## 11 **Highlight**

12 In a durum wheat mixture, increased susceptibility to *Septoria tritici* blotch is linked to  
13 delayed defense response induction, likely triggered by early root competition resulting  
14 from contrasting root architectures. This reveals a novel root-mediated mechanism by  
15 which plant-plant interactions modulate susceptibility to aerial pathogens.

16

## 17 **Abstract**

18 The interactions between co-cultivated plant cultivars are increasingly recognized as  
19 influencing their susceptibility to pathogens in mixtures. However, the underlying  
20 mechanisms remain largely unexplored. Using a model of durum wheat cultivar  
21 mixtures where susceptibility to *Septoria* foliar disease is increased, we combined aerial  
22 and root phenotyping with transcriptional analyses and untargeted metabolomics to  
23 elucidate the potential signaling cascade driving this modulation of susceptibility. We  
24 observed contrasting root architectures between cultivars in mixture. Molecular analysis  
25 showed a delayed induction of defense-related genes and metabolites following  
26 pathogen inoculation in plants grown in mixture compared to pure stand. The findings  
27 suggest that root architecture potentially triggers a competitive response that could  
28 delay the induction of defense responses following pathogen inoculation. Altogether,  
29 these results point to a possible interplay between root architecture, resource  
30 competition, plant metabolism, and defense modulation in shaping plant-pathogen  
31 interactions within varietal mixtures.

3 interactions, belowground processes, resource competition, defense delay

## 5 **Introduction**

6  
7 Due to their recognized ecological and agronomic benefits, cultivar mixtures are  
8 increasingly practiced, for instance in France with 18.1% of bread wheat and 6.7% of  
9 durum wheat areas sown with cultivar mixtures in 2023–2024 (Arvalis). In particular,  
10 varietal mixtures allow more durable and efficient resistance against disease epidemics.  
11 However, while most intraspecific mixtures reduce disease severity, a significant  
12 proportion of varietal mixtures (about 18%) can instead increase susceptibility to  
13 *Zymoseptoria tritici*, the fungal pathogen responsible for Septoria tritici blotch (STB)  
14 (Kristoffersen *et al.*, 2022). Importantly, genetic interactions between the two cultivars  
15 can mediate the loss of mixture benefits (Montazeaud *et al.*, 2022). Likewise in  
16 controlled culture conditions, plant-plant interactions can positively or negatively  
17 influence plant health, particularly by modulating susceptibility to pathogens, a  
18 phenomenon known as Neighbor-Modulated Susceptibility (NMS) (Pélissier *et al.*, 2021;  
19 Mathieu *et al.*, 2025b). Hence, cultivar mixture is a promising tool to control epidemics,  
20 but plant-plant interactions can revert the services provided by intraspecific diversity.  
21 Therefore, understanding the encoded mechanisms driving such detrimental  
22 interactions is essential to identify and counter-select unfavorable combinations when  
23 designing mixtures. The durum wheat mixture of two French varieties, Cultur and  
24 Atoudur, provides a relevant model system for this purpose. In this mixture, the  
25 presence of Atoudur increases the susceptibility of Cultur to STB in comparison to pure  
26 culture (Pélissier *et al.*, 2021), but the mechanisms underlying this effect remain  
27 unknown.

28  
29 Plant-plant interactions can be envisioned as a two-step process: first, plants exchange  
30 signals, through the soil or air; second, these signals trigger morphological and/or  
31 physiological responses in the plant under consideration (later called focal plant).

32 Regarding signaling, direct plant-plant interactions can be mediated by molecular cues  
33 or access to resources (Mathieu *et al.*, 2025a). A previous study on the Cultur-Atoudur  
34 mixture demonstrated that the introduction of a physical barrier between root genotypes  
35 disrupted the modulation of susceptibility to leaf rust (Pélissier *et al.*, 2021). This  
36 indicated the involvement of belowground interaction, though the underlying mechanism

1 remains unknown. Belowground direct plant-plant interactions are often related to root  
2 exudates (Mathieu *et al.*, 2024a) and/or nutrient availability (Craine and Dybzinski,  
3 2013). However, the belowground signals by which plants influence one another,  
4 especially within varietal mixtures, are still poorly understood. In the case of the Cultur-  
5 Atoudur mixture, further investigation is needed to elucidate whether changes in  
6 disease severity are driven by root exudates, which could be examined by placing  
7 exudate-capturing barriers between roots, or by differential access to nutrients,  
8 assessable for instance through root architecture measurements.

9 The modulation of susceptibility by plant-plant interactions may arise from two key  
10 response mechanisms. First, plant-plant interactions can influence leaf morphological  
11 traits, which may, in turn, affect plant susceptibility. Indeed, traits such as plant height  
12 and heading date are negatively correlated with resistance to STB; i.e., STB-resistant  
13 cultivars tend to be shorter and exhibit earlier heading (Camacho-Casas *et al.*, 1995).  
14 Notably, overlapping genetic loci that influence both heading date and disease  
15 resistance have been identified (Gerard *et al.*, 2017). Second, plant-plant interactions  
16 may alter immune responses, leading to changed susceptibility as observed in the case  
17 of leaf rust pathogen in wheat (Pélissier *et al.*, 2021). More generally, wheat-STB  
18 interactions are associated with many molecular changes that have been largely  
19 described (Brennan *et al.*, 2019). Investigating whether plant-plant interactions influence  
20 these molecular changes could enhance the yet limited molecular understanding of  
21 susceptibility modulation in mixtures (Subrahmaniam *et al.*, 2018). To test these two  
22 possibilities in the Cultur-Atoudur mixture, aerial traits could be measured to assess  
23 morphological changes, and gene expression and metabolite accumulation could be  
24 analyzed to investigate potential immune modulation.

25

26 In this study, we investigated how plant-plant interactions within wheat varietal mixtures  
27 influence susceptibility to STB. The objectives were to (i) further identify the possible  
28 belowground processes that modulate susceptibility, (ii) characterize the morphological  
29 and molecular changes associated with responses to neighboring plants, and (iii)  
30 determine how plant-plant interactions alter molecular responses to STB infection.  
31 Using the model of durum wheat cultivar mixtures between Cultur and Atoudur, we  
32 combined aerial and root phenotyping with transcriptional analyses and untargeted  
33 metabolomics to propose a potential mechanistic framework underlying the modulation  
34 of susceptibility.

35

36

## 1 **Materials and methods**

2

### 3 **Plant material**

4 The study utilized two varieties of durum wheat susceptible to *Septoria tritici* blotch  
5 (STB): Cultur and Atoudur, obtained from RAGT in 2007 and 2010, respectively. The  
6 lines were selected for their difference in STB severity between pure and mixed  
7 conditions (Pélissier *et al.*, 2021).

8

### 9 **Plant growth conditions**

10 The wheat plants were cultivated in a greenhouse at PHIM (Montpellier, France) under  
11 controlled conditions. The photoperiod was 16 hours of light and 8 hours of darkness,  
12 with a temperature of 24°C/20°C and a PAR intensity of 250  $\mu\text{mol/s/m}^2$ .

13

14 Plants were grown in 8cm x 8cm x 8cm pots filled with a soil mixture consisting of 50%  
15 topsoil, 50% Neuhaus N2 soil, and 133.3 g of TopPhos for 100L soil. Each pot contained  
16 two rows: one with four plants of the focal genotype, on which phenotype is observed,  
17 and the other with four plants of the neighboring genotype.

18

19 For root phenotyping, plants were cultivated in rhizoboxes (20 cm x 40 cm x 2 cm) filled  
20 with the same soil mixture, enabling detailed observation of root architecture. The  
21 rhizoboxes were inclined at a 30° angle relative to the horizontal plane to encourage  
22 root development along the lower face of the box. The sides of the rhizoboxes were  
23 shielded from light to prevent unwanted light exposure. In each rhizobox, two plants of  
24 the same genotype (pure) or two plants of different genotypes (mixture) were sown  
25 against the glass panel, with a spacing of 5 cm between them.

26

### 27 **Inoculation and symptom assessment**

28 The Cultur genotype, either grown in pure stands or mixed with the Atoudur genotype,  
29 was cultivated under control conditions or with either an empty porous barrier or the  
30 same porous barrier containing polyvinylpyrrolidone (PVPP) to block the exchange  
31 of chemical molecules, notably phenolics, between genotypes (Durán-Lara *et al.*, 2015).  
32 The Cultur genotype was inoculated with the *Zymoseptoria tritici* strain "P1A" (Ballini *et al.*,  
33 2020) by applying an inoculum of  $10^6$  spores/mL to the last ligulated leaf 21 days

1 after germination using a brush. Following inoculation, plants were placed in transparent  
2 plastic bags for three days to maintain high humidity and promote pathogen growth. 17  
3 days post-inoculation, STB symptoms were assessed using an Epson Perfection V370  
4 Photo scanner. The SeptoSympto tool (Mathieu *et al.*, 2024b) was used to quantify the  
5 surface area of necrosis, which refers to the lesions.

## 7 **Root and aerial trait assessment**

8 Root and aerial traits were evaluated at different growth stages under both pure and  
9 mixed conditions (Supplementary Fig. S1). Root traits for the Cultur and Atoudur  
10 genotypes were assessed 21 days after germination, at the 3-leaf stage allowing the  
11 root disentanglement. Roots were thoroughly washed before being scanned using  
12 WinRhizo software. Root parameters including root volume, diameter, and the number  
13 of forks were quantified. Aerial traits were measured 38 days after germination, focusing  
14 on the Cultur genotype in both pure and mixed conditions. Plant height, leaf number,  
15 and tiller number were scored. Chlorophyll content was also assessed using a Dualex  
16 sensor, providing insights into photosynthetic potential and plant health. Additionally, the  
17 flowering rate at 56 days after germination was scored on the Cultur genotype in pure  
18 and mixture.

## 20 **Sample collection**

21 Leaf samples were collected from the Cultur genotype, with each sample comprising a  
22 pool of the last expanded leaves from three different pots (12 leaves total per sample).  
23 Root samples were taken from the same three pots. After grinding, samples were  
24 divided for transcriptional and metabolomic analyses.

25 Leaf samples were collected at 10 and 21 days after germination (day of inoculation)  
26 from Cultur grown in pure stands or mixed with Atoudur, and at 7 and 14 days post-  
27 inoculation from Cultur grown in pure stands or mixed with Atoudur under mock or  
28 inoculated treatments (Supplementary Fig. S1). Root samples were collected at 21 days  
29 after germination (day of inoculation) from Cultur grown in pure stands or mixed with  
30 Atoudur (Supplementary Fig. S1). For leaves, the central sections were cut into 0.5 cm  
31 pieces, while for roots, the tips were cut into 0.5 cm sections. The samples were  
32 immediately stored in liquid nitrogen.

## 1 **Primer design for the high-throughput RT-qPCR chip**

2 A systematic literature review was conducted to identify gene biomarkers of 22  
3 physiological processes and 41 sub-processes (Supplementary Fig. S2, Supplementary  
4 Table S1). If available, we preferably selected studies showing gene transcriptional  
5 regulation (by RT-qPCR, microarray or RNA-seq) in the wheat leaf of young seedlings.  
6 When we could not find studies reporting transcriptional regulation of genes under one  
7 given process, we selected studies showing the implication of genes using mutant  
8 approaches. If available, we selected already designed PCR primers based on our  
9 bibliography analysis. However, if no primers were already published for the gene  
10 identified, we designed our own primers. The design of primers followed a set of  
11 stringent criteria, as generally suggested in RT-qPCR protocols (e.g. PrimerExpress  
12 Software v2.0 Application Manual, Applied Biosystems). To minimize the risk of  
13 amplifying contaminating genomic DNA, primers spanning at least one exon-exon  
14 junction, or annealing to different exons, were designed when possible. The specificity  
15 of each primer was confirmed by comparing its sequence with all predicted wheat  
16 coding sequences (CDS) using the Primer3Plus software to ensure that at least one  
17 primer of each pair targets a unique site within the set of predicted wheat CDS. Primer  
18 specificity and amplicon length were checked for each pair of primers using  
19 MFEprimer3.1 and verification of hairpin and homo/heterodimerization was checked  
20 with *itdna* OligoAnalyzer.

21

## 22 **Primers for the *Zymoseptoria tritici* RT-qPCR**

23 Gene expression of *Zymoseptoria tritici* was analyzed in inoculated Cultivar leaves, either  
24 grown in pure stands or mixed with *Atoudur*, at 7 days post-inoculation during the  
25 biotrophic phase. A total of five effector-encoding genes and three housekeeping genes  
26 were examined. The primers used for RT-qPCR are listed in Supplementary Table S2.

27

## 28 **RNA extraction**

29 Total RNA was extracted using the protocol described in (Delteil *et al.*, 2012). Initially,  
30 frozen leaf tissues were ground in liquid nitrogen. Cells were lysed by adding 1 mL of  
31 Tri-reagent to the powdered sample. Nucleic acids were then separated by adding 200  
32  $\mu$ L of chloroform, incubating for 10 minutes at room temperature, followed by  
33 centrifugation at 13000g for 15 minutes at 4°C. The upper aqueous phase was  
34 collected, and 560  $\mu$ L of isopropanol was added to precipitate the nucleic acids  
35 overnight at -80°C, followed by centrifugation at 13000g for 20 minutes. The resulting  
36 pellet was washed twice with 500  $\mu$ L of 70% ethanol and centrifuged at 13000g for 5

1 minutes at 4°C, and then air-dried for 10 minutes before resuspension in 50 µL of  
2 ultrapure water on ice for 1 hour. DNase treatment was performed on 50 µL of RNA  
3 using the ThermoFisher kit, followed by purification. 200 µL of RNA was mixed with 200  
4 µL of phenol:chloroform:alcohol (25:24:1), and centrifuged at 16,000g for 10 minutes at  
5 4°C. The upper phase was collected and precipitated with 18 µL of 3M sodium acetate  
6 and 495 µL of pure ethanol at -80°C for 1 hour, followed by centrifugation at 16000g for  
7 30 minutes. The pellet was washed with 1 mL of 70% ethanol, centrifuged for 5 minutes,  
8 dried, and resuspended in 50 µL of ultrapure water. RNA quality and quantity were  
9 assessed using a Nanodrop spectrophotometer and verified for integrity via 2% agarose  
10 gel electrophoresis. The absence of DNA contamination was confirmed by qPCR using  
11 the Promega kit with EGM34 and EGM35 primers. For cDNA synthesis, RNA was  
12 diluted to 625 ng/µL in 8 µL, combined with 2 µL oligo(dT) and 3 µL H<sub>2</sub>O, and incubated  
13 at 95°C for 5 minutes. Subsequently, 4 µL 5X buffer, 2 µL 10mM dNTPs, and 1 µL RT-  
14 MMV enzyme (Promega) were added, and the mixture was incubated at 37°C for 30  
15 minutes to generate cDNA.

16

### 17 **Fluidigm chip preparation**

18 Gene expression analysis was conducted using a Fluidigm chip assay. Samples  
19 obtained post-reverse transcription were pre-amplified with Fluidigm products following  
20 the 'Pre-amplification of cDNA for Gene Expression with delta GeneAssays' protocol  
21 provided by the manufacturer (Biomark, Standard Biotech Inc. San Francisco, CA,  
22 USA). Initially, 0.5 µL of 100 µM forward and reverse primers were diluted in 200 µL of  
23 DNA suspension buffer. A pre-mix was prepared by combining 105.6 µL of PreAmp  
24 Master Mix, 52.8 µL of the diluted primer mix, and 237.6 µL of DNase-free H<sub>2</sub>O. Each  
25 well of a 96-well plate was filled with 3.8 µL of the pre-mix and 1.75 µL of 1/10 diluted  
26 cDNA sample. The plate was incubated with the following program: 2 minutes at 95°C,  
27 followed by 10 cycles of 15 seconds at 95°C and 4 minutes at 60°C. Post pre-  
28 amplification, a clean-up reaction was performed by preparing an exonuclease mix (168  
29 µL of DNase-free H<sub>2</sub>O, 24 µL of Exonuclease I Reaction Buffer, and 48 µL of  
30 Exonuclease I at 20 U/µL). Each well received 2 µL of this mix, and the plate was  
31 incubated for 30 minutes at 37°C for digestion, followed by 15 minutes at 80°C to  
32 inactivate the enzyme. Subsequently, 43 µL of DNA suspension buffer was added to  
33 each well, diluting the samples to one-tenth of their concentration, and the plate was  
34 stored at -20°C. For Fluidigm chip preparation, the "primers" and "samples" plates were  
35 arranged. The "primers" plate was prepared by mixing 3 µL of assay loading reagent,  
36 2.7 µL of DNA suspension buffer, and 0.3 µL of 100 µM primers (forward + reverse). The  
37 "samples" plate mix contained 360 µL of SoFast EvaGreen Super Mix and 36 µL of DNA  
38 binding dye sample loading reagent, with 3.4 µL of this mix and 2.75 µL of pre-amplified

1 samples added to each well, achieving a final volume of 5  $\mu$ L per well. The software to  
2 obtain the data was Fluidigm Real-Time PCR Analysis, with the quality threshold set at  
3 0.65. Gene expression for 95 genes, identified from the literature, was measured and  
4 normalized using the  $2^{-\Delta\Delta C_t}$  method (Livak and Schmittgen, 2001), with the 2  
5 reference genes Tubulin and ATPase Ta54227, implemented using the R package  
6 FLUIDIGR. Genes with undetected expression (CT = 999) were excluded from the  
7 dataset. Any gene or sample with 20% or more missing data was removed from the  
8 analysis.

9

## 10 **Metabolomic analysis**

11 LC-MS-based untargeted metabolomics was performed from ethanol extracts as  
12 described previously (Berger *et al.*, 2024). Briefly, 5mg of dried leaf, root and soil  
13 metabolite extracts were extracted in 2 x 300  $\mu$ L (ethanol/water 80% v/v, Formic acid  
14 0.1% v/v, Methyl vanillate 250 $\mu$ g/mL), sonicated (15 min, 4°C), centrifuged (5 min, 10  
15 600 g, 4°C) and filtered (sterile 0.22 $\mu$ m Durapore membrane, Merck), then analyzed by  
16 UHPLC-Q-Exactive Orbitrap MS/MS-based untargeted metabolomics using a Vanquish  
17 ultra-high-pressure liquid chromatography (UHPLC) system coupled to a QEX+ mass  
18 spectrometer interfaced with an electrospray (ESI) ionisation source (ThermoScientific,  
19 Bremen, Germany). Mass spectrometry (MS) spectra were acquired in the negative ion  
20 mode at 35k resolution and LC-MS/MS acquisitions (top N=2) were acquired at stepped  
21 normalized collision energies of 15, 30 and 40. The LC-MS analytical sequence of 26  
22 injections was randomized and included 18 unique biological samples (n = 3, 5  
23 genotypes and 1 bulk soil control), 2 extraction blanks (prepared without biological  
24 material to rule out potential contaminants detected by untargeted metabolomics) and 6  
25 Quality Control (QC) samples prepared by mixing 50  $\mu$ L from each sample and  
26 biological standard. QC samples were used for i) the correction of signal drift during  
27 long batches, and ii) the calculation of coefficients of variation for each metabolomic  
28 feature so only the most robust ones are retained for chemometrics (Broadhurst *et al.*,  
29 2018). Raw LC-MS data were processed following the DIA MS2 deconvolution method  
30 using MS-DIAL software (v. 4.9; (Tsugawa *et al.*, 2015)) following optimized parameters.  
31 Annotations were performed based on MS1 spectra and MS2 DDA fragmentation  
32 information using FragHUB database, including thousands of phytochemicals (Dabanc  
33 *et al.*, 2024). Thus, putative annotation of differentially accumulated metabolites resulted  
34 from MS-DIAL screening of the MS1 detected exact HR m/z and MS2 fragmentation  
35 patterns (Tsugawa *et al.*, 2015). Additionally, the InChiKeys of annotated features were  
36 employed within ClassyFire to generate a structural ontology for chemical entities  
37 (Djombou Feunang *et al.*, 2016). Curation of 6369 raw metabolomic signals (SN > 10,  
38 CV QC < 30%) resulted in 1168 LC-MS features, the intensities of which were

1 standardized by the mass of the dry extracts. Among these, 1104 remained unidentified,  
2 having no match with either MS1 or MS2. Another 32 features were suggested to be  
3 annotated metabolites, having a match with MS1 only (referred to as level 3 MS ID),  
4 while 64 features were positively annotated as metabolites, matching both MS1 and  
5 MS2 (referred to as level 2 MS ID). These 1168 features were normalised (Pareto  
6 scaling) for normality and comparison purposes and underwent uni- and multivariate  
7 statistical analyses (Principal Component and Clustering analyses) using  
8 MetaboAnalyst (v 6) (Pang *et al.*, 2021).

9

## 10 **Data analyses**

11 All statistical analyses were performed in R v.4.3.1 (R Core Team, 2023).

12

### 13 Phenotypic analyses

14

15 Boxplots were created to visualize STB symptoms, aerial and root phenotypes using the  
16 ggplot2, see, and stats packages. To evaluate the blend effect (pure vs. mixed), contrast  
17 tests were conducted following an aligned and ranked linear model with the ARTool  
18 package (Equation 1):

19

$$20 \quad (1) \quad y_{ik} = \mu + \alpha_i B_i + \epsilon_{ik}$$

21 where  $y_{ik}$  is the phenotypic observation;  $\mu$  is the intercept;  $\alpha_i$  corresponds to the effect  
22 for the blend type  $i$ ;  $B_i$  corresponds to the blend type  $i$ ; and  $\epsilon_{ik}$  is the error term.

23 Root phenotyping differences between Cultur and Atoudur under mixed conditions were  
24 further assessed with non-parametric contrast tests.

25

### 26 Transcriptional analyses

27

28 Transcriptional profiles were visualized using Principal Component Analysis (PCA) with  
29 the factomineR and factoextra packages, focusing on leaf transcriptional profiles at 10  
30 and 21 days after germination (dag) and defense gene expression at 7 and 14 days  
31 post inoculation (dpi). Boxplots of log2 fold-changes in the expression of 14 defense-  
32 related genes in Cultur leaves grown in pure stands *versus* mixed with Atoudur at 7 and

1 14 dpi, and barplots of fold-changes in gene expression under mixed conditions  
2 compared to pure stands at 10 and 21 dag were generated using the ggplot2, see, and  
3 stats packages. The effects of blend conditions on PCA coordinates and gene  
4 expression at 10 and 21 dag were analyzed with non-parametric ANOVA followed by  
5 Benjamini-Hochberg correction (Equation 1). Additionally, log<sub>2</sub> fold-changes for  
6 defense-related genes were compared between pure and mixed conditions using  
7 Wilcoxon tests.

8

9

## 10 Metabolomic analyses

11

12 The analyses were performed on the metabolites with the highest confidence level in  
13 metabolite identification based on the LC-MS profile of authentic pure standards,  
14 including retention time, m/z ratio, and fragmentation spectra when available (level 1  
15 identification).

16

17 Metabolomic profiles were visualized using heatmaps (gplots package), Principal  
18 Component Analysis (PCA) (factomineR and factoextra packages), Partial Least  
19 Squares Discriminant Analysis (PLS-DA) and volcano plots (MetaboAnalyst v6).  
20 Heatmaps were generated for leaf and root metabolomic data at 21 dag and 7 dpi.  
21 Hierarchical clustering for heatmaps was conducted using the complete clustering  
22 method with Euclidean distance. PCA was performed on leaf and root metabolites at 21  
23 dag. The effects of blend conditions on PCA coordinates were analyzed with non-  
24 parametric ANOVA (Equation 1).

25

26 For metabolite analysis at 21 dag, log<sub>2</sub> fold-changes between the mixed and pure  
27 conditions and z-scores (Equation 2) were calculated. Metabolites were considered  
28 significantly differentially accumulated if they showed a log<sub>2</sub> fold-change of less than -1  
29 or greater than 1 and a z-score below -2 or above 2.

30

$$31 \quad (2) \quad z = (x - \mu) / \sigma$$

32 where z is the vector of z-scores; x is the log<sub>2</sub> fold-change of metabolite accumulation  
33 between mixture and pure condition;  $\mu$  is the mean log<sub>2</sub> fold-changes; and  $\sigma$  is the  
34 standard error of the log<sub>2</sub> fold-changes.

1

2 For metabolite analysis at 7 dpi, a similar approach was used, with log<sub>2</sub> fold-changes  
3 calculated between inoculated and mock-treated conditions. This comparison was  
4 conducted separately in pure and mixed conditions.

5

## 6 **Results**

7

### 8 **The neighbor Atoudur genotype increases susceptibility to *Septoria tritici* blotch** 9 **and impacts phenological traits in the Cultur genotype**

10 As previously reported (Pélissier *et al.*, 2021), Cultur was more susceptible to STB  
11 when grown with Atoudur than in pure stands (Fig. 1A). Additionally, the expression of  
12 *Zymoseptoria tritici* effector genes was assessed at 7 dpi. We found an up-regulation of  
13 *Z. tritici* genes in Cultur leaves when grown with Atoudur at 7 dpi, consistent with  
14 increased symptoms (Supplementary Fig. S3). These results indicate that Cultur has  
15 increased susceptibility to STB when grown with Atoudur in comparison to pure culture.

16 To assess whether traits other than STB severity are influenced by the Cultur-Atoudur  
17 interaction, we examined aerial and root traits of Cultur in pure and mixed conditions.  
18 Chlorophyll content was decreased in Cultur leaves in mixture, in contrast to plant  
19 height, and leaf or tiller number (Fig. 1B and Supplementary Fig. S4A). Root traits  
20 remained unchanged in Cultur grown in pure stand or mixed with Atoudur at the  
21 seedling stage (Supplementary Fig. S4B). However, at 8 weeks after germination, the  
22 flowering rate was higher in Cultur grown with Atoudur than in pure (Fig. 1C), indicating  
23 a mixture effect on subsequent developmental stages. The results show that plant-plant  
24 interactions specifically impact wheat susceptibility to STB, leaf chlorophyll content and  
25 heading date.

26

### 27 **The increased STB severity in the Cultur genotype under mixed conditions is** 28 **driven by neighbor root proximity independently of PVPP-captured metabolites**

29 We tested several hypotheses related to root-based mechanisms potentially involved in  
30 plant-plant interactions: enhanced susceptibility in the mixture could be due either to  
31 differential soil metabolite contents or to differential competition in the soil. First, we  
32 introduced a porous barrier between genotypes to hamper direct root contact. Under  
33 these conditions, no significant difference in STB symptoms was observed between  
34 pure and mixed conditions (Fig. 2A) in contrast with no barrier (Fig. 1A). Similarly, when  
35 the barrier was filled with polyvinylpyrrolidone (PVPP), known to block the exchange

1 of metabolites, notably phenolics (Durán-Lara *et al.*, 2015), STB symptoms remained  
2 unchanged between pure and mixed conditions (Fig. 2A). Untargeted metabolomic  
3 analysis confirmed that the soil metabolite profiles differed between the control and  
4 PVPP-filled barrier conditions (Supplementary Fig. S5A): PVPP strongly reduced the  
5 abundance of a specific subset of metabolites (93 metabolites significantly regulated out  
6 of 2838, ~70% with decreased accumulation; Supplementary Fig. S5B), indicating  
7 effective blockage of soluble exudates, likely including phenolics. Therefore, these  
8 results suggest that physical impediment of root-root contacts is sufficient to suppress  
9 the neighbor-mediated increase in susceptibility to disease.

10  
11 Second, we measured various root traits in mixtures to evaluate if obvious root  
12 architecture could be responsible for differential competition. Interestingly, this analysis  
13 revealed differences between the two genotypes, with Atoudur displaying a significantly  
14 more prominent root system than Cultur, including root volume, root diameter and root  
15 branching (Fig. 2B). Altogether, these results are in line with the idea that Cultur trait  
16 changes are induced by close root-root contacts with Atoudur.

### 17 18 **A metabolic slow-down in Cultur when co-cultivated with Atoudur**

19 We next addressed the question of the molecular responses in the focal plant using  
20 metabolomic and transcriptional approaches, in both roots and leaves, in the absence of  
21 infection.

22 In the roots, a significant effect was detected in the metabolomic profiles of Cultur (Fig.  
23 3A). We observed a small cluster of slightly up-accumulated metabolites in the mixture,  
24 including two phenylpropanoids (cluster R1 in Supplementary Fig. S6A, Supplementary  
25 Fig. S7, Supplementary Table S3). In contrast, there was a large cluster of metabolites  
26 that were tendentially down-regulated (cluster R2 in Supplementary Fig. S6A,  
27 Supplementary Fig. S8, Supplementary Table S3). This cluster was enriched in  
28 metabolites involved in primary metabolism pathways (75% of metabolites present in  
29 this cluster; Supplementary Table S3), even though the strongest down-regulations  
30 were observed for phenylpropanoids. Thus, the presence of Atoudur roots in the  
31 neighborhood of Cultur has a general negative impact on metabolic activity in Cultur  
32 roots.

33  
34 In the leaves, a slight effect of the mixture was observed in the leaf metabolomic profiles  
35 of Cultur (Fig. 3B). In Cultur leaves, we identified a cluster of mildly up-accumulated  
36 metabolites related to specialized metabolism (43% annotated as phenylpropanoids) in

1 the mixture (cluster L2 in Supplementary Fig. S6B, Supplementary Fig. S9,  
2 Supplementary Table S3). Conversely, a separate cluster of down-accumulated  
3 metabolites was observed (cluster L1 in Supplementary Fig. S6B, Supplementary Fig.  
4 S10, Supplementary Table S3), with 8 metabolites related to primary metabolism among  
5 the 12 metabolites also down-regulated in mixed roots (cluster R2 in Supplementary  
6 Fig. S6A, Supplementary Fig. S8, Supplementary Table S3).

7  
8 While these metabolic changes in the leaves were slight, significant global changes  
9 were seen in the transcriptional profiles of *Cultur* both at 10 days after germination (Fig.  
10 4A) and at 21 dag (before inoculation) (Fig. 4B). In particular, at 10 dag, there was a  
11 down-regulation of *SS4* and *SHMT* genes used as markers for carbon metabolism (Fig.  
12 4C and Supplementary Fig. S11), and at 21 dag, a down-regulation of marker genes for  
13 cell expansion (*PIF3*), potassium (*HAK25*) and nitrogen (*AMT1.1*) metabolisms (Fig. 4D  
14 and Supplementary Fig. S12). These changes were consistent with metabolic data from  
15 *Cultur* leaves at 21dag showing a reduction of metabolites associated with primary  
16 metabolism (Supplementary Fig. S6B).

17  
18 Altogether, these analyses in roots and leaves indicate that, as early as 10 days of co-  
19 culture, interactions at the root level resulted in detectable changes at the molecular  
20 level in the leaves. However, with the exception of the *PR3* gene, no massive change in  
21 the expression of 15 tested defense genes could be detected before infection. In fact,  
22 the changes observed were more global and reflective of an induced resource scarcity  
23 at the whole organismic level in the *Cultur* genotype when grown nearby the competitive  
24 *Atoudur* genotype.

### 25 26 **Delayed induction of defense gene expression and reduced accumulation of** 27 **specialized metabolism compounds in *Cultur* grown with *Atoudur***

28 To analyze the impact of the *Cultur*-*Atoudur* interaction on the response to  
29 *Zymoseptoria tritici* inoculation, we compared leaf expression of induced defense genes  
30 between inoculated and mock-treated *Cultur* in pure and mixed conditions. This analysis  
31 was conducted at two time points: 7 and 14 days post-inoculation (dpi), corresponding  
32 to the biotrophic and necrotrophic phases of pathogen development, respectively.

33  
34 At 7 dpi, *Cultur* in pure stands showed distinct defense responses between mock and  
35 inoculated leaves, whereas no difference was observed in mixed conditions (Fig. 5A).

1 This divergence between mixed and pure conditions was linked to an absence of  
2 induction of defense genes in mixed conditions compared to a two-fold induction in pure  
3 conditions (Fig. 5B). By 14 dpi, however, the defense response was similar between  
4 pure and mixed conditions, with no further difference in gene expression (Fig. 5C & 5D).  
5 These findings suggest a delay in defense gene induction in response to STB  
6 inoculation when Cultur is grown with Atoudur.

7 We also examined metabolites at 7 dpi and observed that 60% of regulated metabolites  
8 in response to inoculation under pure condition showed no difference in the mixed  
9 condition. A notable cluster of specialized metabolism compounds, including  
10 triterpenoids, and precursors of phenolics and alkaloids, displayed this pattern similar to  
11 defense genes at 7 dpi (Fig. 6, Supplementary Table S3).

12

## 13 Discussion

14

15 Varietal mixtures are increasingly being considered as a sustainable strategy for  
16 improving yield and managing diseases in cropping systems (Borg *et al.*, 2018). In order  
17 to ensure their benefits and guide the design of more resilient mixtures, it is essential to  
18 identify and understand any potential drawbacks, such as the enhanced susceptibility  
19 observed in the durum wheat Cultur variety to *Septoria tritici* blotch (STB) when grown  
20 in mixed stands with Atoudur. Our findings reinforce the role of root-mediated  
21 interactions in increasing STB severity in Cultur, consistent with the previous work of  
22 (Pélissier *et al.*, 2021), who observed similar belowground effects influencing  
23 susceptibility to leaf rust. To further explore whether this root-based signal involves  
24 resources or signaling molecules, we used a porous barrier that permitted nutrient and  
25 small molecule diffusion while decreasing physical root contacts. Our results suggest  
26 that the increased susceptibility in Cultur requires close physical root contacts and/or  
27 unequal spatial occupation and/or diffusible molecules at short distance. Differences in  
28 root architecture between Cultur and Atoudur, with the latter showing a more developed  
29 root system, suggest that competition for space, and consequently for resources, could  
30 be the trigger of the observed phenotypes. Future work could quantify soil nutrient  
31 availability and plant nutrient status, compare plant responses under contrasting fertility  
32 conditions, or use hydroponic systems that decouple root architecture from nutrient  
33 uptake to verify whether differential nutrient acquisition indeed contributes to the  
34 increased susceptibility in Cultur. Indeed, particularly under nutrient-limited conditions,  
35 competition for nutrients, water and space plays a critical role in plant fitness, including  
36 productivity and development (Schenk, 2006).

37

1 The analysis of the molecular responses in the focal *Cultur* plants provided hints into the  
2 processes that the neighboring *Atoudur* genotype induced. Indeed, our transcriptional  
3 and metabolomic analyses revealed shifts in metabolic pathways towards a metabolic  
4 shutdown in roots, characterized by a downregulation of primary metabolism. In  
5 particular, the decreased levels of amino acid derivatives, such as  $\gamma$ -  
6 glutamylphenylalanine and N-acetylleucine, likely reflect a remobilization of nitrogen  
7 toward specialized metabolite synthesis (Trovato *et al.*, 2021; Cai and Aharoni, 2022),  
8 consistent with the reduced expression of the ammonium transporter AMT1.1. Similarly,  
9 the down-regulation of energy-related metabolites—including adenosine, xanthine, and  
10 several fatty-acyl derivatives—together with the decreased transcript levels of *SS4* and  
11 *SHMT*, may suggest carbon-related metabolic stress. The reduction of carbohydrate  
12 derivatives, such as xylitol and 6-phosphogluconate, further indicates a reorientation of  
13 carbon flux away from growth-promoting pathways toward stress-related metabolism  
14 (Huang and Dudareva, 2023). Moreover, the negative regulation of carbon metabolism  
15 and cell expansion pathways, along with the observed reduction of chlorophyll content,  
16 could suggest a competition-induced inhibition of photosynthesis-related pathways,  
17 consistent with previous studies (Horvath *et al.*, 2006; Schmidt and Baldwin, 2006;  
18 Masclaux *et al.*, 2012; Pierik *et al.*, 2013). On the other hand, the increase in  
19 phenylpropanoids, known to be involved in defense and stress responses (Chowdhary  
20 *et al.*, 2022), further indicates that *Atoudur* activates stress-related pathways in *Cultur*.  
21 Similar patterns, including the up-regulation of flavonoids (Bowsher *et al.*, 2017), were  
22 observed in response to competitive interactions (Schmidt and Baldwin, 2006; Masclaux  
23 *et al.*, 2012). Together, the transcriptomic and metabolomic shifts indicate that *Atoudur*  
24 induces a reallocation of resources in *Cultur*, whereby investment in growth-related  
25 primary metabolism is reduced in favor of secondary metabolism pathways linked to  
26 defense (Monson *et al.*, 2022; Zrimec *et al.*, 2025). These molecular changes support  
27 the hypothesis that a growth-defense trade-off is initiated early in the interaction, before  
28 any later observable phenotypic changes. For instance, early flowering, a well-  
29 documented response that enables increased plant survival in stressful environments  
30 (Takeno, 2016), was observed in the *Cultur-Atoudur* mixture. This change in phenology  
31 is also a hallmark of competition in plants (Moreno-Colom and Montesinos-Navarro,  
32 2025). In that respect, the mis-regulation of the *PIF3* gene in *Cultur* grown with *Atoudur*  
33 is consistent with the regulation of reproduction, as observed in *Arabidopsis* (Galvão *et al.*,  
34 2019) and further supports competition-driven molecular alterations in the *Cultur-Atoudur*  
35 mixture.

36

37 The increase in STB symptoms in *Cultur* mixed with *Atoudur* was associated with an  
38 early increase in pathogen effector gene expression, a delay in the activation of defense  
39 genes and decreased accumulation of specialized metabolites, including terpenoids and

1 precursors of phenolics and alkaloids, particularly at the biotrophic stage. The delay in  
2 pathogen-specific defense response is important, as early defense mechanisms play a  
3 key role in inhibiting disease progression (Brennan *et al.*, 2019). Furthermore, (Seybold  
4 *et al.*, 2020) reported a delayed accumulation of phenylpropanoid compounds and  
5 flavonoids in a susceptible wheat cultivar compared to a resistant one when exposed to  
6 *Z. tritici*. This suggests that these compounds, known for their antimicrobial and  
7 antioxidant properties (Treutter, 2006), are essential in resistance to STB infection.  
8 Therefore, the compromised defense gene expression and immune-related metabolites  
9 observed in Cultur grown with Atoudur likely facilitated pathogen activity, resulting in  
10 increased STB severity. Investigating plant responses and pathogen development at  
11 earlier stages after inoculation may help to further characterize the onset of this delay. It  
12 is tempting to speculate that this compromised defense resulted from a trade-off  
13 between growth and defense triggered by the abovementioned competition. However,  
14 this remains to be formally demonstrated.

15

16 Our integrated approach, combining aerial and root phenotyping, transcriptional  
17 analysis, and the first untargeted metabolomics in a varietal mixture, provides new  
18 insights into root-mediated mechanisms influencing susceptibility to diseases. The  
19 findings suggest that the increased STB severity observed in Cultur when co-cultivated  
20 with Atoudur could be primarily driven by root architecture differences leading to  
21 resource competition rather than allelochemical signaling (Fig. 7). While Atoudur's large  
22 roots may induce early molecular changes before pathogen inoculation in Cultur, these  
23 changes likely reflect competitive stress and potentially impact the phenology of Cultur.  
24 Competition and the subsequent reduction of primary metabolism may indirectly reduce  
25 the expression of processes like defenses, thus explaining the observed delay in  
26 defense responses (Fig. 7). These correlative results highlight the interplay between  
27 root architecture, resource competition, plant metabolism, and defense response in  
28 modulating plant-pathogen interactions in varietal mixtures. They also provide  
29 mechanistic insights into cases where mixtures have negative effects, an essential yet  
30 neglected aspect of mixture research to prevent undesirable outcomes and promote  
31 agro-biodiversity. Future research should further disentangle these root-mediated  
32 mechanisms and assess their potential in enhancing crop resilience in mixtures.

## 2 **Figure legends**

3

4 **Fig. 1.** Effects of neighbor genotype on Septoria tritici blotch symptoms, chlorophyll  
5 content and flowering rate in a durum wheat cultivar mixture. **A** Septoria tritici blotch  
6 symptoms measured as the part of necrotic leaf area 17 days after inoculation and **B**  
7 chlorophyll content assessed 38 days after germination, both on the Cultur genotype  
8 grown either in pure stands or in mixtures with Atoudur. Statistical comparisons between  
9 Cultur in pure and mixed conditions were conducted using non-parametric contrast  
10 tests. Significance levels are denoted as follows : . :  $p < 0.1$ , \* :  $p < 0.05$ , \*\* :  $p < 0.01$ , \*\*\* :  
11  $p < 0.001$ . **C** The flowering rate of the Cultur genotype assessed 56 days after  
12 germination.  $\chi^2$  test showed significantly higher flowering in Cultur when grown with the  
13 neighbor Atoudur genotype.

14

15 **Fig. 2.** Effects of neighbor genotype and root barrier on Septoria tritici blotch symptoms,  
16 and assessment of root traits in a durum wheat cultivar mixture. **A** Septoria tritici blotch  
17 symptoms of the Cultur genotype were assessed by necrotic leaf area 17 days after  
18 inoculation. Cultur was grown in pure stands or mixed with Atoudur, with either an empty  
19 barrier or a barrier filled with polyvinylpolypyrrolidone (PVPP) between genotypes. No  
20 statistical difference between Cultur symptoms in pure and mixed conditions were  
21 observed based on non-parametric contrast tests. **B** Root phenotyping of Cultur and  
22 Atoudur in mixed conditions, measured 21 days after germination (day of inoculation).  
23 Statistical comparisons between Cultur and Atoudur phenotypes were conducted using  
24 non-parametric contrast tests. Significance levels are denoted as follows : . :  $p < 0.1$ , \* :  
25  $p < 0.05$ , \*\* :  $p < 0.01$ , \*\*\* :  $p < 0.001$ .

26

27 **Fig. 3.** Effects of neighbor genotype on metabolomic profiles in a durum wheat cultivar  
28 mixture. **A,B** Principal component analysis (PCA) of **A** root and **B** leaf metabolomic  
29 profiles from Cultur grown in pure stands or mixed with Atoudur, sampled 21 days after  
30 germination (day of inoculation). Statistical analyses between pure and mixed  
31 conditions for each PCA dimension were performed using a non-parametric ANOVA.

32

33 **Fig. 4.** Effects of neighbor genotype on transcriptional profiles in a durum wheat cultivar  
34 mixture. **A,B** Principal component analysis (PCA) of transcriptional profiles from Cultur  
35 leaves grown in pure stands or mixed with Atoudur, sampled **A** 10 days after

1 germination or **B** 21 days after germination (day of inoculation). Statistical analyses  
 2 between pure and mixed conditions for each PCA dimension were performed using a  
 3 non-parametric ANOVA. **C,D** Scatterplots showing log<sub>2</sub> fold-changes in gene  
 4 expression of *Cultur* between mixed and pure conditions *versus* the -log<sub>10</sub> p-value for  
 5 each gene, with samples collected at **C** 10 days after germination and **D** 21 days after  
 6 germination (day of inoculation). Statistical analysis was performed using a non-  
 7 parametric ANOVA followed by Benjamini-Hochberg correction to compare *Cultur* gene  
 8 expression in pure vs. mixed conditions for each gene.

9

10 **Fig. 5.** Defense gene expression in mock-treated and inoculated focal leaves grown in  
 11 pure stands vs. in a durum wheat cultivar mixture. **A,C** Principal component analysis  
 12 (PCA) of defense gene expression profiles in *Cultur* leaves at **A** 7 days and **C** 14 days  
 13 after inoculation, comparing inoculated and mock-treated leaves grown in either pure  
 14 *Cultur* stands or mixed with *Atoudur*. **B,D** Log<sub>2</sub> fold-changes in expression of 15  
 15 defense genes between inoculated and mock-treated *Cultur* leaves grown in pure  
 16 stands *versus* mixed with *Atoudur* at **B** 7 days and **D** 14 days after inoculation. The  
 17 defense genes are listed in Supplementary Table S1. Statistical analyses between pure  
 18 and mixed conditions were performed using a Wilcoxon test. Significance levels are  
 19 denoted as follows : . : p < 0.1, \*: p < 0.05, \*\*: p < 0.01, \*\*\*: p < 0.001.

20

21 **Fig. 6.** Metabolomic profiles of focal leaves grown in pure stands vs. in a durum wheat  
 22 cultivar mixture under mock-treated and inoculated conditions. **A** Heatmap of  
 23 metabolomic profiles in *Cultur* leaves, grown in pure stands *versus* in a mixture with  
 24 *Atoudur*, analyzed at 7 days post inoculation. **B** Boxplots of metabolites showing  
 25 differences in *Cultur* metabolite accumulation between inoculated and mock-treated  
 26 conditions in pure stands and not in the mixed condition. Metabolites meeting the  
 27 significance criteria (log<sub>2</sub> fold-change < -1 or > 1 and z-score < -2 or > 2 in pure stands,  
 28 with log<sub>2</sub> fold-change > -1 or < 1 and z-score > -2 or < 2 in mixture) are marked in red to  
 29 indicate significant differential accumulation only in pure stands.

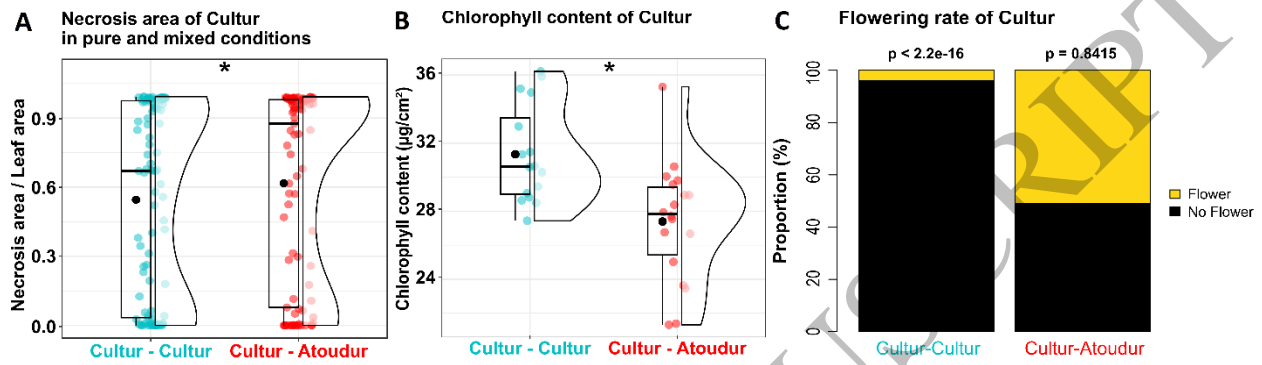

30

31 **Fig. 7.** Scheme of the proposed signaling cascade in a durum wheat varietal mixture. In  
 32 the *Cultur-Atoudur* mixture, a belowground signal—presumably associated with root  
 33 architecture rather than root-derived metabolites—triggers a competitive response  
 34 characterized by the down-regulation of primary metabolism and an increase in  
 35 phenylpropanoid accumulation in *Cultur*. Additionally, the delayed activation of defense  
 36 following *Septoria tritici* blotch (STB) inoculation likely explain the observed higher

1 susceptibility to STB in this varietal mixture. Created with BioRender.com under  
2 agreement #HJ2926JXGQ.
