### ABSTRACT

We report the discovery of five galaxy candidates at redshifts between  $15.9 < z < 18.6$  in *JWST* observations from the GLIMPSE survey. These robust sources were identified using a combination of Lyman-break selection and photometric redshift estimates. The ultra-deep NIRCcam imaging from GLIMPSE, combined with the strong gravitational lensing of the Abell S1063 galaxy cluster, allows us to probe an intrinsically fainter population (down to  $M_{UV} = -17.5$  mag) than previously achievable. These galaxies have absolute magnitudes ranging from  $M_{UV} = -17.7$  to  $-18.0$  mag, with UV continuum slopes between  $\beta \simeq -2.3$  and  $\beta \simeq -3.0$ , consistent with young, dust-free stellar populations. The number density of these objects,  $\log_{10}(\phi/[Mpc^{-3} \text{ mag}^{-1}]) = -3.43^{+0.28}_{-0.64}$  at  $M_{UV} = -18$  is in clear tension with pre-*JWST* theoretical predictions, extending the over-abundance of galaxies from  $z \sim 10$  to  $z \sim 18.6$ . These results, together with the scarcity of brighter galaxies in other public surveys, suggest a steep decline in the bright-end of the UV luminosity function at  $z \sim 17$ , implying efficient star formation and possibly a close connection to the halo mass function at these redshifts. Testing a variety of star formation histories suggests that these sources are plausible progenitors of the unusually UV-bright galaxies that *JWST* now routinely uncovers at  $z = 10 - 14$ . Overall, our results indicate

that the luminosity distribution of the earliest star-forming galaxies could be shifting towards fainter luminosities, implying that future surveys of cosmic dawn will need to explore this faint luminosity regime.

*Keywords:* High-redshift galaxies (734), Early universe (435)

## 1. INTRODUCTION

According to the standard paradigm of structure formation, the same primordial fluctuations that gave rise to hot and cold spots in the cosmic microwave background (CMB) will eventually grow, collapse, and form the first galaxies during cosmic dawn, ushering in the epoch of first light (e.g. Loeb & Furlanetto 2013). These first galaxies have remained outside of our observational reach for decades. That is because they are faint and highly redshifted. Even the deepest *Hubble Space Telescope* (*HST*) surveys have fallen short of observing first light (Oesch et al. 2016). The ultraviolet (UV) light from the first galaxies drops precipitously due to absorption by foreground neutral gas (the Lyman- $\alpha$  break, see e.g., Steidel et al. 1996), which makes galaxies above  $z \gtrsim 10$  invisible in the *HST* IR filters.

The *James Webb Space Telescope* (*JWST*) was designed to observe the first galaxies. With its enormous collecting area and unprecedented near infrared imaging and spectroscopic capabilities, *JWST*/NIRCam is sensitive to faint light up to  $5 \mu\text{m}$  (Rieke et al. 2023). These are exactly the wavelengths required to discover galaxies forming stars during the first few hundred million years of cosmic history, as their Lyman- $\alpha$  break falls at  $2.0 \mu\text{m}$  and  $2.5 \mu\text{m}$  at redshifts 16 and 20, respectively. This means that broad imaging bands, such as the F200W and F277W can be paired to search for continuum “dropouts” up to  $z \sim 20$ , a mere 180 million years after the Big Bang.

*JWST* has successfully used this technique to discover dozens of galaxies at  $10 < z < 15$ . These observations have revealed a surprising over-abundance of UV-bright galaxies at  $z > 10$ , challenging pre-*JWST* predictions (to name just a few, Adams et al. 2023; Austin et al. 2023; Atek et al. 2023; Curtis-Lake et al. 2023; Donnan et al. 2023; Finkelstein et al. 2023; Pérez-González et al. 2023; Castellano et al. 2024; Carniani et al. 2024a; McLeod et al. 2024; Robertson et al. 2024; Chemerynska et al. 2024). Attempts to explain this over-abundance of bright galaxies at extreme redshifts invoke extremely efficient star formation in the early Universe, bursty star formation histories, a lack of dust attenuation, a top-heavy initial mass function (IMF), more efficient formation of dark matter halos, or modifications to the  $\Lambda$ CDM paradigm (e.g., Pacucci et al. 2022; Boylan-Kolchin 2023; Dekel et al. 2023; Ferrara et al. 2023;

Finkelstein et al. 2023; Harikane et al. 2023; Sun et al. 2023; Li et al. 2024).

The ancestors of these UV-bright galaxies at even higher redshift ( $z > 15$ ) have remained elusive. Many observational campaigns have searched for detections of first light galaxies, but few candidates pass rigorous scrutiny. Extremely dusty star-forming galaxies (Naidu et al. 2022; Zavala et al. 2023; Arrabal Haro et al. 2023), and spurious detections can masquerade as faint F200W drop-out galaxies. A key issue with detecting first-light galaxies is that they are expected to be intrinsically faint as they have had little time to assemble significant stellar mass. The discovery and characterization of these elusive primordial galaxies provides empirical constraints on the astrophysics shaping their formation.

Here we report on observations from *JWST*’S GLIMPSE survey (Atek et al., 2025, in prep.). GLIMPSE was specifically aimed to detect galaxies during the epoch of first light, by pairing ultra-deep NIRCam imaging across seven wide and two medium bands with the gravitational lensing of the foreground galaxy cluster Abell S1063. With even modest magnification factors of 2, the 30.6 mag GLIMPSE observations can reach absolute magnitudes ( $M_{\text{UV}}$ ) of  $-18$  at  $z \sim 17$ , probing the faint galaxies that likely existed during the epoch of first light. We use these observations to identify five robust  $z \gtrsim 16$  candidates, observed within a single NIRCam pointing, and assess the validity of these candidates via model fitting, morphology and properties of their stellar populations.

Throughout this work we assume a flat  $\Lambda$ CDM cosmology with  $\Omega_{\text{m},0} = 0.3$ ,  $\Omega_{\Lambda,0} = 0.7$  and  $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$ , and a Chabrier (2003) initial mass function (IMF) between  $0.1 - 100 M_{\odot}$ . All magnitudes are expressed in the AB system (Oke 1974).

## 2. OBSERVATIONS AND DATA

Detailed descriptions of the observations, data reduction, cluster light removal, and source extraction will be presented in the GLIMPSE survey (Atek et al., 2025, in prep.); and are briefly summarized below.

### 2.1. GLIMPSE Survey

This work uses the ultra-deep imaging from the public GLIMPSE survey (PID: 3293, PIs: H. Atek & J. Chisholm). GLIMPSE targets Abell S1063 (AS1063

hereafter), one of the highest-magnification regions in the Hubble Frontier Fields (HFF; Lotz et al. 2017), with 7 broadband filters (F090W, F115W, F150W, F200W, F277W, F356W, F444W) and 2 medium-band filters (F410M, F480M). The total duration of the survey is  $\sim 155$ h of science time, reaching unprecedented observed depths, down to 30.6 mag uniformly across all wide bands. Specifically, the bands used in the  $z > 15$  drop-out selection - F200W and F277W have integration times of 19 and 23 hours respectively. Furthermore, the lensing magnification of Abell S1063 also means that we can probe intrinsically faint sources which would otherwise be invisible in the deepest *JWST* blank field surveys.

GLIMPSE observations use a MEDIUM8 readout pattern for all exposures, and adopt a 6 position primary dither pattern to cover the short wavelength intra-module gaps while maximizing the full-depth area. In addition, we use a subpixel dither with 4 positions to best sample the PSF. This was done to optimize the S/N, with dithers large enough to mitigate the fixed pattern noise, imperative when searching for high- $z$  targets.

## 2.2. Data Reduction

NIRCam imaging data for all 7 broad and 2 medium band filters in AS1063 are reduced following the procedure in Endsley et al. (2024) using the `jwst_1293.pmap` context map. We implement crucial enhancements over the standard STScI pipeline, including corrections for cosmic rays, stray light, 1/f noise, and detector artifacts (Bradley et al. 2023; Rigby et al. 2023). Given the depth of the GLIMPSE campaign and the presence of bright cluster galaxies (bCGs), we model and subtract the background on an amplifier basis with SEP (Barbary 2016), while manually masking out the bright regions. This further improves the image background and allows the mosaics to reach  $\sim 0.3$  mag deeper across all filters. Our final data-set achieves  $5\sigma$  aperture-corrected nominal depths of 30.6 mag across all broad-bands in  $D=0''.2$  apertures.

We also process and incorporate the deep *HST* ACS and WFC3 mosaics from the Hubble Frontier Fields (Lotz et al. 2017) and BUFFALO (Steinhardt et al. 2020) programs. The *HST* images are based on Gaia-aligned mosaics from the CHArGE archive (Kokorev et al. 2022), which are hosted on the Dawn *JWST* Archive (Valentino et al. 2023). We drizzle our final mosaics onto a  $0''.02/\text{pixel}$  grid for the *JWST* short wavelength (SW) filters, and  $0''.04/\text{pixel}$  for *JWST* long wavelength (LW) and *HST*.

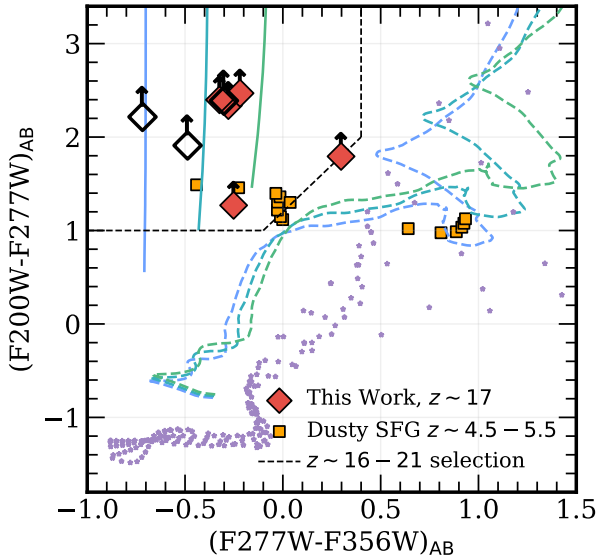

## 2.3. Cluster Light Contamination

Careful handling of the contamination light from the bCGs and intra-cluster light (ICL) is necessary for our science objectives. Improper treatment of the ICL could potentially lead to inaccurate colors which in return affect the derived photometric redshifts, negatively impacting the high- $z$  selection in the proximity of the cluster. To model and subtract the bCG and ICL light, we follow the robust methods described in Ferrarese et al. (2006), Shipley et al. (2018) and Weaver et al. (2024) for the Hubble Frontier Fields-Deep Space (HFFDS) and UNCOVER/Mega Science photometric catalogs (Suess et al. 2024). After both the bCGs and the ICL have been modeled and subtracted, we perform an additional local background subtraction pass in the affected areas, largely following the same methodology as in Section 2.2.

## 2.4. Source Extraction

We construct empirical point-spread functions (PSFs) by stacking the available stars in the field, and match all available bCG-subtracted *JWST* and *HST* images to our lowest resolution PSF - F480M. The sources are detected using SExtractor (Bertin & Arnouts 1996), which we run in a single mode on an inverse-variance weighted combination of the native PSF F277W, F356W and F444W images. We then use PHOTUTILS (Bradley et al. 2020) to measure flux densities in circular apertures with varying diameters from  $D = 0''.1 - 1''.2$ . The photometric errors are determined separately for each object and filter, taking into account both the aperture size and the depth variation across the image. In the vicinity of each source, we place 2000 random apertures in source-free parts of the image (as determined by the segmentation map). The standard deviation of the flux density within empty apertures, plus the Poisson noise are then used as the final uncertainty. This method is generally preferable over just using the weight/error maps, as it better accounts for effects of correlated noise (e.g. see Endsley et al. 2023; Weaver et al. 2024). The aperture corrections are calculated by assuming a point-source profile. We use the empirical F480M symmetric PSF curve of growth to determine the fraction of the total flux that falls outside of each specified aperture size and then use that as our correction factor.

In order to select high-fidelity high- $z$  candidates, we flag all sources that fall on the edge of the mosaic, intersect with diffraction spikes from bright stars, or are close ( $< 2''.0$ ) to the modeled and subtracted bCGs. As galaxies at high- $z$  are generally small, we will only use the total fluxes within a  $D = 0''.2$  aperture for the remainder of our work.

**Figure 1. High- $z$  color-color selection.** Our final high- $z$  sample, which we also present in Figure 2 is shown with red diamonds. The additional,  $\sim 4\sigma$  sources from our selection are shown with black open symbols. The color-color Lyman break selection is indicated with black dashed line. Solid lines show the tracks followed by starburst galaxies at  $z \sim 17$  (Chevallard & Charlot 2016) with varying levels of attenuation  $A_V = 0-0.5$  (shown with blue to green). We highlight low-redshift quiescent galaxies (Polletta et al. 2007), whose Balmer break could mimic the Lyman break at higher redshifts, as dashed lines. Extreme dusty starbursts (Naidu et al. 2022; Arrabal Haro et al. 2023; Zavala et al. 2023) at  $z \sim 4.5 - 5.5$  (orange squares) look quite similar to a high- $z$  galaxy with this selection alone (see Section 3.3 for why these are disfavored). Finally, cool stars and brown dwarfs (Chabrier et al. 2000; Allard et al. 2001) are shown in purple.

### 3. DATA ANALYSIS

Our goal is to find galaxies above  $z > 16$ . Previous experience has demonstrated that a single selection technique, however, is insufficient to provide robust  $z > 16$  candidates, and might result in low- $z$  contaminants (e.g. see Naidu et al. 2022). To mitigate that, we combine our selection to use the Lyman Break (Section 3.1) and photometric redshift test (Section 3.2) which stringently tests for low- $z$  contamination (Section 3.3) and uses the size estimates (Section 3.5) to further test their robustness.

#### 3.1. Lyman Break Selection

The first selection applied to the photometric catalog is based on identifying dropouts in the rest-frame UV, using the Lyman- $\alpha$  break technique. We define a selection window in color-color space to isolate dropouts

between the F277W and F200W filters, while simultaneously excluding objects with red continua in the rest-frame UV between the F277W and F356W filters. These color criteria are determined from running synthetic photometry on a set of galaxy templates generated using BEAGLE (Chevallard & Charlot 2016). We used starburst templates in the redshift range  $15 < z < 20$ , incorporating IGM attenuation following Inoue et al. (2014), with varying levels of attenuation between  $A_V = 0$  and  $A_V = 0.5$ , based on the SMC extinction law (Gordon et al. 2003). We also consider low-redshift quiescent galaxies that could mimic a Lyman break, using SEDs from the SWIRE template library (Polletta et al. 2007). In addition, we include cool stars and brown dwarfs, using stellar templates from Chabrier et al. (2000) and Allard et al. (2001). The color-color tracks for all these simulated sources are shown in Figure 1, along with the adopted selection window, which is defined by the following criteria:

$$\begin{aligned} M_{200} - M_{277} &> 1.0 \\ M_{200} - M_{277} &> 1.2 + 2.0(M_{277} - M_{356}) \\ M_{277} - M_{356} &< 0.5 \end{aligned}$$

In addition to the color criteria, we require that sources are well detected (at the  $> 3\sigma$  level in all three of the broad-band LW filters), and have a SNR of  $\gtrsim 4$  in at least one band, while remaining undetected (at the  $< 2\sigma$  level) in bands blueward of the Lyman break (F090W, F115W, and F150W). This first selection leads to a sample of  $\sim 40$   $z \gtrsim 16$  galaxy candidates.

#### 3.2. Photometric Redshift

To calculate photometric redshifts ( $z_{\text{phot}}$ ) for all objects in the GLIMPSE catalog, we use the PYTHON version of EAZY (Brammer et al. 2008). We choose the BLUE\_SFHZ\_13 model subset<sup>1</sup> that contains redshift-dependent SFHs, and dust attenuation values. More specifically, the linear combinations of log-normal SFHs included in the template set are not allowed to exceed redshifts that start earlier than the age of the Universe (for more detail see Blanton & Roweis 2007). These models are further complemented by a blue galaxy template, derived from a *JWST* spectrum of a  $z = 8.50$  galaxy with extreme line equivalent widths (Carnall et al. 2022).

Our work is concerned only with the F200W dropouts, for which the *HST* data are simply too shallow to be useful. Therefore, in our analysis we only focus on the

<sup>1</sup> <https://github.com/gbrammer/eazy-photoz/tree/master/templates/sfzh>

GLIMPSE *JWST* bands. We fit the aperture corrected  $D = 0''.2$  *JWST* flux densities, including the upper limits, using the  $0.01 < z < 30$  redshift grid. The uncertainties on the photometric redshifts are computed from the 16th and 84th percentiles of the redshift probability distributions -  $p(z)$ . The best-fit EAZY SEDs are only used to validate the color-color high- $z$  selection.

In order to select  $z > 16$  galaxy candidates with EAZY we then require that the sources must be detected ( $S/N > 3$ ) in at least 3 bands, similarly to our color-color selection, and have a well constrained  $p(z)$  ( $\text{FWHM} < 2.5$ ) without a prominent secondary redshift solution. Cross-referencing our EAZY high- $z$  sample with the color-color selected F200W dropout from Section 3.1 results in 15 candidates at  $z \simeq 15.5 - 19.2$ .

In addition to EAZY, we use BEAGLE (Chevallard & Charlot 2016) and the methods outlined in Endsley et al. (2024), to independently derive photometric redshifts. Briefly, we use the BEAGLE models constructed from updated Bruzual & Charlot (2003) stellar templates that use the PARSEC isochrones (Bressan et al. 2012; Chen et al. 2015). These models have been passed through CLOUDY (Ferland et al. 2017) to self-consistently produce nebular (both line and continuum) emission (Gutkin et al. 2016). We explore different parametric star formation histories (including constant, burst, and a two-component star formation history), stellar ages (between 1 Myr and 30 Gyr), metallicities ( $0.0063 - 0.5 Z_{\odot}$ ), and attenuation laws (we settle on the SMC law; Pei 1992). The two codes agree exceptionally well (Figure 2) on the high- $z$  solutions.

### 3.3. Low- $z$ Confusion

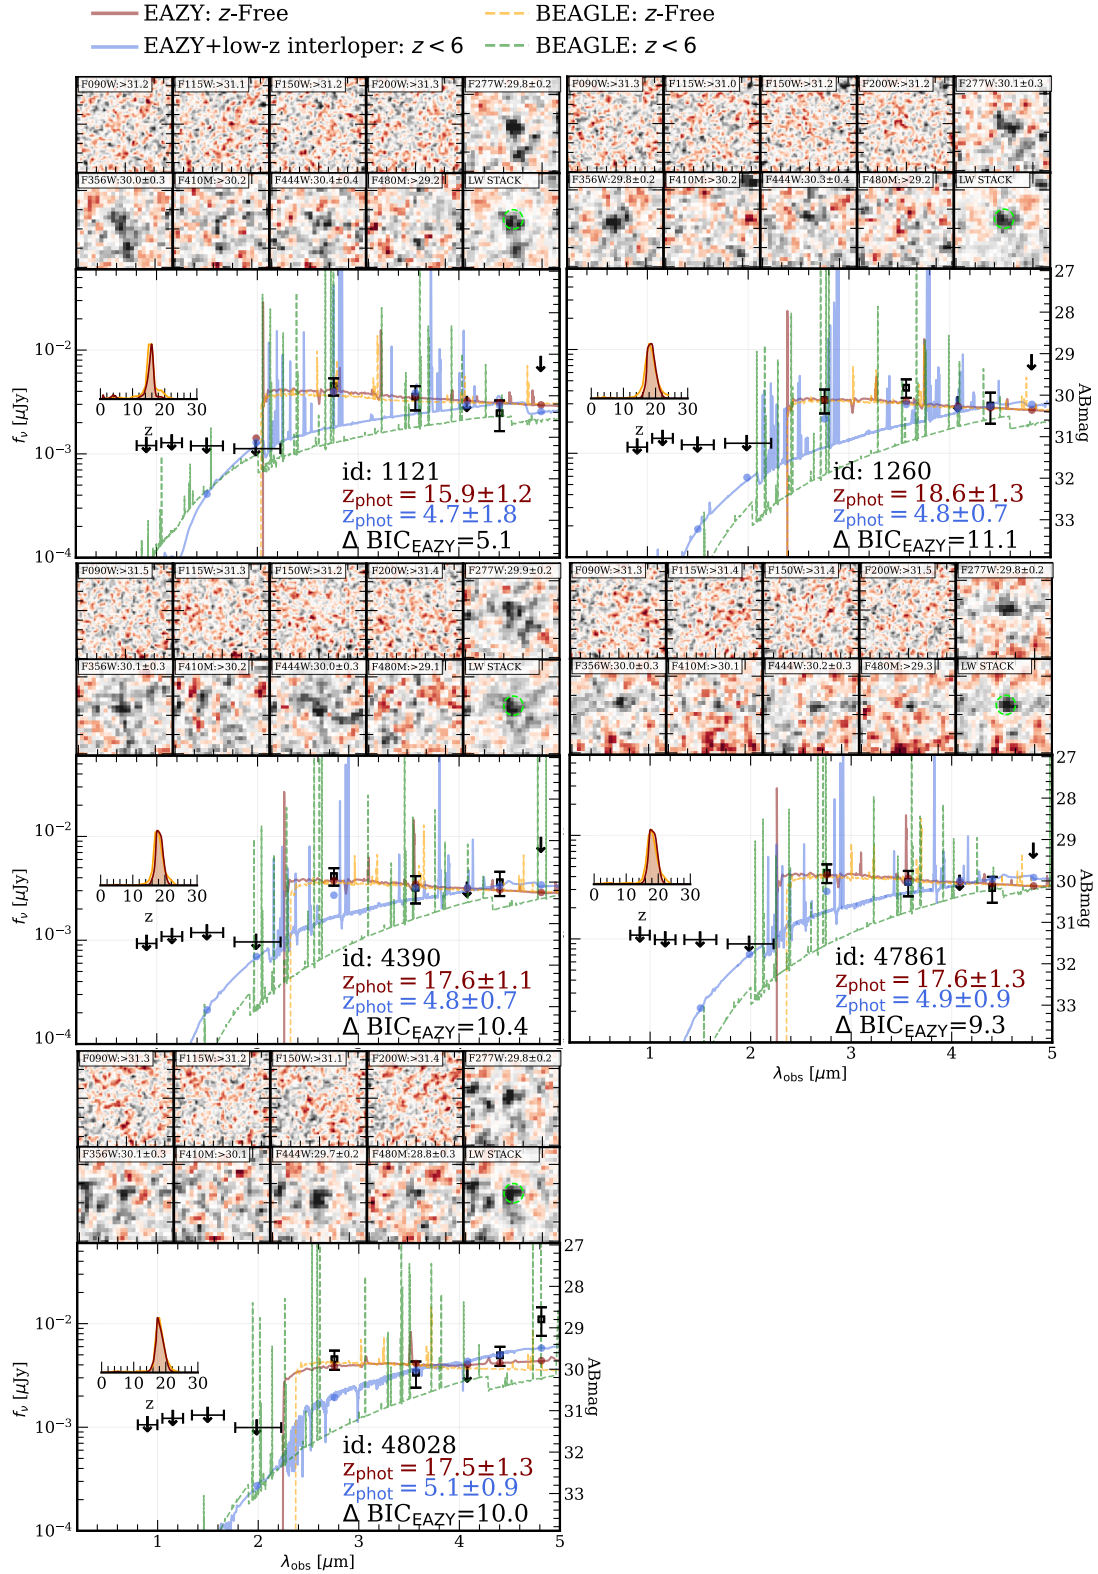

The early days of *JWST*, initial discoveries saw a slew of  $z > 16$  galaxy candidates, for which valid concerns have been raised in the literature regarding the ability of photometric redshifts to pick out true high- $z$  candidates (Arrabal Haro et al. 2023; Donnan et al. 2023; Zavala et al. 2023). These works have shown that dusty extremely star-forming galaxies at  $z \sim 5$  can masquerade as high- $z$  objects and bias our view of high-redshift galaxies. For example, the so-called ‘‘Schrödinger’’ galaxy was initially photometrically-identified at  $z > 16$  (Naidu et al. 2022; Donnan et al. 2023), and then had its redshift revised to a  $z \sim 5$ , via extreme emission lines found in NIRSPEC spectra, as an interloper (Arrabal Haro et al. 2023; Zavala et al. 2023). Despite this misidentification, these outliers provide invaluable insight into the potential pitfalls of our methodology. Subsequently, identification methodologies have been improved, and the techniques used to process (e.g. various pipeline improvements and calibrations) and analyze

*JWST* data have significantly matured, such that the vast majority of  $\sim 95$  photometrically-identified  $z > 10$  galaxies have been spectroscopically confirmed at high-redshift (Arrabal Haro et al. 2023; Hainline et al. 2024; Harikane et al. 2024). At this moment, these initial misidentifications provide a road map to rigorously scrutinize the  $z > 16$  candidates, however at the moment no galaxies with  $z > 14$  have been confirmed spectroscopically.

To address the potential contamination from low- $z$  interlopers, we re-fit all of our 15 high- $z$  candidates with the EAZY BLUE\_SFHZ\_13 model suite, plus an additional dusty starburst template (Naidu et al. 2022; Arrabal Haro et al. 2023), to mimic the low- $z$  interlopers. The redshift grid in this case is forced to be  $z < 6$ , to match the redshift range of dusty interlopers. Deciding which model is better relies on the Bayesian Information Criterion (BIC) test (Schwarz 1978). This test computes which template is the most likely fit to the observed data, while penalizing models that have too many free parameters. In our case a high- $z$  fit is statistically preferred over forced low- $z$  ( $z < 6$ ) solutions with the additional ‘‘Schrödinger’’ template, when a BIC difference reaches 5 or more (using the criteria defined in Jeffreys 1961). We find that almost half - 7/15 - of our high- $z$  objects can be fit equally well with a low- $z$  dusty starburst template ( $\Delta\text{BIC} < 5$ ). These galaxies are removed from our final sample, leaving us with 8  $z \sim 17$  galaxy candidates. While these are robustly detected ( $\sim 3\sigma$ ) in 3 bands, we further limit our final sample to only include galaxy candidates that reach at least  $5\sigma$  in one or more bands. This is done to ensure that only the best high- $z$  candidates end up in our final sample. This leaves us with 5 objects which we show in Figure 2. We show SEDs of the remaining 3/8 objects with peak  $\text{SNR} > 4$  in the Appendix A. We also would like to note that the morphology of our objects (Figure 2), does not change from band-to-band when moving to redder filters, as it would for dusty galaxies.

### 3.4. Gravitational Magnification

To take into account the effects from gravitational lensing we use a new strong lensing (SL) model of AS1063 constructed for GLIMPSE with the updated version of the Zitrin et al. (2015) parametric method that was recently used for several *JWST* SL clusters (e.g. Pascale et al. 2022; Furtak et al. 2023; Meena et al. 2023). We model the cluster with two smooth dark matter (DM) halos parametrized as pseudo-isothermal elliptical mass distributions (PIEMDs; Kassiola & Kovner 1993): one centered on the bCG, and the other on a group of galaxies in the north-east of the cluster (e.g.

**Figure 2.** Most secure  $z \gtrsim 16$  candidates from GLIMPSE. For each source we show 1'' cutouts in all broad and medium band NIRC2 filters, a detection (F277W+F356W+F444W) LW stack with a D=0''.2 aperture (green) overlaid. On the SED plot, we show the best fit high-z vs low-z EAZY models (maroon and blue), as well as the same for BEAGLE (dashed orange and green). The colored circles represent the integrated flux density for each solution. We explicitly highlight the difference between a low-z interloper and high-z EAZY solution with a  $\Delta\text{BIC}_{\text{EAZY}}$  statistic on each panel, as discussed in Section 3.3. In the inset panel we show the  $p(z)$  for both EAZY and BEAGLE fits with a free redshift solution. Detections are shown as black squares,  $3\sigma$  upper limits are shown as downward arrows.

Bergamini et al. 2019; Beauchesne et al. 2024). In addition, we model 303 cluster member galaxies as dual pseudo-isothermal ellipsoids (Elíasdóttir et al. 2007). The model is constrained with 75 multiple images of 28 sources, 24 of which have spectroscopic redshifts (Balestra et al. 2013; Monna et al. 2014; Richard et al. 2021; Beauchesne et al. 2024; Topping et al. 2024). The model achieves an average image reproduction error of  $\Delta_{\text{RMS}} = 0.54''$ . We refer the reader to Furtak et al. (in prep.) for more details on the lens model. A previous (*HST*-based) version of this model was recently used in Topping et al. (2024).

Magnifications are computed analytically at the position of each galaxy candidate and adopting its photometric redshift. The magnifications and their uncertainties are listed in Table 1.

### 3.5. Size Measurements

The cutouts we show in Figure 2 imply that our sources are quite compact, yet appear to be resolved. To measure the effective radii we model each source with GALFIT (Peng et al. 2002, 2010), using a Sérsic (Sérsic 1963) profile where the source position, brightness, effective radius, Sérsic index, and axis ratio are allowed to vary. When fitting, we take into account the effects of the PSF, which we measure empirically from the bright stars in the field. We perform this procedure on our brightest band - F277W, to ensure optimal S/N per pixel is achieved to accommodate robust size measurements. We find that the on-the-sky sizes of our sources, range from  $R_{\text{eff}} \sim 0''.10 - 0''.24$ . A source can be considered to be resolved when its effective radius is larger than the empirical PSF half-width at half maximum (HWHM). Since the HWHM of F277W PSF is  $\sim 0''.046$ , we can consider all our sources to be resolved.

Taking the redshift and gravitational magnification into account, we convert our angular sizes to physical effective radii. These range from  $R_{\text{eff}} = 250 - 550$  pc. We list the de-lensed sizes in Table 1.

## 4. RESULTS

### 4.1. Stellar Population Properties

After completing the multiple stages of selecting our final  $z > 16$  sample, we now compute a range of relevant physical parameters. The uniqueness of our sample lies in the unprecedented depth of the GLIMPSE observations, which we further push to their limit with gravitational lensing in order to obtain these candidates. On average, our sources have 3 individual band detections, with the rest of the *JWST* photometry being upper limits. While this is perfectly adequate to constrain the redshift, deriving any physical parameters, especially stellar

mass, from SED fitting codes would be simply unreasonable. As such, we will only focus on the observable stellar population parameters that can be derived from the rest-UV photometry alone.

We estimate the absolute UV magnitude for each galaxy from the observed F277W band, which samples  $\lambda_{\text{rest}} \sim 1500 \text{ \AA}$  at this redshift. We find that our targets cover a very narrow range of derived  $M_{\text{UV}} = -17.91_{-0.10}^{+0.21}$ , after accounting for lensing magnification. We derive the UV-slope  $\beta$  for each object by assuming  $f_{\lambda} \sim \lambda^{\beta}$ , and fitting it to all the photometric points that fall within the  $\lambda_{\text{rest}}$  in 1260 – 2500  $\text{\AA}$  range, which effectively traces the observed F277W-F356W color. We find that our  $\beta$  values span a range from  $-3.0$  to  $-2.3$ , with a median of  $-2.81 \pm 0.16$ . We also show this distribution in Figure 3. Finally, we derive the  $\text{SFR}_{\text{UV}}$  directly from our de-lensed  $M_{\text{UV}}$ , by following the relation from (Kennicutt & Evans 2012). We find that the  $\text{SFR}_{\text{UV}}$  ranges from 0.7 to 1.0  $M_{\odot} \text{ yr}^{-1}$ . Since our derived  $\beta$  values imply negligible dust reddening, we do not apply a correction for dust when deriving the SFR. All the de-lensed physical parameters are listed in Table 1.

### 4.2. Number Density

We compute the number density of  $16 < z < 20$  sources in GLIMPSE by utilizing a  $1/V_{\text{max}}$  method (Schmidt 1968), where  $V_{\text{max}}$  corresponds to the maximum volume a galaxy could occupy and still be detected in the appropriate filter for our redshift range. Due to lensing, the effective area, and therefore volume, covered by our observations, is smaller than it would be in a blank field. In addition, an accurate derivation of the UV number density requires a robust estimate of the completeness of our survey, for a given selection function and depth. To account for the former, we use our magnification maps and together with the  $p(z)$  for our sources (to account for the redshift range), we derive a total survey volume of  $17055 \pm 71 \text{ Mpc}^3$ .

The second step to derive the effective volume consists of computing the survey completeness through the lensing cluster. To do that, we use the same approach adopted in Atek et al. (2018) and Chemerynska et al. (2024). Briefly, the procedure includes generating a large set of mock galaxies that are distributed directly in the source plane, which in turn was generated from our lensing model. The properties of the simulated objects span the redshift, size and luminosity range of our objects. More details regarding this procedure will be presented in Chemerynska et al. in prep. Combining this with our derived volume, we find an effective survey volume  $V_{\text{max}} = 13714 \pm 1784 \text{ Mpc}^3$ .

<sup>1</sup>  $\text{BIC}(\text{low-}z) - \text{BIC}(\text{high-}z)$ .

**Figure 3. UV continuum slope and de-lensed luminosity.** The black dashed line shows the best fitting  $\beta$ - $M_{\text{UV}}$  relation from Cullen et al. (2023) for SFGs at  $z = 8 - 16$ . Grey shaded area corresponds to the 68 % confidence interval. Our secure ( $> 5\sigma$ ) sources at  $z \sim 17$ , shown with red diamonds, appear to be consistent with the predicted trend within 1-sigma, although systematically shifted to bluer slopes. We show the tentative ( $\sim 4\sigma$ )  $z > 16$  galaxy candidates with open symbols.

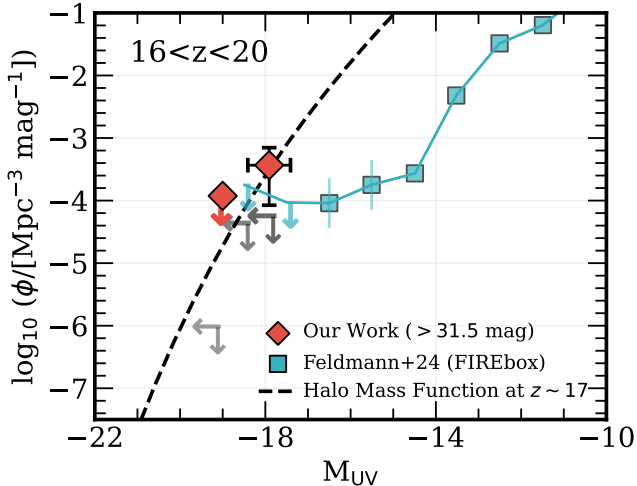

All of our objects cover nearly the same range of  $M_{\text{UV}}$ , so to derive the final number density we will just assume a single bin with a width of 1 magnitude –  $M_{\text{UV}} = -18.0 \pm 0.5$ . The final number density for our sample in the  $16 < z < 20$  range is therefore equal to  $\log_{10}(\phi/[\text{Mpc}^{-3} \text{ mag}^{-1}]) = -3.43^{+0.28}_{-0.64}$ .

## 5. DISCUSSION

**Figure 4. Theoretical comoving number densities of  $z > 16$  galaxies in the literature.** Our completeness-corrected densities are shown in red. Black lines are median values, shaded areas show 68 % percentiles. Values have been homogenized in terms of redshift interval ( $16 < z < 20$ ) and de-lensed. While high, our predictions generally align with the upper edge of the theoretical predictions (Mason et al. 2015; Dayal et al. 2014; Behroozi et al. 2019; Muñoz et al. 2023; Wilkins et al. 2023; Feldmann et al. 2024; Li et al. 2024).

### 5.1. Stellar Populations at High Redshift

**Figure 5.** Observed abundance of bright galaxies at  $z > 16$ . We report the approximate magnitude limits for a number of deep extragalactic surveys corresponding to the  $2\sigma$  depth of the dropout filter - F200W, which is required for the Lyman break identification. In varying shades of gray, we show CEERS (Bagley et al. 2023; Finkelstein et al. 2023) and PRIMER (both COSMOS and UDS Donnan et al. 2023) combined, JADES (Origins Field, Eisenstein et al. 2023) and NGDEEP (Leung et al. 2023; Bagley et al. 2024). The dashed line is a scaled version of the Halo Mass Function that assumes a 30% star formation efficiency of the gas, no dust, and a continuous star formation history. The dashed line is simply a toy model to illustrate how the UVLF at these redshifts could steeply decline.

In this section, we reflect on the implications of our derived parameters if the selected sample truly resides at  $z \sim 17$ .

First, we compare our calculated  $R_{\text{eff}}$  with empirical results for spectroscopically confirmed galaxies at  $z \sim 13 - 14$ . Both Carniani et al. (2024a) and Curtis-Lake et al. (2023) report UV sizes in the range of  $\sim 100 - 300$  pc, consistent with our findings. While high-redshift size predictions from simulations are limited, the TNG50 simulations have accurately reproduced galaxy morphologies across a wide redshift range (e.g., see Tacchella et al. 2019). The latest high- $z$  size evolution analyses in Costantin et al. (2023) and Morishita & Stiavelli (2023) suggests a scaling relation of  $\sim 8.66 \times (1+z)^{-1.15}$  kpc. Extrapolating this to  $z \sim 17$  predicts  $R_{\text{eff}} \sim 300$  pc, aligning with our measurements within  $1\sigma$ . Generally, the relatively large sizes of our objects may indicate that UV light from these galaxies arises from extended stellar populations, as observed in Carniani et al. (2024a). Furthermore, the spatially resolved nature of our sources, combined with an absence of a PSF-like, centrally concentrated component,

**Figure 6.** The abundance of bright sources at cosmic dawn. We trace the possible evolutionary paths of our objects from  $z \sim 17$  to some of the brightest spectroscopically confirmed high- $z$  objects at  $z \simeq 11-14$  (Arrabal Haro et al. 2023; Bunker et al. 2023; Curtis-Lake et al. 2023; Carniani et al. 2024a; Castellano et al. 2024). Shown are the tracks of constant star-formation at  $1 M_{\odot}/\text{yr}$  (purple), and a  $\Lambda\text{CDM}$ -limited maximal possible accretion scenario (pink line and black shaded region, Dekel & Krumholz 2013), where all gas is converted to stars. The overabundance of bright galaxies observed at high- $z$  so far is fully consistent with our observations. We only show the  $M_{\text{UV}}$  uncertainties that are larger than the marker size.

suggests that the UV emission is not dominated by unobscured AGN, unlike other high- $z$  galaxies (Maiolino et al. 2023; Harikane et al. 2023).

Using our derived  $\text{SFR}_{\text{UV}}$  and  $R_{\text{eff}}$ , we calculate the UV-based star formation rate surface density, finding a median value of  $\Sigma_{\text{SFR,UV}} = 0.93_{-0.66}^{+0.92} M_{\odot} \text{ yr}^{-1} \text{ kpc}^{-2}$ . This is 5 – 10 times lower than values reported for spectroscopically confirmed objects at  $z \sim 14$  by Carniani et al. (2024a) and is similarly lower when extrapolating the trend in Calabrò et al. (2024). However, higher  $\Sigma_{\text{SFR,UV}}$  found at  $z < 15$  likely reflect observational biases and small number statistics at high- $z$ , with the bulk of the population likely containing less intense star-formation. Moreover, if the accretion rate changes exponentially with redshift for galaxies such as ours, even small changes in redshift will likely lead to significantly more accretion. We will explore this further in Section 5.3.

The UV slopes in our sample also do not exhibit unusual characteristics. We find a median  $\beta$  of  $-2.81$ , consistent with a largely dust-free stellar plus nebular con-

tinuum. This is reasonable, as our objects are observed just  $\sim 200$  Myr post-Big Bang, with limited time for substantial dust production. Within the uncertainties of our  $\beta$  values, our sources align with the  $\beta$ - $M_{\text{UV}}$  luminosity relation from the surveys used in Cullen et al. (2023), which are based on recent *JWST* data for  $z = 8 - 16$  star-forming galaxies. Finally, we do not observe extremely negative beta slopes that have been postulated for metal-free Population III stars (e.g. see Jaacks et al. 2018).

### 5.2. Where are the Bright High- $z$ Galaxies?

The GLIMPSE imaging data are contained within a single NIRCcam pointing, with the effective area further limited by lensing effects. Despite the relatively small volume surveyed, we identify 5 robust high- $z$  candidates, all exhibiting characteristics consistent with a star-forming population at this epoch. We now discuss the number density derived from our sample, comparing it with theoretical predictions from both pre- and post-*JWST* launch models (see Figure 4).

Regardless of the simulation type—whether semi-analytic (Dayal et al. 2014; Mason et al. 2015; Behroozi et al. 2019) or hydrodynamical (Rosdahl et al. 2022; Wilkins et al. 2023)—we find that our derived number density at  $16 < z < 20$  at  $M_{\text{UV}} = -18.0 \pm 0.5$  significantly exceeds the pre-*JWST* theoretical expectations, with a discrepancy of over  $3 - 5\sigma$ . This mirrors an observed discrepancy in the UVLF suggested by spectroscopically confirmed  $z \sim 12 - 14$  objects (Donnan et al. 2023; Finkelstein et al. 2023; Casey et al. 2024; Carniani et al. 2024a; Chemerynska et al. 2024; Harikane et al. 2024; Robertson et al. 2024). In contrast, post-*JWST* calibrated simulations, including semi-analytic models (Muñoz et al. 2023), analytic predictions that include the feedback-free burst scenario (Li et al. 2024), and FIREbox hydrodynamical simulations (Feldmann et al. 2024), show better, generally within  $1 - 2\sigma$ , agreement.

We find the best agreement with the FIREbox simulations presented in Feldmann et al. (2024). This might suggest that the abundance of UV-luminous galaxies at  $z \gtrsim 11$  (Arrabal Haro et al. 2023; Maiolino et al. 2023; Curtis-Lake et al. 2023; Castellano et al. 2024; Carniani et al. 2024a) could be due to a relatively constant star-formation efficiency (SFE) that is largely independent of  $M_{\text{halo}}$  (Chemerynska in prep.). We will explore the connection of our sample to these lower- $z$  UV-bright galaxies in the next section. Encouragingly, our sample, while showing somewhat higher number densities at this absolute magnitude, remains broadly consistent with many post-*JWST* theoretical predictions.

Over the past two years, *JWST* has identified dozens of bright  $M_{\text{UV}} < -18$  high- $z$  galaxy candidates at  $z = 10 - 14$ , challenging pre-*JWST* expectations (Adams et al. 2023; Austin et al. 2023; Atek et al. 2023; Curtis-Lake et al. 2023; Donnan et al. 2023; Finkelstein et al. 2023; Castellano et al. 2024; Carniani et al. 2024a; Robertson et al. 2024; Chemerynska et al. 2024; McLeod et al. 2024; Leung et al. 2023; Pérez-González et al. 2023). Surprisingly, despite the large areas and depths of various surveys, none have detected bright galaxies beyond  $z > 16$ . Given the detection limits of  $\sim 30 - 30.5$  mag in the F200W/F277W filters (used for Lyman break dropout selection at  $z > 15$ ), bright galaxies with  $M_{\text{UV}} < -19$  would likely have been identified by these surveys if they indeed existed at these redshifts. Selecting these galaxies at  $z > 16$  requires deep F200W (drop-out band) and F277W photometry, as the break has to be unambiguous ( $> 1$  mag). To compute the expected number densities from various extragalactic surveys, based on non-detections (Gehrels 1986) we do the following. Using the quoted F200W  $2\sigma$  depths for CEERS (Bagley et al. 2023; Finkelstein et al. 2023), PRIMER (both COSMOS and UDS), JADES Origins Field (Eisenstein et al. 2023; Robertson et al. 2024), and NGDEEP (Leung et al. 2023; Bagley et al. 2024), we assume  $M_{200} - M_{277} \geq 1$  mag and then compute the expected  $M_{\text{UV}}$  and the corresponding number density (from  $V_{\text{max}}$ ) for each survey using the reported survey area. These are shown in Figure 5 as gray upper limits, alongside the GLIMPSE number density at  $M_{\text{UV}} = -18$  and an upper limit at  $M_{\text{UV}} = -19$ . The discrepancy between the limits at  $M_{\text{UV}} < -19$  and our observed number densities at  $M_{\text{UV}} = -18$  is quite jarring. The upper limits reach  $\sim 10^{-6} \text{ Mpc}^{-3} \text{ mag}^{-1}$  (for CEERS plus PRIMER) at  $M_{\text{UV}} \sim -19$ , in a stark contrast to GLIMPSE where we predict there are  $\gtrsim 2000\times$  more galaxies per volume at  $M_{\text{UV}} = -18$ . If  $M_{\text{UV}} < -18$  galaxies existed at this epoch, they surely should have been detected by now.

So where are they? One possibility is that because of cosmic variance, the current deep fields have missed some of the bright  $z > 15$  galaxies. After all, the depths of GLIMPSE are comparable to JADES and NGDEEP, as such we would expect these surveys to find a  $z > 15$  source. In this scenario, wider-field surveys that reach  $M_{\text{UV}} \sim -20$  mag would discover bright  $z > 15$  galaxies. For instance, objects brighter than  $M_{\text{UV}} \sim -18$  are too rare to appear in the FIREbox simulated volume at this redshift (see Figure 5).

Furthermore, this difference can be potentially due to the bright end of the UVLF at  $z > 16$  lying exactly at the GLIMPSE detection limit of  $M_{\text{UV}} \sim -18$ , explain-

ing why we are seeing these objects for the first time (though see a candidate in NGDEEP found by both [Leung et al. \(2023\)](#) and [Austin et al. \(2023\)](#) at  $z_{\text{phot}} \sim 15.6$ , with  $M_{\text{UV}}$  of  $\sim -19.2$ , which implies a  $\log_{10}(\phi/[\text{Mpc}^{-3} \text{mag}^{-1}]) \sim -4.65$ ). The steepness of the UVLF implied by the GLIMPSE detections against the brighter limits can be fit if the UVLF closely tracks the halo mass function, as we show in [Figure 5](#) (translating halo mass to SFR with a toy model given by the cosmic baryon fraction, zero dust, and 30% efficiency of gas into stars over a fixed 100 Myr timescale). We note that the most plausible way to reproduce the observed number density is with a constant and relatively high SFE.

The lensing magnification present in AS1063, as opposed to deep blank fields such as JADES and NGDEEP, could also play a role in this discrepancy. We speculate that even the modest lensing magnification of  $\mu \sim 1.5$ , which will double the exposure time on source (adding  $\sim 0.5$  mag in depth), will provide the additional sensitivity needed to uncover these early galaxies. There simply was no feasible way to see these relatively rare objects prior to GLIMPSE.

### 5.3. Abundance of Bright Galaxies at $z \sim 12 - 14$

Our observations indicate that one possible explanation for the lack of  $M_{\text{UV}} < -19$  galaxies at  $z \sim 17$  is that brighter galaxies are extremely rare at high- $z$ , so only “faint” galaxies would be abundant enough to be found in the volume probed so far at this epoch. Therefore one can imagine that the over-abundance of bright galaxies observed at  $z = 12-14$  have likely evolved from earlier (fainter) galaxies, such as the ones presented here, that are surprisingly abundant for their relatively faint UV luminosities. In return, this suggests that the discrepancy between theoretical predictions and observations may begin as early as  $z = 18$ , potentially during the epoch when the first galaxies formed.

To test that, we would like to see how different SFHs starting at  $z \sim 17$  reproduce the observed bright galaxies at  $z < 14$ . To do this we consider two cases. First, we consider a constant SFH which begins forming stars at the median redshift of our sample ( $z \sim 17.6$ ) at a rate of  $\sim 1 M_{\odot} \text{yr}^{-1}$  (to match our derived SFRs). As the second case, we would consider the maximum growth rate allowable for these galaxies by forming stars at 100% of the accretion rate set by the Extended Press-Schechter approximation in a  $\Lambda$ CDM Universe (e.g., see eq. 7 in [Dekel & Krumholz 2013](#), with a 0.3 dex scatter as in [Ren et al. 2018](#) and [Mirocha et al. 2021](#)). This in turn creates an exponentially increasing star formation history that puts a maximum limit on the luminosity growth experienced by these galaxies observed at these redshifts.

Since we want to show the absolute limit possible, given our observations, we start to evolve this SFH at the maximum redshift of our sample -  $z = 18.6$ , instead of the median. Both scenarios begin at  $M_{\text{UV}} \sim -18$ . To evolve these SFHs we have used the toolkit within BAGPIPES ([Carnall et al. 2019](#)), which outputs  $M_{\text{UV}}$  in a pre-defined grid of lookback-time. We show the results of our modeling, alongside the bright spectroscopically confirmed galaxies in [Figure 6](#).

We find that if our galaxies followed a constant SFH and continued forming stars at their current rate, they can easily reproduce the objects observed in [Curtis-Lake et al. \(2023\)](#) and the fainter one of the two galaxies presented in [Carniani et al. \(2024a\)](#). Reproducing some of the brightest ( $M_{\text{UV}} < -20$ ) known galaxies at  $z \geq 10$  would, however, require very (nearly 100%) efficient star-formation episodes. Following the maximal exponential accretion scenario, we find that galaxies in our sample can, in fact, become as bright as JADES-GS-z14-0 ( $M_{\text{UV}} = -20.81$  at  $z = 14.17933$ ; [Carniani et al. 2024a,b](#); [Schouws et al. 2024](#)), or GNz11 (although the stellar contribution to the  $M_{\text{UV}}$  could be lower, due to the potential AGN; [Oesch et al. 2016](#); [Bunker et al. 2023](#); [Maiolino et al. 2023](#)), without a need to invoke any exotic cosmological framework. Curiously, the SFH for JADES-GS-z14-0 presented in [Carniani et al.](#) predicts  $\text{SFR} \sim 1 M_{\odot} \text{yr}^{-1}$  at  $z \sim 17 - 18$ , which matches our sample if it were a potential progenitor. This further reemphasizes that these  $z \sim 17$  candidates could plausibly grow to become the extremely bright  $z \sim 14$  galaxies without extraordinarily new cosmologies.

## 6. CONCLUSIONS

In this study, we leverage ultra-deep GLIMPSE NIR-Cam imaging covering the AS1063 lensing cluster to identify a unique sample of high-redshift ( $z > 16$ ) galaxy candidates. Using a combination of observed colors alongside an extensive suite of SED modeling routines, we select five robust candidates at  $z \simeq 15.9 - 18.6$ , which all fit into our single NIRCcam pointing.

We examine the stellar population properties of our sample, such as their delensed, absolute UV-brightness,  $\beta$  slopes and sizes, finding that these high- $z$  galaxies fit very well into the picture of galaxy evolution being established at  $z \sim 10 - 14$ . Crucially, our findings reveal a significant excess in number density of galaxies at  $M_{\text{UV}} = -18$  of  $\log_{10}(\phi/[\text{Mpc}^{-3} \text{mag}^{-1}]) = -3.43^{+0.28}_{-0.64}$ , compared to theoretical predictions from both semi-analytic and hydrodynamical simulations calibrated before the *JWST* launch, mirroring similar discussions for bright galaxies at lower  $z \sim 10 - 14$  (e.g. see [Oesch et al.](#)

2016; Carniani et al. 2024a; Finkelstein et al. 2023; Arrabal Haro et al. 2023).

Surprisingly, none of the current extragalactic *JWST* surveys have managed to successfully identify brighter objects beyond  $z > 16$ . No bright ( $M_{UV} < -19$ ) galaxy candidates have been identified by substantially larger areas covered by CEERS and PRIMER (Bagley et al. 2023; Finkelstein et al. 2023; Donnan et al. 2023). The same is the case for moderately large and deep observations from JADES (Eisenstein et al. 2023) and NGDEEP (Leung et al. 2023; Bagley et al. 2024). What our observations seem to indicate is that this dearth of bright galaxies at high- $z$  is driven by the shape of the UVLF itself, which can be accommodated by very efficient star formation on top of the steep halo mass function, requiring significantly fainter intrinsic observations to discover  $z > 16$  galaxies in reasonable volumes. It is unsurprising, therefore, that the unique sensitivity of GLIMPSE – achieved through a combination of lensing magnification and ultra-deep imaging – has managed to potentially reveal some of the earliest galaxies in the Universe.

Finally, by evaluating various star-formation scenarios, we demonstrate that  $M_{UV} \sim -18$  galaxies at  $z \sim 17$  can easily grow into the observed UV-bright galaxies seen by *JWST* at  $z \sim 10 - 14$ , without violating the standard cosmological framework. The extreme SFE, coupled with a steep HMF are both sufficient to explain the observed trends. This connection further emphasizes the idea that faint, yet numerous, high- $z$  galaxies play a crucial role in the stellar mass assembly of galaxies in the early Universe.

## ACKNOWLEDGMENTS

We thank Steven Finkelstein and Volker Bromm for helpful discussions which helped improve the quality of this manuscript. VK acknowledges support from the University of Texas at Austin Cosmic Frontier Center. HA and IC acknowledge support from CNES, focused on the *JWST* mission, and the Programme National Cosmology and Galaxies (PNCG) of CNRS/INSU with INP and IN2P3, co-funded by CEA and CNES. The BGU lensing group acknowledges support by grant No. 2020750 from the United States-Israel Binational Science Foundation (BSF) and grant No. 2109066 from the United States National Science Foundation (NSF), and by the Israel Science Foundation Grant No. 864/23. JBM acknowledges support through NSF Grants AST-2307354 and AST-2408637. ASL acknowledges support from Knut and Alice Wallenberg Foundation. AA acknowledges support by the Swedish research council Vetenskapsradet (2021-05559). This work has received funding from the Swiss State Secretariat for Education, Research and Innovation (SERI) under contract number MB22.00072, as well as from the Swiss National Science Foundation (SNSF) through project grant 200020\_207349. This work is based on observations made with the NASA/ESA/CSA *James Webb Space Telescope*. The data were obtained from the Mikulski Archive for Space Telescopes at the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-03127 for *JWST*. Some of the data products presented herein were retrieved from the Dawn *JWST* Archive (DJA). DJA is an initiative of the Cosmic Dawn Center, which is funded by the Danish National Research Foundation under grant No. 140.

*Software:* BAGPIPES (Carnall et al. 2019), BEAGLE (Chevallard & Charlot 2016), EAZY (Brammer et al. 2008), GALFIT (Peng et al. 2002), grizli (Brammer 2023), sep (Barbary 2016), SExtractor (Bertin & Arnouts 1996)

*Facilities:* *JWST*, *HST*

## APPENDIX

A. REMAINING HIGH- $Z$  CANDIDATES

In this section, we show an additional three  $z > 16$  candidates which did not end up in our final sample due to not having at least one  $\text{SN} > 5$  detection. We show these objects in Figure 7.

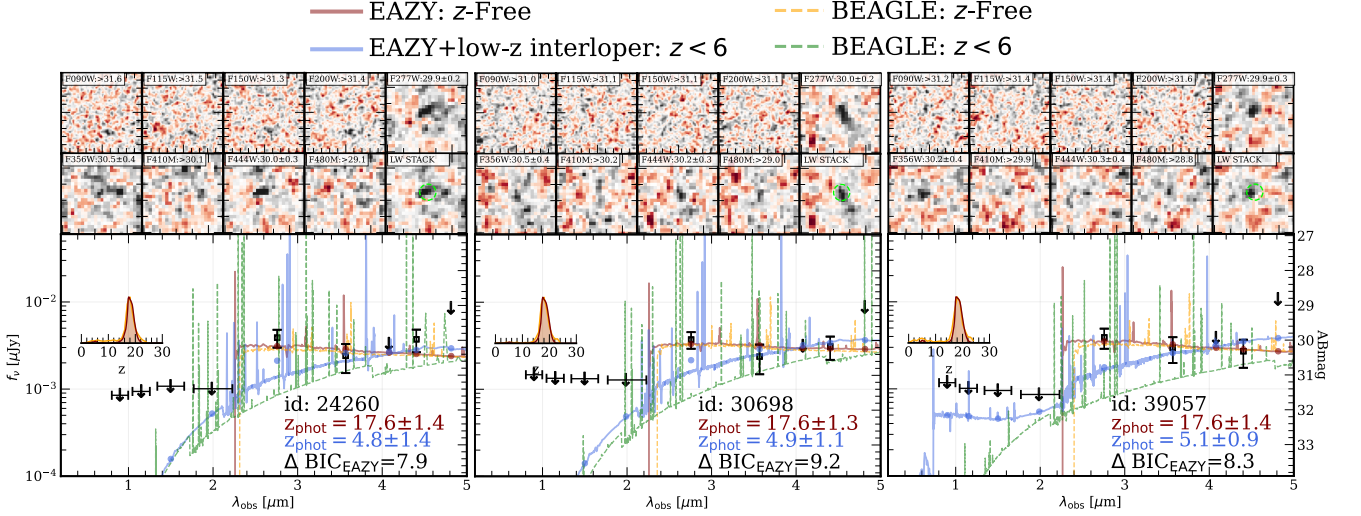

Figure 7. Additional  $z \gtrsim 16$  candidates from GLIMPSE. Colors and symbols are the same as in Figure 2.
