3 1 ABSTRACT.  
4  
5  
6

7 2 In-cell NMR spectroscopy provides atomic resolution insights into the structural properties of  
8  
9  
10 3 proteins in cells, but it is rarely used to solve entire protein structures *de novo*. Here, we  
11  
12 4 introduce a paramagnetic lanthanide-tag to simultaneously measure protein pseudocontact shifts  
13  
14 5 (PCSs) and residual dipolar couplings (RDCs) to be used as input for structure calculation  
15  
16 6 routines within the Rosetta program. We employ this approach to determine the structure of the  
17  
18 7 protein G B1 domain (GB1) in intact *Xenopus laevis* oocytes from a single set of 2D in-cell  
19  
20 8 NMR experiments. Specifically, we derive well-defined GB1 ensembles from low concentration  
21  
22 9 in-cell NMR samples ( $\sim 50 \mu\text{M}$ ) measured at moderate magnetic field strengths (600 MHz), thus  
23  
24  
25  
26 10 offering an easily accessible alternative for determining intracellular protein structures.

1 Physical methods to delineate structural insights into the three-dimensional properties of  
2 biomolecules such as X-ray crystallography, NMR spectroscopy or electron microscopy,  
3 typically require experimental conditions and sample states that are vastly different from the  
4 crowded intracellular environments in which these molecules natively occur<sup>1</sup>. For these reasons,  
5 considerable effort is put into the development of biophysical methods to directly study  
6 biomolecules inside live cells. While high-resolution X-ray crystallography and single molecule  
7 electron microscopy are inherently excluded from such *in vivo* experiments, due to the  
8 requirement of crystalline or vitrified samples and the use of high-energy X-ray or electron  
9 beams to generate experimental data, solution NMR spectroscopy can provide non-destructive  
10 atomic-resolution information on individual biomolecules in cells. Specifically, in-cell NMR  
11 spectroscopy<sup>2,3</sup> takes advantage of the isotope-labeling effect to selectively ‘visualize’ isotope-  
12 enriched, NMR-active proteins, RNA or DNA against the backdrop of all other non isotope-  
13 labeled and NMR-inactive intracellular components. This enables direct NMR measurements  
14 under truly physiological *in vivo* conditions. Following this rationale, in-cell NMR has been used  
15 to derive insights into intracellular protein conformations,<sup>4</sup> conformational equilibria,<sup>5</sup> folding  
16 and stability behaviors,<sup>6-8</sup> protein dynamics,<sup>9</sup> protein-protein and quinary protein interactions,<sup>9,10</sup>  
17 physiological redox states,<sup>11</sup> metal-binding properties<sup>12</sup> and post-translational protein  
18 modifications.<sup>9,13,14</sup> By contrast, the use of in-cell NMR to determine entire protein structures in  
19 live cells is generally hampered by the limited lifetimes of in-cell NMR samples, their inherently  
20 low concentrations of intracellular, isotope-enriched biomolecules (i.e. protein, RNA or DNA)  
21 and their concomitantly poor spectral qualities. Especially lengthy 3D and 4D NMR experiments  
22 - commonly used to derive long-range distance restraints for calculating biomolecular structures  
23 - suffer from these drawbacks.<sup>15</sup> Several advances in NMR methods, including faster acquisition

1 routines and non-uniform sampling procedures<sup>16-18</sup> have helped to ameliorate some of these  
2 shortcomings and enabled the first and only intracellular protein structure to be determined by in-  
3 cell NMR spectroscopy in bacteria, although at exceedingly high, non-physiological intracellular  
4 protein concentrations in the millimolar range<sup>4</sup>. As a result, and given the general poor sensitivity  
5 of 3D and 4D NMR experiments even with such enhancing techniques, comprehensive structure  
6 determination efforts of proteins in live cells are deemed impractical and unfeasible. Here, we  
7 present an alternative approach to determine intracellular protein structures in live eukaryotic  
8 cells that solely relies on 2D NMR experiments and paramagnetic protein tagging to  
9 simultaneously induce pseudocontact shifts (PCSs) and residual dipolar couplings (RDCs). In  
10 turn, we demonstrate how these structural parameters suffice to calculate high-precision in-cell  
11 protein structures with the Rosetta program.

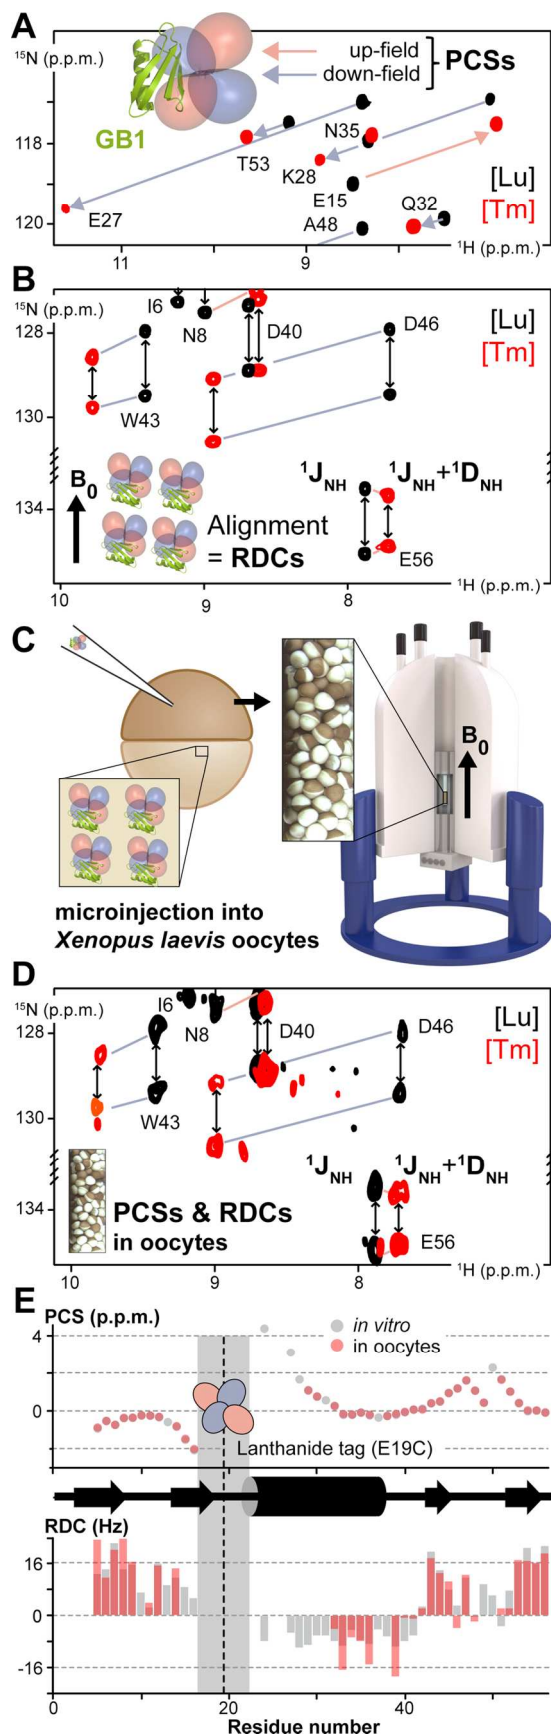

12 Tagging of proteins with different metals of the lanthanide series is known to induce strong  
13 metal-specific distance- and orientation-dependent PCS effects on individual NMR-active atomic  
14 nuclei.<sup>19,20</sup> Such PCSs serve as powerful long-range distance restraints in structure calculation  
15 routines and they can be derived from simple 2D NMR experiments, with different types of  
16 lanthanide-binding protein tags (Fig. 1a).<sup>21-24</sup> Optimizing the rigidity and linker-lengths of  
17 individual tag structures also enables partial alignments of coupled proteins with respect to the  
18 external magnetic field, thus giving rise to measurable RDCs and, thereby, additional  
19 orientational restraints (Fig. 1b).<sup>25-27</sup> In a first step, we designed a modified version of the  
20 classical tetraaza-carboxylic DOTA chelator, known for its excellent metal coordinating  
21 properties, which we termed DOTA-M7Py (Fig. S1). This tag can be covalently coupled to the  
22 sulfhydryl moiety of cysteine residues forming a non-reducible thioether bond.<sup>28-30</sup> With regard  
23 to in-cell PCS and RDC measurements, DOTA-M7Py displays several attractive features. First,

1  
2  
3 1 it is inherently rigid and adopts exclusively the square anti-prismatic  $\Lambda(\delta\delta\delta\delta)$  stereo-confi-  
4 guration for the *4S,3R*-Lu derivative.<sup>31</sup> Second, it is neutral after binding to lanthanide metals.  
5  
6 2  
7  
8 3 Third, its linker portion is short, which reduces tag mobility and generates larger PCS effects,  
9  
10 4 thus providing higher precision structural information. Fourth, it features both hydrophilic and  
11  
12 5 hydrophobic properties (Fig. S1), which augment stable positioning on most protein surfaces,  
13  
14 6 further enhancing PCSs. Fifth, its thioether bond is expected to withstand the reducing  
15  
16 7 environment of the cytoplasm while maintaining DOTA's outstanding affinity towards  
17  
18 8 lanthanide metals ( $K_d < 10^{-25}$  M).<sup>27</sup>  
19

20  
21  
22 9 We initially prepared diamagnetic DOTA-M7Py[Lu], and paramagnetic DOTA-M7Py[Tm]  
23  
24 10 and DOTA-M7Py[Tb] complexes, which we coupled to the Streptococcal protein G B1 domain  
25  
26 11 (GB1) via cysteine residues that we introduced by site-directed mutagenesis at individual GB1  
27  
28 12 positions, i.e., E19C, K28C and E42C. Using purified GB1 samples we recorded 2D  $^1\text{H}$ - $^{15}\text{N}$   
29  
30 13 HSQC spectra at 600 MHz, which revealed the expected PCS effects for the paramagnetic  
31  
32 14 species (up to 6 p.p.m., Fig. 1a; Fig. S2 & S3; Table S1). We also detected strong cross-peak  
33  
34 15 splitting in 2D  $^1\text{H}$ - $^{15}\text{N}$  IPAP-HSQC spectra due to paramagnetic alignment of the GB1 domain  
35  
36 16 and resulting RDC effects<sup>32</sup> (amplitudes reaching 25 Hz at 293 K, 600 MHz, Fig. 1b; Fig. S2 &  
37  
38 17 S4; Table S2). In agreement with the temperature dependency of the tag's mobility, we obtained  
39  
40 18 30 % higher or lower PCS and RDC values at 277 K and 310 K, respectively (Table S1 & S2).  
41  
42 19 Moreover, NMR spectra of the different DOTA-M7Py[Tm]-tagged GB1 samples (E19C, K28C  
43  
44 20 and E42C) revealed both positive and negative PCSs, as well as larger overall RDCs,<sup>19,20</sup> which  
45  
46 21 is particularly useful for structure calculation routines. Therefore, we resorted to using DOTA-  
47  
48 22 M7Py[Tm]-GB1 samples in all further experiments.  
49

1 Next, we microinjected tagged GB1 carrying either diamagnetic (Lu) or paramagnetic metals  
2 (Tm) into *Xenopus laevis* oocytes for in-cell NMR measurements.<sup>3,33,34</sup> We recorded 2D <sup>1</sup>H-<sup>15</sup>N  
3 HSQC spectra at effective NMR concentrations of ~25 μM (intracellular GB1 concentrations  
4 ~50 μM), which revealed PCSs that were virtually indistinguishable from the respective *in vitro*  
5 samples with an overall RMSD of 0.04 p.p.m., corresponding to 24 and 2.4 Hz in the <sup>1</sup>H and <sup>15</sup>N  
6 dimensions, respectively (Fig. 1e; Fig. S2, S5 & S6). We did not detect sample degradation or  
7 metal leakage for up to 24 hours, thus indicating the excellent stability of metal-loaded DOTA-  
8 M7Py in *Xenopus* oocytes. Similarly, we measured in-cell RDCs that were comparable to those  
9 obtained *in vitro* (Fig. 1d-1e, Fig. S7, Table S1 & S2). Because intracellular viscosity leads to  
10 faster T2 relaxation and, accordingly, enhanced <sup>15</sup>N signal decays, we chose to record in-cell  
11 RDC experiments with the <sup>15</sup>N free-induction decay (FID) set to 36 Hz, as opposed to 17 Hz for  
12 RDC measurements *in vitro* (cf Material and Methods). This resulted in average GB1 <sup>15</sup>N line  
13 widths of ~30 Hz, compared to ~12 Hz *in vitro*, which, concomitantly, increased the RMSD of  
14 RDCs measured *in vitro* versus in cells by 5 Hz, explaining also the larger differences of PCS  
15 and RDC RMSDs.

**Figure 1.** (A) Superposition of  $^1\text{H}$ - $^{15}\text{N}$  2D NMR spectra of purified GB1(E19C) coupled to DOTA-M7Py carrying diamagnetic Lutetium (Lu, black) or paramagnetic Thulium (Tm, red). Pseudocontact shift (PCS)-induced up- and down-field chemical shift changes are indicated (subset view). The inset depicts the GB1(E19C) ribbon structure (green) with paramagnetic iso-surfaces drawn at 2 p.p.m. (blue & red) (B) Superposition of 2D IPAP-HSQC spectra of GB1 with peak splitting due to amide scalar- ( $^1J_{\text{NH}}$ ) and residual dipolar-coupling (RDC, i.e.  $^1D_{\text{NH}}$ ). Paramagnetic GB1 alignment with respect to the external magnetic field ( $B_0$ ) is shown schematically. (C) Overview of GB1 sample preparation in *Xenopus laevis* oocytes and (D) superposition of GB1 NMR spectra displaying in-cell PCS and RDC effects (at 600 MHz). (E) Residue-resolved quantification of *in vitro* & in-cell PCS and RDC data at 293 K and 600 MHz.

1  
2  
3  
4 1 Finally, we used in-cell PCS and RDC data as input for GPS-Rosetta, a program that integrates  
5  
6 2 PCSs from multiple paramagnetic centers into unified distance constraints in structure  
7  
8 3 calculation routines.<sup>23</sup> Following the fragment-based rationale used by Rosetta, we generated  
9  
10 4 input libraries of 3- and 9-residue fragments of known protein structures, excluding the structure  
11  
12 5 of GB1 and homologous folds. Using these fragments, we generated 10,000 GB1 structures, out  
13  
14 6 of which we collected the 100 lowest-energy models and compared their conformations to  
15  
16 7 experimentally determined GB1 structures, i.e. X-ray crystallography (PDB code: 2QMT<sup>35</sup>) and  
17  
18 8 solution NMR (PDB code: 1GB1<sup>36</sup>, 2PLP<sup>37</sup>). We found poor convergence of individual models,  
19  
20 9 with a median backbone C $\alpha$  RMSD of 1.85 Å (Fig. 2a). Next, we added a PCS-based ‘weight-  
21  
22 10 ing’ function to steer GB1 models towards conformations that recapitulated the measured values.  
23  
24  
25 11 We used 72, 86 and 96 PCS constraints from the E19C, K28C and E42C GB1 mutants,  
26  
27 12 respectively, and obtained a substantially improved convergence of GB1 structures. The newly  
28  
29 13 determined average C $\alpha$  RMSD of the 100 lowest-energy models was 0.98 Å, and 0.64 Å  
30  
31 14 between the closest model and the crystal structure (Fig. 2b). Lastly, we used the RDC module of  
32  
33 15 Rosetta to include measured RDCs as additional input in our structure calculation routines,  
34  
35 16 which yielded a similar improved convergence of GB1 models (average C $\alpha$  RMSD of 1.04 Å for  
36  
37 17 the 100 lowest-energy structures, 0.64 Å for the closest model and the X-ray structure) (Fig. 2c).

38  
39 18 Upon closer inspection of the 10 lowest energy structures, we noticed a remarkable difference  
40  
41 19 between structures obtained with PCS data alone and the ones for which PCS and RDC values  
42  
43 20 were used. In both ensembles, loop L1 (residues N8 to E15) connecting strands  $\beta$ 1 and  $\beta$ 2 of  
44  
45 21 GB1 displayed two distinct conformations. One identical to the X-ray structure with an average  
46  
47 22 C $\alpha$  RMSD of 1.1 Å, and one with a larger C $\alpha$ -deviation and average RMSD of 1.6 Å. In PCS  
48  
49 23 models, only three out of ten structures adopted the X-ray L1 conformation. In PCS+RDC  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1 models, five out of ten structures did. Previous solution NMR data indicated that L1 is highly  
 2 flexible with backbone order parameters ( $S^2$ ) in the range of 0.5-0.6 ( $S^2$  of GB1 regions with  
 3 secondary structure  $\sim 0.8$ ).<sup>37-40</sup> These *in vitro* solution conformations of L1 are similar to those  
 4 observed in GB1 crystals with an L1 C $\alpha$  RMSD of 1.35 Å (Fig. 2D). From this we concluded  
 5 that combined PCS and RDC data from single 2D in-cell NMR experiments are sufficient to  
 6 determine well-defined protein structures within PCS Rosetta. Our results further confirmed that  
 7 the overall structural features of GB1 in *Xenopus* oocytes are similar to those observed *in vitro*.<sup>34</sup>  
 8

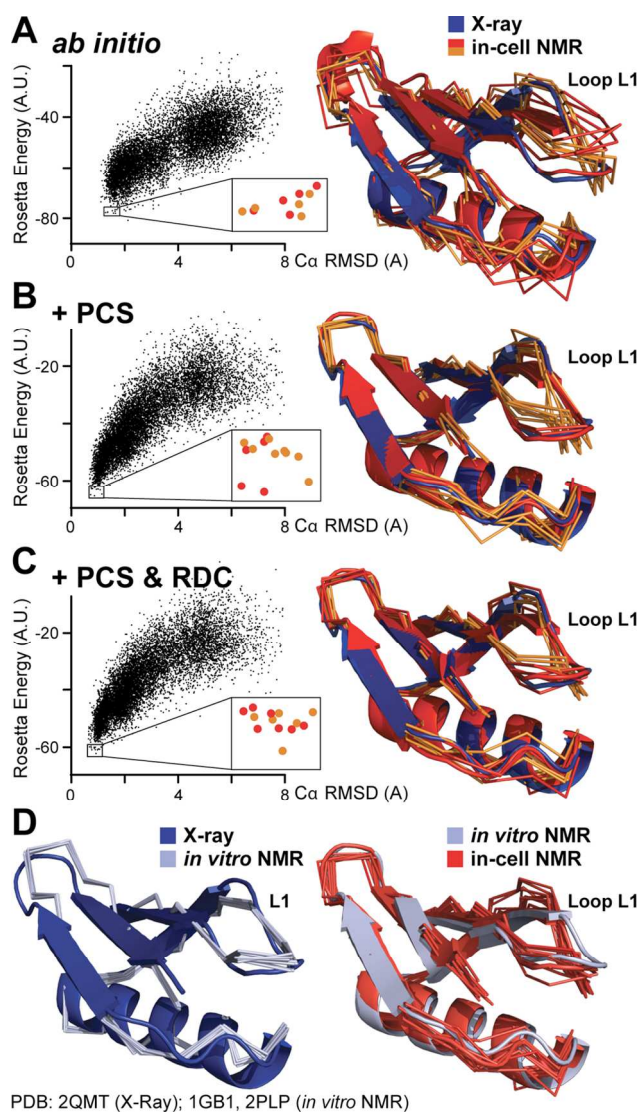

Figure 2. *In vitro* and in-cell structures of GB1. Scatter plots depict Rosetta energy scores and C $\alpha$  RMSDs of 10,000 GB1 models compared to the GB1 X-ray structure (2QMT). 10 lowest-energy structures are magnified and color-coded according their loop L1 conformations (red/orange). A superposition of their structures with the crystal conformation (blue) is shown on the right. GB1 models with L1 conformations corresponding to the one of the GB1 crystal are shown in red, deviating L1 conformers are colored orange. (A) *Ab initio* GB1 models without using experimental restraints, (B) GB1 models calculated with PCS and (C)

1  
2  
3 1 PCS+RDC input data. Rosetta energies contain different energy components and are not  
4  
5 2 comparable. (D) Left: Superposition of high-resolution *in vitro* solution NMR structures of  
6  
7 3 isolated GB1, i.e. 2PLP<sup>37</sup> (dark blue, ribbon representation) and 1GB1<sup>36</sup> (light blue, ensemble  
8  
9 4 representation). Right: Superposition of 2PLP (blue) and 10 lowest-energy in-cell GB1 models  
10  
11 5 (PCS+RDC, red).  
12  
13  
14  
15

16 6 In summary, we show that in-cell NMR-derived PCS and RDC data suffice to solve a protein's  
17  
18 7 structure inside cells. Whereas PCS effects decrease with the distance to the coordinated metal,  
19  
20 8 RDCs are distance-independent and offer valuable structural information for residues distal to  
21  
22 9 the paramagnetic center. PCS and RDC data can jointly be obtained from single 2D NMR  
23  
24 10 experiments on in-cell NMR samples of low intracellular protein concentrations, measured at  
25  
26 11 moderate magnetic field strengths, which makes them easily accessible and highly useful. The  
27  
28 12 presented approach can further be used for determining glycan and nucleic acid structures,<sup>2,41</sup> as  
29  
30 13 well as to probe ligand interactions.<sup>42</sup> In addition, the high rigidity of the DOTA-M7Py tag  
31  
32 14 renders it a useful tool for in-cell EPR studies.<sup>43,44</sup> Given that the intracellular delivery of  
33  
34 15 paramagnetically tagged proteins into cultured mammalian cells by electroporation is  
35  
36 16 straightforward,<sup>9</sup> combined PCS and RDC measurements in live cells also hold great promise for  
37  
38 17 future structure determination efforts in intact mammalian specimens.
