Abstract

This study investigated the effect of different treatment conditions on kaolinite-halloysite type as a support for TiO₂ and their potential application in photocatalysis. These nanocomposites are used to study the photodegradation of methylene blue, a dye widely used in the textile industry and released into the environment. Crystal structure, specific surface area, pore structure and the morphology of kaolinite were all studied using XRD, attenuated total reflectance (ATR), Brunauer-Emmett-Teller (BET), scanning electron microscopy (SEM) and ultraviolet-visible light. The optical band gap increased with increasing kaolin loading from 2.93 to 3.14 eV. Compared with pure TiO₂ photocatalyst, the morphology and structure of kaolinite/TiO₂ composites can significantly improve their ability to adsorb organic pollutants and their photocatalytic activity: The photocatalytic efficiency of kaolinite/TiO₂ was evaluated by degrading the textile dye methylene blue (MB) under UV-light irradiation. The results showed an improvement from 71% using TiO₂ to 98% for nanocomposites kaolinite/TiO₂ using samples amount of 1g/L and C₀= 20 mg/L.

Keywords: Kaolinite; TiO₂; Adsorption; Photodegradation; Methylene blue; Nanocomposites

Introduction

The effluents released by the textile industry, which uses harmful chemicals such as dyes, contain various chromophore groups that have negative effects on flora and fauna. It has been investigated that 1% to 20% of the world's colorant production is wasted and discarded in the dyeing process, which seriously endangers human health, aquatic ecosystems, and the environment [1]. One of these dyes, methylene blue (MB), depicted in **Fig S1**, is a toxic, carcinogenic, and non-biodegradable compound, putting both environmental and human health in great peril. In general, it is directly released into natural water resources, posing a threat to human and animal health [2]

To deal with this problem, various wastewater treatment techniques have been investigated, including physical technologies: adsorption on activated carbon, ultrafiltration, reverse osmosis, coagulation with chemical components and ion exchange on synthetic absorbents. However, these methods are not destructive, as they simply transport organic substances from the water to other phases, effectively creating additional contamination. Thus, less costly alternative treatments are required for final wastewater treatment and regeneration of absorbent materials [3].

As a result, research has focused on other green and non-toxic processes that mineralize pollutants, such as heterogeneous photocatalysis, which relies on using nanostructured semiconductors as catalysts to oxidize organic molecules [4]. Among nanoparticles exhibiting these properties, titanium dioxide (TiO_2), ZnO, and CuO have attracted much attention in the field of photocatalysis [5].

Because of their high efficiency and nanotoxicity, TiO_2 nanoparticles have sparked much interest as a photocatalyst. However, the aggregation of nanoparticles caused by energy reduction restricts the number of active sites on the surface of TiO_2 , which results in decreasing

its specific surface area [6]. When these nanoparticles are used as photocatalysts for wastewater treatment, such a problem should be considered. A simple solution to this issue is to load TiO₂ nanoparticles on specific supports (i.e., supported clay [7], supported activated carbon [8], and apatite [9]) to improve their dispersion.

Clay comes mainly from raw minerals, with different types of geometry and morphology. They can be used for the disposal and storage of hazardous chemicals, especially for contaminated water remediation. In several industries, clay minerals, such as montmorillonite [10], zeolite [3], and kaolinite [11], have been used as raw materials for hundreds of industrial applications due to their abundant availability and inexpensive nature. Clay is thus used as a promising adsorbent in various adsorption methods thanks to its distinct characteristics and high removal performance [12].

Kaolinite is a clay mineral with a multi-layered structure and an exceptional formula Al₂Si₂O₅(OH)₄. It is often used in a variety of sectors and applications: paper [13], ceramics [14], paints [15], cement [16], and wastewater treatment [17]. In this work, we prepared kaolinite/TiO₂ nanocomposites by mixing kaolinite with TiO₂ at well-defined proportions, and they were calcined at a fixed temperature (800°C) while varying the calcination time. These treatments were chosen to investigate their effects on the structural and catalytic properties of the clay minerals, particularly in the context of their application as supports for TiO₂ in photocatalysis for removing methylene blue (MB) dye from aqueous solution.

The primary objective of this study was to elucidate how the different treatment conditions influence the physicochemical properties of the clay samples and their suitability as support for TiO₂. Systematic analysis of the structural changes induced by these treatments and evaluation of their impact on the photocatalytic performance were conducted. Valuable insights can be gained for the rational design of efficient photocatalytic materials.

Materials and methods

Materials

Titanium (IV) isopropoxide (TIP) ($C_{12}H_{28}O_4Ti$; 98%), ethanol (C_2H_6O ; 96%), nitric acid 65%, HCl, and NaOH were purchased from Sigma Aldrich (Germany). Methylene blue dye was purchased from Biochem (France). A local kaolinite-halloysite clay was collected in Djebel Debbagh mine (Guelma, northeast Algeria) designated DD2. These chemicals were used without any further purification or treatment.

Clay preparation

Two ways of preparing the support were used. In the first way, natural Kaolinite was ground during 3 and 8 h, noted as **KH2B3** and **KH2B8** respectively. Grinding was carried out in a FRITSCH planetary ball mono mill (Idar-Oberstein, Germany) at a rotation speed of 200 rpm. In the second way, the clay was first calcined at 600°C for 2 h, then ground for 3 and 8 h: they are labeled **KH2600B3** and **KH2600B8**, respectively. After each grinding of the natural kaolinite, sieving was performed using a 100-micron sieve to ensure a homogeneous particle distribution and to enrich the kaolinite phase of interest this essential step helps eliminate coarser particles, thereby improving the quality of the analyses and the reproducibility of the results (**Fig. 1**).

Synthesis of kaolinite/TiO₂ nanocomposites

The kaolinite/TiO₂ nanocomposites were synthesized using the sol-gel method [18]: 1 mL of TTIP was mixed and stirred for 1 h in 7 mL ethanol at 40°C, and the pH of the solution was adjusted with the addition of diluted nitric acid to pH = 1.5. The produced sol was applied dropwise to a suspension of 20 mL containing 0.5 g kaolinite. The resultant suspension was agitated for 24 h, washed, and then heated to 80°C for 24 h to produce the final powder impregnated with TiO₂. Next, this powder was calcined at 450°C for 2 h at a rate of 5 °C/min.

TiO₂ nanoparticles were synthesized using the same method without adding kaolinite. The synthesized samples were noted as **KH2** (raw kaolinite), **KTB3**, **KTB8**, **KT600B3**, **KT600B8** and TiO₂ (**Fig. 1**).

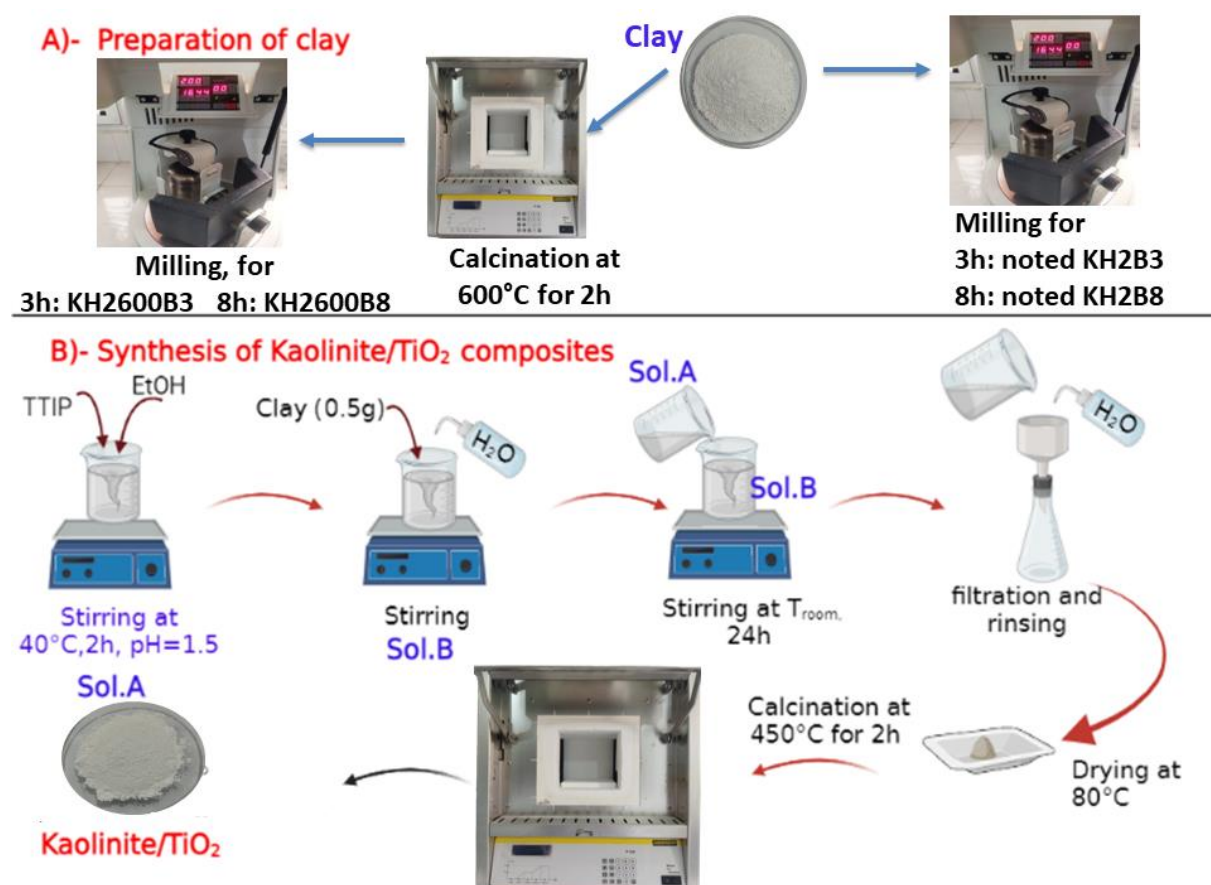

Figure 1. Preparation and synthesis of kaolinite-halloysite and Kaolinite-Halloysite/TiO₂

Characterization of kaolinite/TiO₂ composite

The samples were examined using X-ray diffraction (XRD) on a PANALYTICAL (Almelo, Netherlands) diffractometer with Cu K α radiation. The structural morphology and element analysis of kaolinite-TiO₂ composites were investigated using a JEOL JSM-7610F Plus emission scanning electron microscope (UHR-FESEM) (Tokyo, Japan). Infrared spectroscopy spectra (diamond ATR) were obtained at room temperature using a Bruker Platinum

spectrometer (Billerica, USA) in a 400–4000 cm^{-1} range. The UV-visible absorption spectra (UV-vis DRS) of the samples were obtained using a UV-Vis spectrophotometer Agilent Technologies Cary 60 (Penang, Malaysia). Nitrogen adsorption/desorption isotherms were measured at 77 K using the Quantachrome (Boynton Beach, USA) instrument. The pore volume was calculated using the t -plot method, and the sample-specific surface area was calculated using the conventional BET (Brunauer–Emmett–Teller) method. The samples were degassed and dehumidified by heating them at 200°C for 8 h. To evaluate the mineralization of MB the total organic carbon (TOC) content was analyzed using a Shimadzu TOC-VCSH instrument (Japan).

Point of zero charge (pHzpc)

To determine the pHzpc, pH tests were carried out as follows [19]. The procedure consisted of adding a 0.1 M NaOH or HCl solution to 50 mL of closed flasks containing a 0.1% NaCl solution to adjust the pH of each flask between 2 and 10 (**Fig. S2**). In each flask, we added 0.15 g of adsorbent. To determine the final pH, with pH meter-LC-pH-2B (Zhejiang, China), the suspensions was kept at room temperature with continuous stirring for 48 h.

Adsorption kinetic experiments

The kinetic study of adsorption was carried out by mixing a sample weight of 0.1 g with 100 mL of MB solutions ($C_0 = 20 \text{ mg/L}$) at 25°C and pH = 7.6. A given volume was taken at different time intervals. After separating the adsorbent–adsorbate mixture, MB dye concentrations were determined by spectrophotometry 200–800 nm (Agilent, Cary 60 UV-vis). The MB dye concentrations were determined with measurements taken specifically at 665 nm, the absorption maximum for methylene blue. Experimental data of adsorption kinetics were analyzed using the pseudo-first-order (PFO) and pseudo-second-order (PSO) model (**Fig 7a**) [20][21].

Photocatalytic experiments

Methylene blue (MB) photodegradation experiments have been made to evaluate the practical reliability of the obtained composites. All experiments were performed at 25°C. The reactor is a batch system placed in a chamber, with seven 9W UV-A lamps at a wavelength of $\lambda = 365$ nm positioned inside the chamber. The distance between the lamps and the beaker is 15 cm. The light intensity used during the experiments is 200 lux. A 100 mL sample of MB solution (20 mg/L) was placed in the beaker, followed by the addition of 100 mg/L of the photocatalyst. First, the solution was stirred by Selecta Multimatic 5N stirrer (Wertheim, Germany) at 300 rpm in the dark to achieve an adsorption-desorption equilibrium. Then, the suspension was irradiated under the UV light source according to the irradiation time under constant stirring. During this process the samples were regularly taken from the beaker, centrifuged, and the liquid phase analyzed using a UV-vis spectrometer. The photodegradation rate of MB was determined by Equation 4.

$$\text{MB (\%)\textbf{Photodegradation}} = \frac{C_0 - C_t}{C_0} * 100 \quad (4)$$

where C_0 and C_t are the initial concentration of dye in the solution and its concentration at time t , respectively.

Results and discussions

XRD spectrum

Fig. 2a shows the XRD spectrum of KH2. The presence of the kaolinite (JCPDS card No. 96-900-9235) and halloysite sheets was identified (JCPDS Card No. 29-1487) respectively

[22] [23]; quartz was present in small amounts. Intensive milling can induce structural changes in halloysite crystals. This could include amorphization, crystal defects, and even polymorphic transitions. Such alterations in crystal structure can manifest as shifts in peak positions or the disappearance of certain peaks in the XRD pattern, causing a decrease in peak intensity after about 8 h [24]. However, when the kaolin is calcined at 600°C, only a dome is noticed, which characterizes the transformation of kaolinite into metakaolinite form. Metakaolinite is characterized by a disordered crystal structure. As a result, it becomes amorphous, i.e., loses its regular crystalline arrangement and becomes structurally disordered [25].

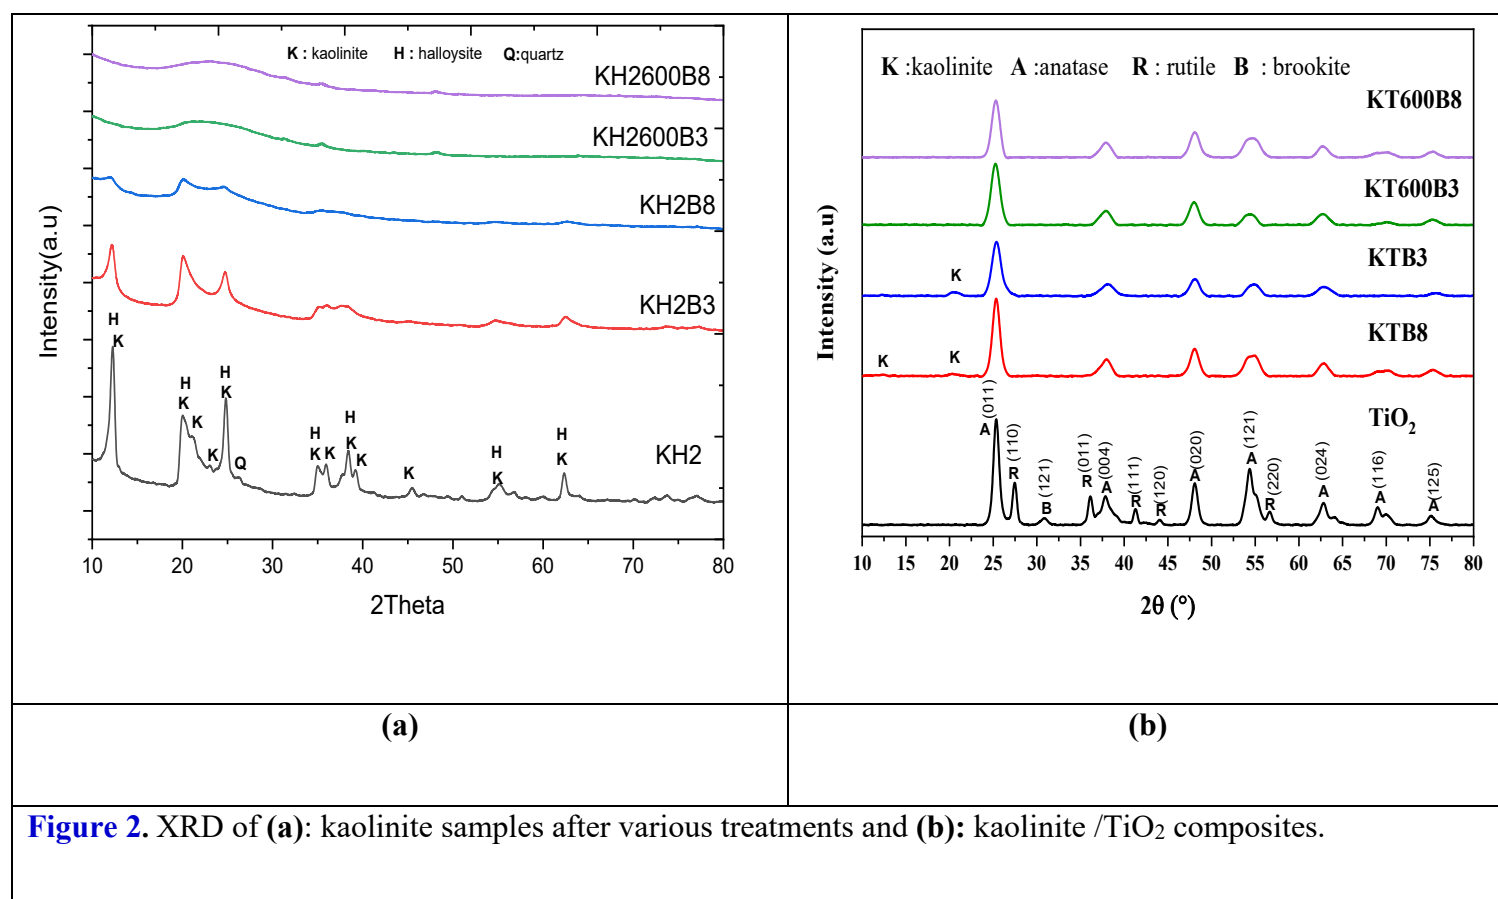

Fig. 2b represents the XRD diagram of the synthesized TiO₂ and kaolinite/TiO₂ composites respectively. The XRD spectra of TiO₂ revealed the presence of three phases, the peaks at 25.3°2θ, 36.9°2θ, 37.7°2θ, and 48.0°2θ (JCPDS card No. 96-900-9087) were attributed

to anatase phase. Some peaks at $27.4^{\circ}2\theta$, $36.1^{\circ}2\theta$, $39.2^{\circ}2\theta$, and $44.1^{\circ}2\theta$ (JCPDS card No. 96-900-1682) were assigned to rutile phase, and the peak at $30.80^{\circ}2\theta$ were attributed to brookite phase (JCPDS card No. 96-900-4138) [26].

A progressive decrease in the intensity of kaolinite-specific reflections was observed due to the immobilization of TiO_2 in the crystalline structures of kaolinite- TiO_2 composites with varying grinding times, with or without heat treatment of the clay[27]. Once TiO_2 is immobilized in the kaolinite crystal structure, the resulting composite can exhibit useful synergistic properties, such as better stability and enhanced photocatalytic reactivity. A series of TiO_2 characteristic peaks at around $25.3^{\circ}2\theta$, $38.3^{\circ}2\theta$, $48.1^{\circ}2\theta$, $53.9^{\circ}2\theta$, $55.1^{\circ}2\theta$ and $62.7^{\circ}2\theta$ matched the TiO_2 anatase crystals in a planar array. It is possible to infer that the presence of kaolinite speeds up the synthesis of anatase and prevents it from turning into rutile. [28]. According to the small size of TiO_2 nanoparticles, the pure TiO_2 reference exhibits the anatase phase's distinctive widened diffraction peaks (JCPDS card No. 96-101-0943) [29] [30] [31]. After the incorporation of titanium dioxide, the samples showed an increase in the signal at $2\theta = 25^{\circ}$, possibly due to the anatase phase of TiO_2 , which overlaps the signal of kaolinite[32]. However, no distinct kaolinite features were observed in the kaolinite/ TiO_2 composite samples after calcination for KT600B3 and KT600B8, which could be attributed to the loss of stacking in the kaolinite layers and the completion of the dehydroxylation reaction during this period; kaolinite was in amorphous metakaolinite form, so no obvious peak was shown in **Fig. 2a**. It is widely reported that smaller grain sizes result in increased photocatalytic activity. Smaller grains can reduce surface defect density, promote uniform adsorption of reactive molecules, and minimize unwanted charge carrier recombination reactions. According to Scherrer's formula[33], the average grain size of TiO_2 and TiO_2 nanoparticles in kaolinite is 18 and 10 nm, respectively.

The diffraction peaks of the kaolinite/TiO₂ composites correspond well with those of the TiO₂ anatase phases and kaolinite, indicating that the kaolinite structure is preserved during the TiO₂ nanoparticle introduction. Meanwhile, the diffraction intensities of kaolinite in kaolinite/TiO₂ composites dropped, showing that TiO₂ was successfully loaded on the surface of kaolinite [34].

SEM and EDX analysis

The nano-morphology was revealed with an in-lens secondary electrons detector, while the material contrast was obtained with a retractable backscattered electrons detector. In the first mode, using secondary electrons, clear high-resolution images provided the shape and the size of TiO₂ particles.

The samples were directly observed in their natural state, without prior metallization (no carbon layer evaporation nor conductive metal sputtering). Different electron optical parameters were selected in the second mode, namely backscattered electrons. Images at relative low magnifications (2500 X for the large ones and 10k X for the inserts) were performed to study the spatial distribution of TiO₂. A higher accelerating voltage of 7 kV and larger probe current at a shorter working distance of 6 mm made the acquisition of a sharp atomic number contrast possible. This mode of imaging allowed us to track the presence of TiO₂ particles onto the clay. Titania appears with a brighter contrast because titanium is heavier than any other element present in the as-prepared nanopowders. **Fig. 3a** shows that the KH2 raw clay has a mesoporous mixture between sheet-like kaolinite, which is partially light-covered, and halloysite, which is of tubular morphology [35]. In the case of pure TiO₂ (**Fig. 3b**), it was revealed that the particles are randomly distributed, and they also contain small spheres with the formation of agglomerates. Based on the SEM analyses of the morphology of clay/TiO₂ nanocomposites, it can be shown that well-distributed, but not uniformly sized,

spherical TiO_2 particles form on the surface of the clay, with an average size of approximately 10 nm. The adsorption capacity and photocatalytic activity of the nanocomposites might change due to the varying degrees of dispersion of TiO_2 particles on the clay surface [28]. The KT600B3 and KT600B8 nanocomposites showed significant changes compared to the other two nanocomposites, KTB3 and KTB8, indicating that calcination causes the structure of the clay to become more disordered.

Figure 3. SEM images of composites (a) KH2, (b) TiO_2 , (c) KTB3, (d) KTB8, (e) KT600B8 and (f) KT600B3

BET analysis

The nitrogen adsorption/desorption isotherms of samples are presented in [Fig.4](#); the samples' mesoporous adsorbents correlate to type IV's adsorption isotherm. This indicates that mesoporosity makes up most of the overall porosity, comparable to holes that resemble slits in layered materials. [Table.1](#) shows that the BET surface area of all solid samples [36] Increasing

the calcination temperature and grinding time caused a decrease in the specific surface area, and an increase in the size of kaolinite/TiO₂ crystallites. The dried catalyst KTB3 had the highest specific surface area and the catalysts calcined at 600°C (KT600B3, KT600B8) and KTB8 milled at 8 h had the smallest crystallite size[37].

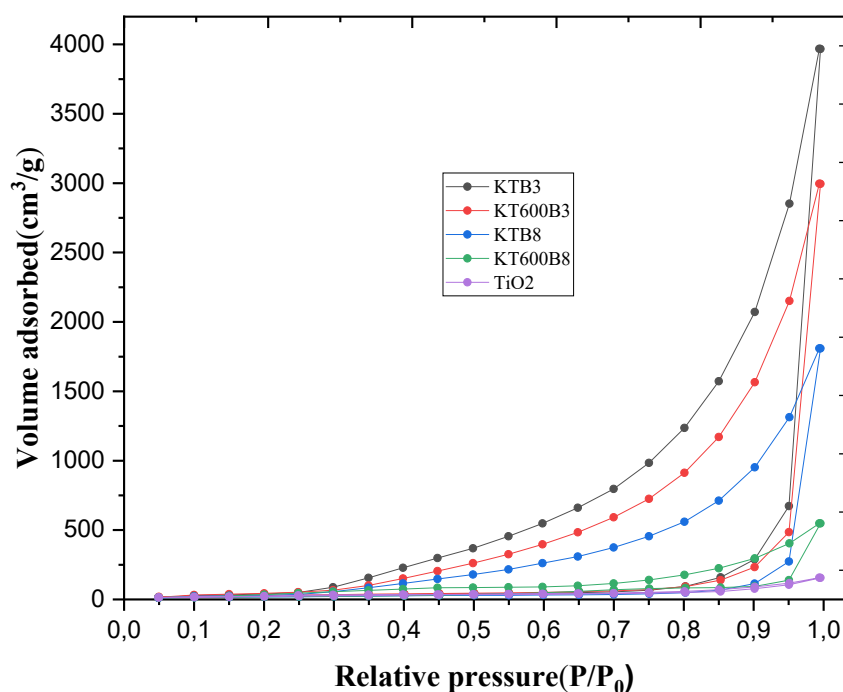

Figure 4. Nitrogen adsorption/desorption isotherms of samples at 77°K

Table 1 Mean pore diameter, pore volume and specific surface area of solid samples.

Samples	Mean pore diameter (nm)	Pore volume (cm ³ /g)	BET surface area (m ² /g)
KTB3	8.85	4.715	197.9
TiO ₂	2.82	0.863	72.52

KT600B3	7.43	0.630	106.57
KTB8	8.29	0.223	91.77
KT600B8	6.82	0.2834	81.4

Infrared spectrum (ATR)

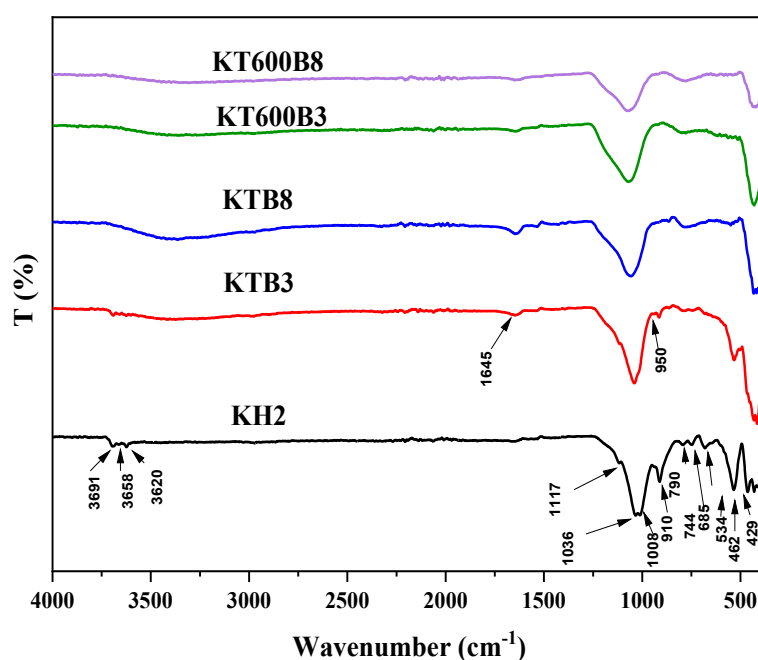

Figure 5. Infrared spectrum of kaolinite/TiO₂ composites

Fig. 5 shows the ATR spectrum (vibrational bands and interfaces of interaction) for each sample. For KH2, the bands at 1036 cm⁻¹ and 1008 cm⁻¹ correspond to the stretching vibrations of the Si–O structural lattice (Si–O–Si and O–Si–O). The other bands at 1117 cm⁻¹ are due to the Si–O stretching vibration at the apex and the out-of-phase stretching vibration of the inner surface hydroxyl, respectively[38]. The deformation band at 428 cm⁻¹ corresponds to the Si–O groups [39]. The stretching vibration of the inner surface hydroxyl (OH), which is seldom ever

affected by intercalation, is thought to be responsible for the absorption bands at 3691, 3620, 3658, and 910 cm^{-1} . O-Al-translational OH vibration causes the bands at 790, 744, and 685 cm^{-1} , whereas Si-O-vibration Al is responsible for the bands at 534 and 462 cm^{-1} . Kaolinite/TiO₂ nanocomposites exhibit the stretching and bending vibrations of water molecules adsorbed groups at 1632 cm^{-1} [40]. Keep in mind that there is no difference in the hydroxyl vibration peaks of kaolinite before and after loading. The stretching vibration of Ti–O is responsible for the peaks in the spectra between 400 and 900 cm^{-1} , which are a strong sign of the existence of TiO₂. The peak at 950 cm^{-1} , which is attributable to the antisymmetric stretching vibration Si–O–Ti, shows that titanium dioxide and kaolinite were combined chemically to produce the kaolinite/TiO₂ composite [41][42]. The change of kaolinite to metakaolinite also results in a shift in the band structure that manifests as structural dehydroxylation and metakaolinite production, which causes a shift in the Al³⁺ coordination of the octahedral area 1250–400 cm^{-1} . Amorphous SiO₂ was identified as the source of broad bands with maxima at 950 and 1120 cm^{-1} . Metakaolinite was created by calcining kaolinite at 600°C. Amorphous silica was also seen vibrating between 1200 and 1050 cm^{-1} [43]. The faster elimination of vibrations perpendicular to the mineral layers was found for KTB3 and KTB8 in the Si–O stretching zone. Mechanical treatments such as grinding have the most impact on these bands, even if XRD results show that the kaolinite was converted into a non-crystalline substance. As a result, this band might represent the whole amount of silica. The intensity of Si–O–Al oscillations was significantly reduced, indicating that the bond between the octahedral and tetrahedral layers was easily deteriorated. It was observed with treatment time that the Si–O bending bands at 429 and 462 cm^{-1} gradually decreased. Even after a prolonged treatment period, the band at 429 cm^{-1} did not fade [44]. When grinding kaolin during different times, the 3691, 3620, 3658, and 910 cm^{-1} absorption bands of the inner surface hydroxyl groups decreased with the grinding times [45].

In the low-wavenumber region, hydroxyl deformation modes were observed between the surface water molecules formed by breaking Si–O or Al–O–Si bonds (internal hydroxyls). In parallel with the weakening of the stretching vibration band, the intensities of these bands also decreased during grinding. Due to its stability after milling, the band at 1036 cm^{-1} is thought to reflect the overall amount of silica present and can be therefore used as a reference for comparing different samples.

Figure S4 shows the IR spectra obtained for the pure TiO_2 ; the band at 428 cm^{-1} is attributed to the bending vibrations of the framework bonds Ti–O and Ti–O–Ti[46].

Methine (–CH–) and methylene (–CH₂–) groups are represented by the tiny peaks at 2972 and 2871 cm^{-1} , respectively. The characteristic peak at 1650 – 1597 cm^{-1} is associated with the stretching frequency of carboxylate (–COO), indicating that the organic component does not completely evaporate at 450°C [47].

DRS UV-vis spectra

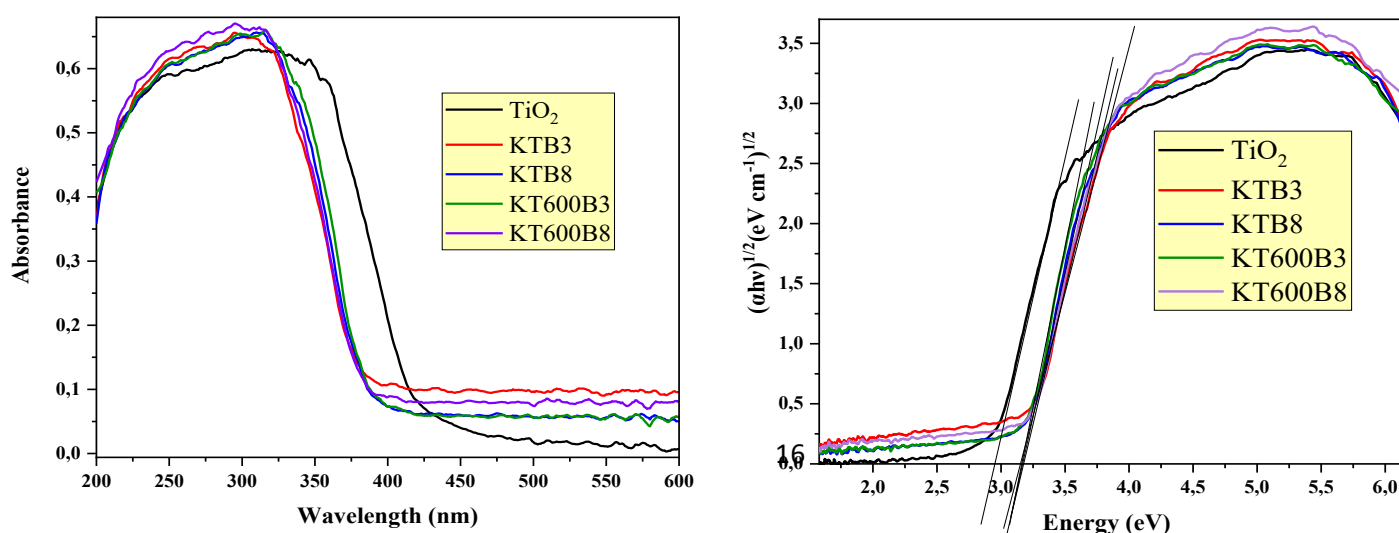

Figure 6. DRS UV-vis spectra of pure TiO₂ and kaolinite/TiO₂ composite

Fig. 6 shows the DRS UV-vis spectra of pure TiO₂ and the various kaolinite/TiO₂ composites. The band gap calculation is most important from the point of energy conversion efficiency. The optical band gap of the photocatalyst was estimated using equation of Tauc:

$$\alpha h\nu = A(h\nu - E_g)^n \quad (5)$$

where A represents a constant, $h\nu$ is photon energy, α is absorption coefficient, E_g represent forbidden band, and $n = 1/2$ (for a direct transition) or $n = 2$ (for an indirect transition).

The intersection of the linear part of the Tauc plot $(\alpha h\nu)^{1/2}$ with the energy-axis gives the value of the band gap [48]. The optical bandgap energy values of the nanomaterials prepared (TiO₂, KTB3, KTB8, KT600B3, and KT600B8) were 2.93, 3.13, 3.14, 3.14 and 3.14 eV respectively. This finding implies that kaolinite causes the absorption edge of TiO₂ to shift to a higher energy region. On the one hand kaolinite may increase catalytic activity by delaying the recombination of separate charges produced by UV radiation in the TiO₂ crystal lattice [49]. Consequently, the presence of SiO₂ in the kaolinite/TiO₂ composites leads to slightly improving the ability of TiO₂ nanoparticles to absorb light as long as they form a chemical bond with SiO₂ [50].

Adsorption study

Adsorption kinetics

Figure 7a. Adsorption kinetics of methylene blue on KTB3

Figure 7b UV-Vis spectra of methylene blue photodegradation by KTB3 as a function of time

The study of the adsorption kinetics of MB in an aqueous solution is demonstrated by adsorption rate curves and modelled by the pseudo-first-order and pseudo-second-order kinetic plots expressed in Eqs. (6) and (7), respectively [51][52]

$$\frac{dq_t}{dt} = k_1(q_e - q_t) \quad (6)$$

$$\frac{dq_t}{dt} = k_2(q_e - q_t)^2 \quad (7)$$

Integrating both equations, the corresponding nonlinear forms are obtained as the following equations:

$$q_t = q_e(1 - e^{-k_1 t}) \quad (8)$$

$$q_t = \frac{q_e^2 k_2 t}{1 + k_2 q_e t} \quad (9)$$

where k_1 and k_2 are the pseudo-first-order and pseudo-second-order rate constant, respectively. Physically, q_e represents the adsorption capacity at equilibrium, while k_1 and k_2 reflect the rate of adsorption: a higher rate constant indicates a faster approach to equilibrium. The pseudo-first-order model is often applied when the adsorption process is dominated by diffusion or physical interactions on a homogeneous surface. On the other hand, the pseudo-second-order model is widely used for systems where chemisorption, such as bond formation or electron exchange, governs the kinetics [53]

Fig. 7a revealed that adsorption equilibrium was reached after 60 min for the majority of the prepared materials, and the amount of adsorbate on the surface reached a plateau, indicating that the material surface is saturated and no further adsorption is possible, and demonstrating that the adsorption kinetics of the dye on the synthetic material is relatively

rapid. To further evaluate the adsorption kinetics of MB, kinetic rate constants (k_1 and k_2), equilibrium adsorption capacities (q_e), and correlation coefficients (R^2) were determined. The results of the pseudo-first-order and pseudo-second-order models are presented in **Table 2**. According to the results obtained, the kinetics are described by the pseudo-second-order model, which is in agreement with the work reported by Tran et al [54]. However, the novelty of our study lies in applying this model to the specific TiO₂/kaolinite composite synthesized in this work, which has unique physicochemical properties influenced by its preparation method. These results provide new insights into the adsorption behavior of TiO₂/clay-based composites and their potential for environmental applications, further validating the consistency of pseudo-second-order kinetics in clay-supported adsorption systems. In addition, the calculated q_e values were closer to the experimental values obtained, which explains why the adsorption kinetics of the dyes on the prepared materials follow the PSO models. [55]

Table 2 Kinetics parameters for the adsorption of MB

Samples	PSO model			PFO model		
	R^2	q_e (mg/g)	k_2 (g/mg×min)	R^2	q_e (mg/g)	k_1 (min ⁻¹)
KTB3	0.99	8.95	0.04	0.98	8.51	0.183
KTB8	0.98	5.29	0.009	0.98	3.59	0.051
KT600B3	0.98	5.59	0.011	0.95	4.89	0.049
KT600B8	0.98	4.12	0.015	0.98	3.59	0.051
TiO₂	0.98	1.86	0.105	0,99	1.73	0.111

Adsorption isotherm

The data were modeled using the two most well-known isotherm models, Freundlich (Eq. 10) and Langmuir (Eq. 11), to define the interaction of methylene blue molecules with the KTB3 surface and to study the distribution properties in liquid and solid phases. Equations 10 and 11 provide expressions of the non-linear relationship of these isotherm models [52]

$$q_e = K_F C_e^{1/n_F} \quad (10)$$

$$q_e = \frac{q_m K_L C_e}{1 + k_L C_e} \quad (11)$$

In the formula, C_e is the equilibrium concentration of methylene blue (mg/L), n_F and K_F are the Freundlich constants, q_e and q_m are the amount of MB adsorbed at equilibrium and the maximum adsorption capacity, respectively. K_L (L/mg) is the Langmuir equilibrium constant. Applying Eq. (11), we can determine the maximum amount of MB adsorbed by the nanocomposite (q_m), which is around 29.73 mg/g (Figure S4). Moreover, the adsorption rate decreases with increasing grinding time and degree of kaolinite calcination. The characteristic constants of each system were determined and listed in Table S1. The methylene blue adsorption isotherm shows that the best correlation of experimental results is obtained with the Langmuir model ($R^2 = 0.99$) Table S1[56].

Photocatalytic experiments

Figure 8. The effect of photocatalysis composites (a) Effect of photocatalysis dose (b) effect of initial dye concentration (c) pH effect (d) and first order kinetic (e) on removal of MB with KTB3.

The kinetics and rate constant of methylene blue photodegradation have been studied using the Langmuir-Hinshelwood equation (Eq. 12) obeying first order kinetics [57]:

$$r = -\frac{dC_t}{dt} = \frac{kKC_t}{1+KC_t} \quad (12)$$

where k [mg/ (min L)] and K (L/mg) correspond to the photocatalytic rate constant and the adsorption equilibrium constant, respectively, and C_t is the concentration at time t (min).

When:

- $KC_t \gg 1$, so the value of $1 + KC_t \approx KC_t$
- $KC_t \ll 1$, to be a result, the denominator $1 + KC_t \approx 1$

Using these two mathematical theorems and the low dye concentrations used in photocatalysis, the Langmuir-Hinshelwood equation has been created.

$$-\frac{dC_t}{dt} = k_1 C_t \quad (13)$$

$$k_1 = k \times K \quad (14)$$

The integral of the equation result in:

$$\ln C_t = -k_1 t + A \quad (15)$$

$$C_t = B e^{-k_1 t} \quad (16)$$

where k_1 (min^{-1}) is the first-order model's rate constant.

When $t = 0$ and $C_t = C_0 = B$, as seen below, the nonlinear equation can be simplified:

$$C_t = C_0 \times e^{-k_1 t} \quad (17)$$

This pseudo-first-order model was used to determine the correlation coefficient (R^2). The rate and mechanism of subsequent adsorption and degradation processes could be used to characterize the model of methylene blue degradation kinetics [58]. The results are represented in Table 3.

The experimental results show that supporting TiO_2 on kaolinite results in an improvement in MB removal efficiency from 71% to 98% for pure TiO_2 and KTB3, respectively (Fig. 8a). This result was explained by the large specific surface area of the clay[59]. Supporting TiO_2 on kaolinite can provide more adsorption and photocatalytic active sites for the decomposition of organic molecules, which confirms the synergy effect between both phenomena [60]. KTB3 has better photocatalytic performance; after 80 min, it eliminates 95% because the grinding of kaolinite can provide significantly more adsorbent active sites, therefore, greater photocatalytic performance. On the other hand, the other composites have a less efficient photocatalytic capacity due to the destruction of the kaolinite structure by

calcination at 600 °C and the increase in grinding time. The kaolinite/TiO₂ composite performs better methylene blue degradation than pure TiO₂ [38].

Table 3. Kinetics parameters of nanocomposites for the photocatalysis of MB

Model	PSO			MB (%)
	Photodegradation			
	C_0	K	R^2	
	(mg/L)	(min ⁻¹)		
KTB3	11.48	0.056	0.964	98
KTB8	13.48	0.013	0.964	86
KT600B3	12.40	0.022	0.974	91
KT600B8	13.76	0.011	0.960	81
TiO₂	14.82	0.006	0.943	71

Influence of Photocatalyst amount

A series of studies were conducted with varying dosages of catalysts at an initial dye concentration $C_0 = 21$ mg/L to investigate the dose effect of KTB3 on MB photodegradation at pH = 7.6. **Fig. 8b** shows that the different catalyst doses ranged from 0.2 to 1.5 g/L. The degradation efficiency increases proportionally with photocatalyst dose, up to the optimum of 1 g/L. This is most likely due to an increase in the number of adsorbed MB molecules, which is directly related to the number of KTB3 particles when the photocatalyst dose increases, as well as an increase in the number of electrons excited to produce radicals (\bullet OH) at the optimal dose of 1 g/L, which depends on the operating conditions. Increases in photocatalyst doses have a negative impact on degradation efficiency. The decrease in the efficiency of degradation

beyond 1 g/L can be attributed to the shielding effect of an excess of KTB3 particles and the loss of light caused by diffusion at the saturation of the absorption photons [61].

Effect of dye concentration

In this section, a series of MB solutions with different concentrations from 12 mg/L to 44.5 mg/L have been prepared. It is evident that the rate of photodegradation is affected by dye concentration. It was investigated that degradation yield decreases from 98 to 57% when the dye concentration is increased from 21.38 to 44.5 mg/L (**Fig. 8c**). The rate of degradation is proportional to the generation of $\bullet\text{OH}$ radicals on the catalyst's surface and the likelihood that the $\bullet\text{OH}$ radicals will react with the dye molecule. This means the rate at which the dye is degraded depends on the amount of hydroxyl radicals ($\bullet\text{OH}$) generated on the catalyst surface. The more $\bullet\text{OH}$ radicals generated, the higher the rate of degradation. The photodegradation kinetics are rapid at low initial concentrations (**Fig. 8c**) due to the small number of MB molecules present in the solution. This results in high availability of photogenerated active species, which are responsible for photodegradation. When the initial dye concentration is high, the path length of the photon entering the solution also decreases. Thus, the efficiency of photocatalytic degradation decreases, but at low concentrations, the opposite effect is observed, increasing photon absorption by the catalyst [36]. The large amount of adsorbed dye can also have a competing effect on the adsorption of oxygen and $\bullet\text{OH}$ to the catalyst surface.

Effect of pH, extent of mineralization and scavenging effect

The pH is one of the most critical parameters influencing the photocatalytic process. **Fig. 8d** depicts the effect of pH (from 2 to 10) on MB adsorption on KTB3 (at a starting concentration of MB of 20 mg/L and an adsorbent dosage of 1 g/L) when HCl (0.1 M) or NaOH (0.1 M) are added. The increased pH of the adsorbent medium modifies the clay mineral surface, which may be responsible for the progressive increase in methylene blue adsorption,

and the protonated catalyst surface may strongly attract positively charged dye molecules, resulting in superior photocatalytic degradation. According to the literature, photocatalytic activity increases with increasing pH; however, an excessive amount of H⁺ in the solution causes a decrease in the degradation [62]. **Fig. 8d** shows that when the pH increased from 2 to 7, the degradation of MB increased progressively from 22.7 % to 95.8 % and then decreased to 82.3 % beyond pH 10. This is caused by the electrostatic attraction between the positively charged catalyst and the MB molecules [62]. It can also be explained by the presence of OH⁻ ions in solution, which promote the creation of •OH radicals, encouraging photodegradation.

The mineralization efficiency was determined using the following equation:

$$R(\%) = \frac{TOCi - TOCf}{TOCi} \times 100 \quad (18)$$

The total organic carbon (TOC) analysis revealed a significant difference in mineralization efficiency between the tested samples. The KTB3 catalyst demonstrated exceptional performance, achieving a mineralization rate of 93%, compared to 63% for TiO₂ alone. These findings highlight the superior capability of KTB3 in degrading and mineralizing organic compounds, confirming its potential as an efficient catalyst for advanced treatment applications. The methylene blue stock solution had a concentration of 13.75 mg/L. After treatment, the remaining organic carbon was reduced to 0.96 mg/L for KTB3 (93% mineralization) and to 5.09 mg/L for TiO₂ (63% mineralization), further underscoring the enhanced efficiency of KTB3 under these experimental conditions.

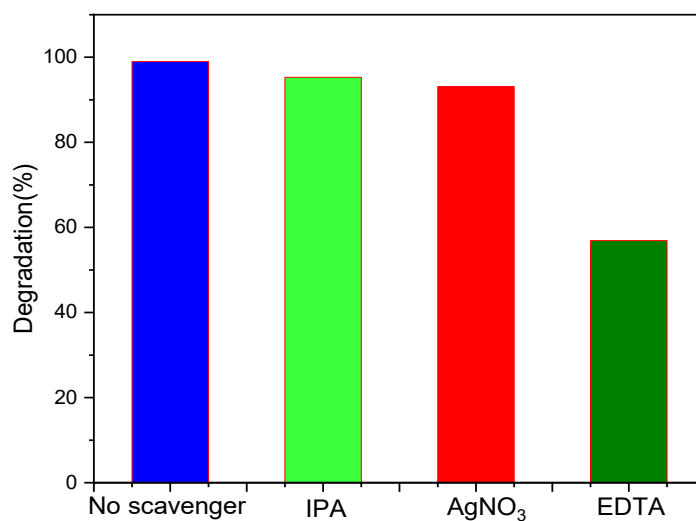

Fig. 9. Photocatalytic removal of MB in presence of several scavengers using KTB3

As concerns the scavenging experiments, the results in **Fig. 9** showed a decrease in photocatalytic degradation when specific scavengers, such as isopropanol (IPA), silver nitrate (AgNO₃), and ethylenediaminetetraacetic acid (EDTA) (Fig. 9), were introduced in the methylene blue degradation reaction using the TiO₂/kaolinite composite KTB3. This reduction in degradation is explained by the ability of these scavengers to neutralize key reactive species involved in the photocatalysis. IPA acts as a hydroxyl radical ($\bullet\text{OH}$) scavenger, limiting their contribution to pollutant oxidation. AgNO₃, as an electron acceptor, traps electrons in the conduction band (e^-), thereby reducing the formation of superoxide radicals ($\text{O}_2^{\bullet-}$). EDTA, as a hole (h^+) scavenger, prevents direct oxidation reactions initiated by these holes [63][64]. The observed decrease in degradation supports the central role of these reactive species ($\bullet\text{OH}$, h^+ , $\text{O}_2^{\bullet-}$) in the photocatalytic process, and the scavenger effect limits their availability, reducing the overall efficiency of the reaction.

Mechanism of kaolinite/TiO₂ assisted photocatalytic degradation

Figure 10. Proposed Mechanism of kaolinite/TiO₂ composites assisted photocatalytic degradation of MB under UV-light. [65]

The mechanism of photocatalysis by TiO₂ has already been described in depth in the literature [66] [67]. When an aqueous TiO₂ dispersion is exposed to light energy above its bandgap energy (3.2 eV), conduction band electrons (e⁻) are produced, triggering photocatalytic activity (Figure 10), holes can combine with OH⁻ or H₂O and become OH[•] radicals as a result. They then react with H⁺ to produce a hydrogen dioxide radical (HO₂[•], hydroperoxyl).

Reaction involving valence band h⁺

Reaction involving conduction band e⁻

Photoholes have a considerable potential by combining with the $\bullet\text{OH}$ that predominates in aqueous solutions.

Upon UV irradiation, the TiO_2 in the kaolinite/ TiO_2 composite absorbs photons ($h\nu$), which generate electron-hole pairs (e^- and h^+) (Equation 19). The photoexcited holes (h^+) in the valence band participate in several reactions, including the oxidation of water to produce hydroxyl radicals ($\bullet\text{OH}$) (Equations 20 and 21). In the presence of excess water, these holes can also produce hydrogen peroxide (H_2O_2) (Equation 22). On the other hand, the electrons (e^-) in the conduction band reduce molecular oxygen (O_2) to form superoxide radicals (O_2^-) (Equation 23), which, in turn, react with protons (H^+) to form hydroperoxyl radicals (HO_2^\bullet) (Equation 24). These reactive species ($\bullet\text{OH}$, O_2^- , and HO_2^\bullet) are capable of decomposing organic pollutants like methylene blue (MB) into non-toxic by-products, such as CO_2 and H_2O (Equation 30). Additionally, the superoxide radical can also react with hydrogen peroxide to form hydroxyl radicals and oxygen (Equations 26 and 27), further enhancing the degradation process. [68]

The grinding of kaolinite improves the photocatalytic performance by increasing the specific surface area, dispersion, and adsorption capacity of the TiO_2 , which helps to improve the overall reactivity and efficiency of the composite in water treatment applications. These

results demonstrate the potential of kaolinite/TiO₂ composites for more efficient and cost-effective photocatalytic water. The photocatalytic performance of the synthesized kaolinite/TiO₂ was compared with previously reported papers, as shown in Table 4.

Table 4. Photodegradation efficiency of Kaolinite/TiO₂ nanocomposites for different dyes.

Nanocomposite	Organic Pollutant	Catalyst amount (g/L)	C_o (mg/L)	Degradation rate (%)	Reaction time	Reference
Kaolinite/TiO ₂	Methyl Orange	1	10	45	7h	[69]
Kaolinite/TiO ₂	Congo-red (CR)	1	20	60	4 h	[70]
kaolinite /Ag- TiO ₂	Methylene blue	0.5	3.198	96.7	120 min	[71]
Kaolinite/TiO ₂	Methylene blue	0.25	10	94	5 h	[72]
Kaolinite/TiO ₂	Rhodamine B	0.5	50	51	120min	[38]
Halloysite /TiO ₂	methylene blue	0.5	30	81.6	4H	[73]
Halloysite- Carbon-TiO ₂	methylene blue	0.2	20	73	80 min	[74]
kaolinite/TiO ₂	methylene blue	1	20	98.3	3h	This study

Conclusions

Based on the above results, a possible mechanism to explain the improvement of photocatalytic properties of clay/TiO₂ nanocomposites was proposed. Kaolinite and halloysite are both natural clays that exhibit interesting adsorption properties. By combining these two materials, they benefit from their complementary properties for more efficient adsorption. The

grinding treatment rate over time was adequate to increase the amount of micropores and mesopores. Crystalline phase development was evaluated using X-ray diffraction data to confirm a kaolinite crystalline phase in clay and that the anatase phase only exists in kaolinite/TiO₂ composites. The photocatalytic activity of the produced nanoparticles for MB removal was investigated using a 365 nm UV light source. This study clearly shows that coating TiO₂ with Kaolinite increased the removal of MB dye. Increasing grinding time of 8 h and calcination at 600 °C also caused structural rearrangement of crystalline layers of kaolinite. At this temperature, kaolinite underwent a transformation into metakaolinite, an amorphous alumino-silicate phase. This structural rearrangement can reduce the specific surface area due to the disruption of the kaolinite sheet crystal structure.
