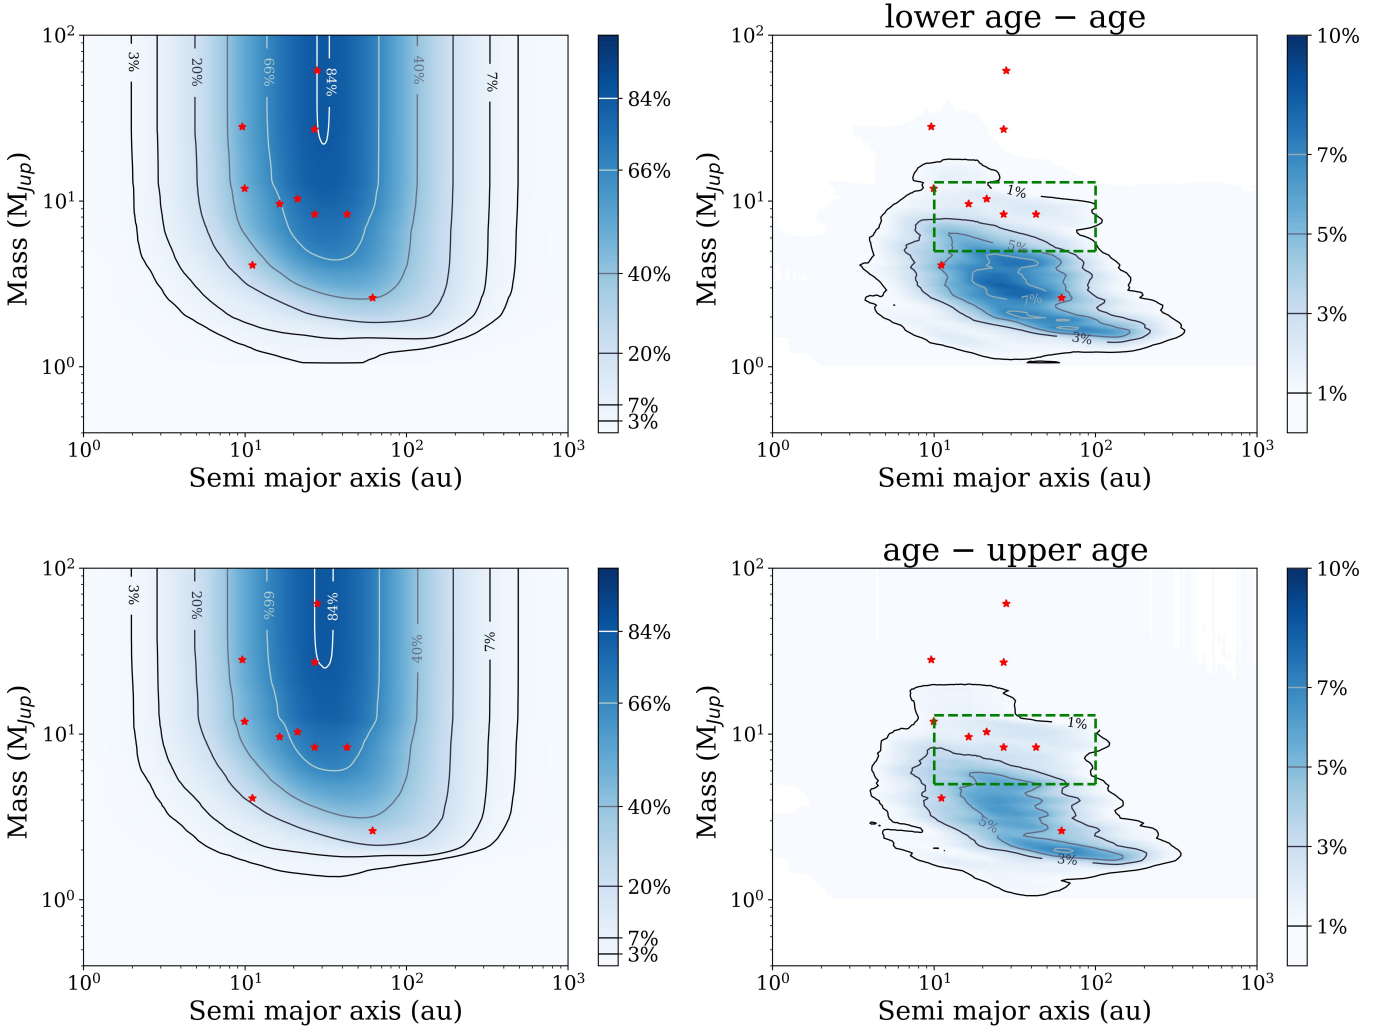

Fig. E.4: Effect of age uncertainty on survey completeness: maps assuming lower (top row) and upper (bottom row) values for stellar ages. Left panels show completeness maps, while right panels indicate the difference relative to the map used for the analysis. The green dashed box indicates our nominal choice of \mathcal{A} .

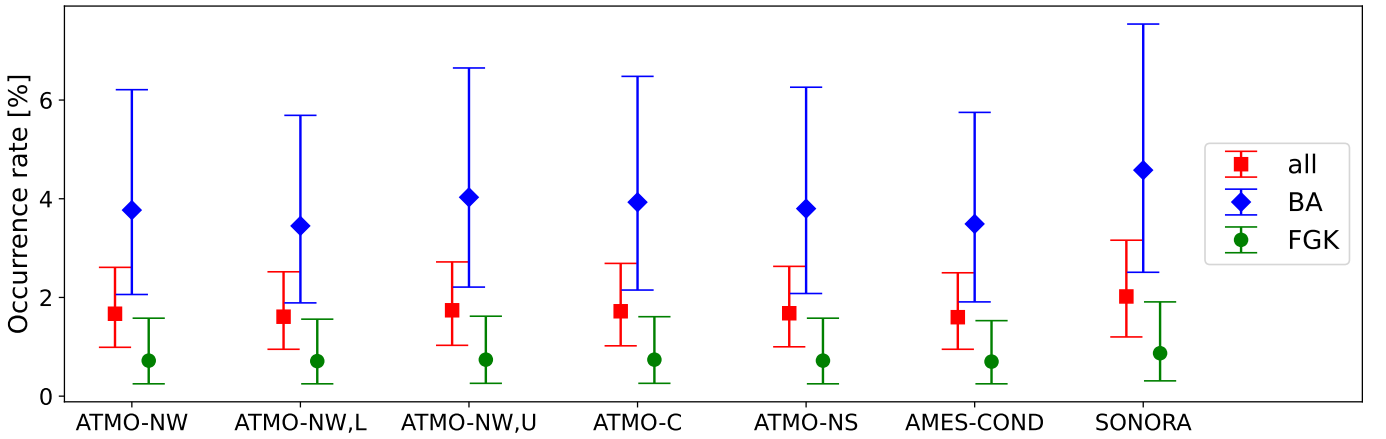

Fig. E.5: Effect of model selection and age uncertainty on planet occurrence ($\mathcal{A} = [5, 13] M_{Jup} \times [10, 100]$ au): results for the entire sample (red squares), the BA subsample (blue diamonds), the FGK subsample (green circles) using: the standard ATMO-NEQ-weak model (ATMO-NW); the same model with lower (ATMO-NW, L) and upper (ATMO-NW, U) ages; the ATMO model with no (ATMO-C) and strong (ATMO-NS) disequilibrium chemistry; the AMES-Cond model (AMES-COND) and the Sonora Bobcat model (SONORA). A Jeffreys prior is assumed (see Section 3.4).
