Following my thesis work on the propagation of elastic waves in heterogeneous media with continuously variable properties, I chose to study the interaction of ultrasound with bone tissue. In this first chapter, we will begin by describing the work I have done to characterize the *bone quality* of adult bone affected by fragilizing diseases such as osteoporosis. Healthy adult bone is a documented and well known material. The challenge is therefore to build a tool for assessing bone quality and monitoring its evolution over the course of life : a diagnostic tool.

When considering ultrasonic modalities for living organisms, it is stressed that they are non-invasive, non-irradiating, non-ionizing, and that they can be used to develop inexpensive, portable devices for the patient's bed. These criteria are important for the patient and take on an additional dimension in the case of paediatric patients for whom the other diagnostic protocols (X-rays, MRI) are heavy (sedation, anaesthesia, dose). In addition, it is now known that the growing bone has specific pathologies and its own mechanical behaviour. You can't just look at child bone as a miniature adult bone. However, in order to diagnose pathologies, however, a reference *healthy* state must be defined. Non-pathological growing bone is a poorly known material. That's why I found it very interesting to contribute to the development of a reference database on childhood bone by developing high-resolution imaging tools and dedicated mechanical characterization protocols. The idea is to make a link between the organization of the fabric and its mechanical properties at different scales. The challenge is certainly to characterize the mechanical behaviour of the child's bone but also to relate it to morphometric parameters accessible by imaging.

But ultrasound is full of resources and, **diagnostic tool**, it can also be **therapeutic vector**. This is the subject of the second part of this first chapter. This second part begins with a study in which bone tissue appears in the *backplane*. The aim was to study the propagation of ultrasound waves within the skull to analyze the effect of ultrasound on the dissolution of a blood clot in the brain. That's when the *theranostic* stakes in ultrasound became apparent in my research. This triggered my interest in ultrasonic stimulation of bone regeneration, a subject that feeds my current research projects.

1.1 Ultrasound & bone : diagnostic tool

After working on the characterization of heterogeneous materials such as concrete during my thesis, I applied these developments to the ultrasonic evaluation of bone resistance to improve the diagnosis of osteoporosis. In 2005, I started to work on **cortical** bone characterization and I still work on that type of bone, which represents 80 % of the human bone mass.

1.1.1 Ultrasound and cortical porosity

In October 2005, in the Biomedical Imaging Laboratory (UMR 7371) directed by Pascal Laugier (DR CNRS), I implemented my skills in ultrasonic acoustics in heterogeneous materials while discovering the field of biomedical. I studied the impact of porosity on the mechanical behaviour of the cortical bone *via* propagation of ultrasonic waves in order to build a numerical model of bone as realistic as possible.

Ultrasonic characterization of the cortical bone

In general, the relevance of ultrasound for assessing bone *in vivo* is now well established, particularly in the area of diagnostic support for osteoporosis, an osteopathy associated with an increased risk of fracture. Ultrasound devices for trabecular bone examination thus have very good performance in terms of prediction of fracture risk, which is equivalent to that of the X-ray absorption technique. Although more recent and less well documented, ultrasound systems for cortical bone examination also have proven ability to predict bone strength and the risk of osteoporotic fracture.

The prospect of a bone quality assessment breaks with current practice, at least in the area of osteoporosis diagnostic support. Currently, the ultrasonic index used to predict fracture risk is the speed of elastic waves or the variation in wave attenuation as a function of frequency. Cortical bone has benefited from upstream studies which, as part of experimental studies or more or less refined academic models, have established that the speed of elastic waves observed results from the combined effect of several properties such as cortical thickness, porosity (ratio of volume occupied by pores to total volume) and mineralization. The cortical bone allows the propagation of several guided modes in a sufficiently wide frequency range (Lamb wave type). These waves are, in current practice, observed in axial transmission configuration, transmitters and receptors aligned along the direction of the bone axis. The velocity of each of these waves has a specific dependence on bone properties. The exceptional diversity of the ultrasonic response of cortical bone suggests the possibility of a multiparametric characterization of bone quality, but this requires the construction of relevant models that take into account the complexity of bone tissue : anisotropy, multi-scale porosity, complex geometry. Improving the representativeness of models is a major challenge.

Numerical simulation of ultrasonic wave propagation in reconstructed bone samples

During my post-doc, my involvement in the project coordinated by Maryline Talmant (CR CNRS), mainly focused on the numerical aspect and the construction of a virtual bone model. The virtual bone model is constructed by numerically simulating *in vitro* axial transmission experiments performed on human radius samples. These simulations are based on a finite difference calculation code developed in the laboratory (www.simsonic.fr) [Bossy et al., 2004]. Bone tissue samples are obtained from microtomographic images

(pixel size 10 microns) at a sufficiently high resolution to reconstruct the vascular pore network. Parallelepiped blocks are then extracted from these reconstructions to be integrated into the calculation code (Figure 1.1). The mechanical properties, i. e. stiffness coefficients and density, used in input data are themselves measured experimentally.

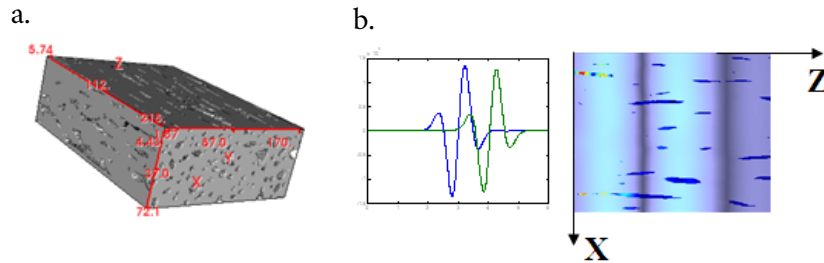

FIGURE 1.1 – Simulation of plane wave propagation (b) through a reconstructed block (a).

Cortical bone is modelled at this scale by a fluid/solid biphasic medium : pores filled with a supposedly perfect fluid and assimilated to water ; a solid, elastic and anisotropic bone matrix. Each of the two phases is characterized by its mechanical properties : coefficients of elasticity and density. In axial transmission, for frequencies less than or equal to 1 MHz, the wavelength is a few millimetres and is larger than the characteristic pore size of a few hundred micrometers maximum. The propagated ultrasonic plane wave "sees" therefore an equivalent homogeneous medium. With reconstituted samples having porosities covering the porosity range of the cortical bone (up to 15 %), it is possible to study the impact of porosity, as a volume fraction, on the mechanical behaviour of the bone (stiffness coefficients and anisotropy) *via* simulation of propagation of ultrasonic bulk waves. The simulation of an axial transmission system (transmitter/receivers) records the signals propagating within the sample blocks. The propagation velocities are then calculated by detecting the first maximum. From the compression and shear velocity values obtained in this way along the three spatial directions, the diagonal coefficients of the stiffness matrix were derived using Christoffel's equation.

These results highlight the strong relationship between ultrasonic measurements and porosity and the impact of porosity on bone anisotropy (Figure reffig : CijPoro). The construction of an ultrasound interaction model with cortical bone must therefore integrate these factors for a better understanding of the physical phenomena induced.

These results (Figure 1.2) have been the subject of several international communications and are presented in an article published in the Journal of Acoustical Society of America [BARON et al., 2007] (see Chapter 4 p. 44).

1.1.2 The cortical bone as a functionnally graded material

The mechanical properties of cortical bone vary according to the anatomical site and individuals. One of the major challenges of ultrasonic characterization of bone quality is to determine relevant parameters that would overcome these inter-site and inter-individual variations. To do this, I proposed to consider a new parameter to characterize the mechanical quality of the cortical bone : the progressive (or even continuous) variation of the mechanical properties (coefficients of elasticity) along the cortical thickness. The choice of this endpoint was made by observing the changes induced by osteoporosis. In the case of this pathology, there is usually a coupled effect : *trabecularization* of the endostasis

FIGURE 1.2 – Stiffness coefficients evolution with cortical porosity.

which leads to thinning of the wall. In other words, the porosity gradually increases in the cortical thickness, which decreases (Figure 1.3 a.). In the description of the process itself, it is suggested that a parameter that integrates both microarchitecture (pore distribution) and bone geometry (cortical thickness) would be an advantage in the evaluation of bone quality and especially of its evolution. This is the case of the gradient of mechanical properties in the radial direction of the long bone.

FIGURE 1.3 – a. Osteoporosis effects : *trabecularization* and thinning of the cortex. b. Cortical bone as a functionally graded material.

Stroh's formalism

During my thesis work, I developed a numerical tool to study the sensitivity of elastic waves to continuous profiles of properties [BARON, 2005]. A waveguide is considered to have mechanical properties represented by the C_{ij} stiffness coefficients and the density ρ that vary in a direction perpendicular to the direction of flat wave propagation. The challenge is to solve the wave equation for rigidity coefficients and density that depend on a space variable. One of the most commonly used solutions is the modelling of the medium

with gradient of properties by a multilayered medium for which the properties are piecewise constant, which makes it possible to solve the wave equation in a classical way on each of the layers, these solutions being then connected together by the boundary conditions. This therefore provides an exact solution to an approached problem. The objective of my thesis work was to provide an approach to the exact problem and thus to formulate an analytical solution of the wave equation by keeping continuous profiles of variation of characteristic properties and to evaluate this solution numerically. The objective was achieved using the Stroh's formalism Stroh1962 and A. Shuvalov's works [SHUVALOV, 2003; SHUVALOV et al., 2005].

Application to cortical bone

The idea was therefore to consider cortical bone as a plane waveguide, whose properties continuously vary in the radial direction of the bone, perpendicular to the direction of propagation of the waves in the case of characterization by axial transmission (Figure 1.3 b.) [BARON et NAILI, 2010] (see Chapter 4 p.63). This model was then extended to include cylindrical waveguides that are more representative of the geometry of long bones [BARON, 2011] (see Chapter 4 p. 75). Changes in physiological properties and characteristics of age-related changes in bone tissue remained to be defined. Based on the results obtained by BOUSSON et al. [2001] and by implementing the homogenization (micromechanical) models described by GRIMAL et al. [2011], I determined realistic property profiles for different ages. I thus verified that the ultrasonic waves were sensitive to these physiological profile variations in a frequency range used conventionally for the ultrasonic characterization of cortical bone [BOSSY et al., 2004; MOILANEN et al., 2007]. This study confirms the relevance of ultrasonic characterization techniques for assessing bone quality and led to a publicization in *Ultrasound in Medicine and Biology* [BARON, 2012] (see Chapter 4 p. 84).

Experimental validation

In parallel, I developed an experimental protocol for characterizing a plate with gradient of properties. The principle consists in generating compression waves at an incidence corresponding to the propagation of specific guided modes. The recorded time signals are then processed by double Fourier transform in order to identify the dispersion curves (phase velocity as a function of the frequency-thickness product) of the propagative modes. The assembly and the protocol were validated on homogeneous and isotropic aluminium plates of different thicknesses (Figure 1.4).

The experimental measurements were carried out at the LMA (UPR CNRS 7051) in August 2012 in collaboration with the SERM (Service d' Études et de Réalisations Mécaniques). The protocol and assembly were therefore validated for a homogeneous and isotropic plate. Materials with gradients of controlled properties representative of the observed variations in mechanical properties in the thickness of human cortical bone have yet to be developed. Within the framework of the DEFI CNRS REPOUSSE (see § 2.1.1 p. 28), I met Laurent Malaquin from the LAAS (UPR CNRS 8001, Toulouse) who develops 3D manufacturing protocols likely to provide materials with controlled porosity gradient and morphologically close to the cortical bone [MÉZIÈRE et al., 2016].

1.1.3 Characterization of human growing bone

Since 2009, I have been working on characterization of the children bone. Children bone are a material for which the reference values of characteristic properties (mechanical, biochemical, structural) are sorely lacking. The determination of these reference values is a crucial issue for clinicians in order to develop diagnostic and therapeutic protocols dedicated to paediatric pathologies. Currently, the most commonly used criterion for diagnosing bone fragility is the measurement of bone mineral density (BMD), conventionally determined by X-ray scanning. However, this technique requires special protocols adapted to paediatric practice (anesthesia, radiation dose). In addition, the BMD measurement gives access exclusively to the bone mineral content (quantitative data) and does not provide any qualitative information on the microstructure or mechanical properties of the bone. The ambition is therefore to provide reference values for the *quality* of the growing bone : mass density, modulus of elasticity, anisotropy, morphometry, collagen biochemistry. The different methods I used to characterize the child's bone have been implemented on samples extracted from surgical waste. The preparation of these small samples (cutting, surface finish) is delicate and requires precise protocols that we have developed specifically.

This research was carried out within the framework of an ANR contract (MALICE 2012-2016), a Carnot financing (CROISSANCE 2016) and two theses that I co-supervised (Emmanuelle Lefèvre 2012-2015 and Marie Semaan 2015-2018). My contribution focused on 2 questions :

- high resolution imaging and morphometric study of children bone ;
- ultrasound evaluation of the anisotropy of children bone.

Morphometry of children cortical bone

It is now clearly established that bone architecture and its multi-scale organisation are determinants of bone quality. One of the challenges is therefore the evaluation of morphometric parameters of bone as a porous material. It is important to note that bone is a multi-level porosity material at different scales from mesoscopic to nanoscopic. The mesoscopic porosity is the vascular porosity of the Havers and Volkmann canals.

On the one hand, the aim is to reliably reconstitute the 3D poral network, in order to respect the privileged orientations and pore geometry and deduce the contribution of the microstructure in the general anisotropy of bone tissue (Figure 1.5) ; on the other hand, to define the elasticity tensor of the supposed anisotropic bone matrix. I have initiated work on the study of growing bone morphometry from image analysis of samples collected in the MALICE project. The objective is to determine characteristic parameters that may reflect the quality of bone in children.

FIGURE 1.5 – Pore diameter distribution along the 3 directions of space for a parallelepipedic sample of adult radius.

In collaboration with Yohann Bala (post-doc ANR MALICE), we reconstructed 54 cubic bone samples of children and adults from RX images obtained by micro-CT (Skyscan 1174, Skyscan NV, Kontich, Belgium) (Figure 1.6). The voxel size has been set at $8.14 \mu\text{m}$. Morphometric analyses were performed using a semi-automatic method (CTAnalyser Software V 1.14.4, Skyscan NV, Kontich, Belgium).

FIGURE 1.6 – 3D reconstruction of the vascular pore network on 3 samples : effect of ageing.

FIGURE 1.7 – Effect of the filter in the detection of small canals in images of children bone (voxel size 19.1 μm). Porosity with and without filter estimated respectively at 7.2% and 2.8%.

We have thus evaluated the evolution of the poral structure as a function of age : the small number of pores but large diameters in childhood give way to a more compact structure (numerous pores but small diameter) in adolescence, leading to a more porous structure (numerous pores and large diameter) with aging. Unfortunately, our study does not cover the 20-50 age group.

To go further in mastering the evaluation of these parameters, I contacted Jérôme Vicente free software developer iMorph (<http://imorph.sourceforge.net/>). The GROWTH project funded by the Carnot Institute has enabled the recruitment of Pierric Mora (post-doc 1 year) who has developed specific image processing tools for morphometric analysis of the growing poral network of cortical bone. These advances are based on the use of a filter developed as part of the vascular network reconstruction [FRANGI et al., 1998] and implemented by Pierric in the iMorph software (Figure 1.7). The results showed the importance of using this filter to obtain a correct estimate of porosity in images with a resolution of less than 10 μm and in the presence of small channels. In the case of 19 μm child bone images, for example, the relative difference in the estimate of filtered and unfiltered porosity can reach more than 150% (Figure 1.7) !

This improved volume porosity estimation and improved geometric parameters of the vascular pores. This work was presented at the European Society of Biomechanics (ESB) congress in July 2017 in Seville and is the subject of a publication to be submitted to *Calcified Tissue International* in the near future.

These analyses were carried out both on anatomical pieces harvested from operating theatres or on corpses (tubular pieces Figure 1.7) and on parallelepipeds extracted from

the same pieces on which mechanical characterization tests will be carried out (see §1.1.3). This will allow us to :

- estimate the representativeness of the extracted blocks and the spatial heterogeneity of the poral network ;
- correlate the morphometric and mechanical properties of the tissue.

Anisotropy of the children cortical bone

One of the challenge in MALICE project and in the PhD thesis of Emmanuelle Lefevre, was to characterize the anisotropy of growing bone at mesoscale and microscale. The parallelepipedic samples are extracted from surgical waste. Due to their very little dimensions, the mechanical characterization of these samples by ultrasound methods or mechanical testing is thorny.

The parallelepipedic samples are tested through 3 different protocols :

- ultrasound transmission in the 3 directions of space ;
- resonant ultrasound spectroscopy ;
- nanoindentation.

Sample preparation and cutting is a major concern as the quality of the measurement depends strongly on the geometry and the surface states. We designed a dedicated sample holder adapted to the low-speed diamond-saw we used (Isomet 4000 - Buelher). This sample holder guarantees the parallelism of the opposite faces and the perpendicularity of adjacent faces.

Characterization by ultrasound transmission - A new experimental set-up has been validated to characterize millimetric parallelepipedic bovine bone samples (Figure 1.8, left). To deal with the small dimensions of the samples, we used pinducers mounted on a sample holder dedicated to small samples. The cortical bone samples were extracted from bovine bone. Several parallelepipeds were cut (between 2- and 10mm side). The set-up is immersed in a water tank and we evaluate the compression wave propagation velocities in the three dimensions of the sample and deduce the 3 first diagonal stiffness coefficients (C_{11} , C_{22} , C_{33} ; 1=radial,2=circumferential, 3=axial). Another experimental protocol was tested to assess the three stiffness coefficients linked with the shear waves propagation generated by shear transducers in contact (Figure 1.8, right).

FIGURE 1.8 – Experimental set-ups for ultrasound characterization of millimetric bone samples.

This preliminary study on bovine bone validated the experimental protocol to apply it on human bone samples, adults and children. The 6 diagonal stiffness coefficients were estimated (Table 1.1) and it seems that adult and children cortical bone tend to be transversely isotropic with $C_{33} > C_{11} = C_{22}$ et $C_{44} = C_{55} > C_{66}$ (1 = radial, 2 = circumferential and

3 = axial).

	Children (n=13) 6-18 yo (13 ± 4) Mean (STD)	Adults (n=16) 50-95 yo (75 ± 13) Mean (STD)	p-values

C ₆₆	3.0 (0.4)	3.6 (1.0)	0.017

TABLE 1.1 – Stiffness coefficients on fibulae. p-values obtained *via* Mann-Whitney test

This work was published in an international peer-reviewed journal [LEFÈVRE et al., 2015] (see Chapter 4 p.95).

These results were put in relation with the morphometry analysis led by Yohann Bala, this work was published in Journal of the Mechanical Behavior of Biomedical Materials in 2016 [BALA et al., 2016] (see Chapter 4 p.104).

Resonant Ultrasound spectroscopy characterization - During the PhD thesis of Marie Se-maan, we tried to complete the children bone stiffness tensor. We develop an experimental set-up inspired from Simon Bernard's work [BERNARD et al., 2013, 2015, 2016]. It was made at the LLMA in collaboration with Cédric Payan and Philippe Lasaygues. It was validated on reference materials and bovine bone samples presentind the same geometry (parallelepipedic) and the same dimensions (millimetric) as the children bone samples. Firstly we used RITA software developped by Pierre-Yves Lebas in Los Alamos based on the theory described in MIGLIORI et al. [1993]. The theoretical eigenfrequencies of the sample are calculated from its known dimensions and mass and making an assumption on the material properties (stiffness tensor C_{ij}). Then a data acquisition was done using shear transducers (Figure 1.9).

FIGURE 1.9 – Resonant ultrasound spectroscopy set-up.

The signal is analyzed to determine the frequencies of the recorded modes. The inverse problem for obtaining the complete tensor of the stiffness coefficients (C_{ij}) is then solved on the basis of a Levenberg-Marquardt scheme [LEBEDEV, 2002]. Cortical bone is

a highly heterogeneous material, which makes its resonance modes difficult to measure and identify, the results obtained with RITA have been found to be highly dependent on the (C_{ij}) values used to initialize the inverse problem resolution. These values are derived from the literature for adult bone [BERNARD et al., 2013] and child bone [LEFÈVRE et al., 2015] and hypothesizes on presumed bone anisotropy : orthotropic for adult bone and transverse isotropic for children bone.

During his post-doctorate, Pierric Mora developed under Python an ultrasonic resonance data inversion module incorporating the Bayesian approach to mode identification described in [BERNARD et al., 2015]. This probabilistic approach is well suited to small numbers and low occurrence, as is the case for our study. It is also called subjective probability, and is based on the consideration of knowledge. The Bayesian approach has shown that, despite a lack of information and incomplete data, it can solve many inverse problems. It differs from the standard statistical approach in that it allows results to be inferred with little information, at the cost of increased computation complexity.

The results obtained on adult bone are in perfect agreement with the literature and were presented at the 2017 European Society of Biomechanics (ESB) congress. The validated protocol was applied for the characterization of child bone. To my knowledge, this is the first time that complete rigidity tensor has been obtained on non-pathological children's bone samples, which represents a significant advance in the knowledge of the mechanical quality of the growing bone.

$$\begin{pmatrix} 16.6(0.8) & 10.3(0.8) & 10.8(0.9) & 0 & 0 & 0 \\ 10.3(0.8) & 16.6(0.8) & 10.8(0.9) & 0 & 0 & 0 \\ 10.8(0.9) & 10.3(0.8) & 24.2(0.7) & 0 & 0 & 0 \\ 0 & 0 & 0 & 4.4(0.4) & 0 & 0 \\ 0 & 0 & 0 & 0 & 4.4(0.4) & 0 \\ 0 & 0 & 0 & 0 & 0 & 3.13(0.07) \end{pmatrix} \text{ (GPa)}$$

This study confirms the anisotropy of children bone and indicates a trend to transverse isotropy (isotropic plane perpendicular to the bone axis). These results have been submitted as a Short Communication in the Journal of Biomechanics.

Nano-indentation - The cortical bone anisotropy is the result of the pore network orientation but also of the anisotropy of the bone matrix. To know the weight of each contribution would help to construct relevant homogenization models.

During Marie Semaan's PhD, we bought an instrumented nanoindentation device (NHT² Anton Parr) in order to characterize the growing bone at the microscopic scale. Using a tip of known geometry, we proceed to the indentation of the material by applying a given force. The Young's modulus is deduced from the penetration depth using the theory developed in OLIVER et PHARR [1992]. The test can be done in the three directions of space giving information on the anisotropy of the bone matrix independently of the pore network. At this scale, the bone tissue is composed of osteonal and interstitial tissues (Figure 1.10). The idea is to relate the mechanical parameters measured at this scale to mechanical properties at the mesoscopic scale obtained. L'idée est de relier les paramètres mécaniques ainsi mesurés aux propriétés mécaniques évaluées à l'échelle mésoscopique par méthodes ultrasonores. Ces mesures nécessitent une préparation des échantillons minutieuse et précise, pour cela nous avons conçu et développé un système de polissage qui assure à la fois le parallélisme des faces opposées et une qualité de surface suffisante pour mener les mesures de nanoindentation.

FIGURE 1.10 – Haversian structure of human cortical tissues. O : osteonal tissue ; I : interstitial tissue.

We validated the experimental protocol on bovine bone. Tests on adult and pediatric bones were performed. The evaluation of the indentation module requires statistical analysis on a large number of points, the characterization by nano-indentation of all collected samples took several months. A publication is in the process of being prepared and is expected to be submitted in early 2018.

Ultrasound therefore appears to be relevant diagnostic tools for bone pathologies. Their non-invasive, non-irradiating and non-ionizing characteristics are strategic criteria, particularly in paediatrics. Moreover, they are inexpensive and portable devices, which makes it possible to envisage a rapid use and patient's bed. These advantages can also be implemented in therapy, as ultrasound waves can also be involved in the treatment of biological tissues.

1.2 Ultrasound and biological tissues : therapeutic vector

Two experiments are discussed here : the first concerns the propagation of ultrasonic waves inside the skull and the second concerns the interaction of ultrasound with bone during regeneration.

1.2.1 Sonothrombolysis

From November 1,2006 to August 31,2007, I held a position as Temporary Teaching and Research Associate at Paris 7 University. I carried out my research at the Langevin Institute in collaboration with Jean-François Aubry (DR CNRS).

My study focused on controlling the safety of therapeutic practices using sonothrombolysis in the treatment of ischemic stroke.

There are two types of Cerebrovascular Accidents :

- 20% are haemorrhagic. Haemorrhage occurs when a cerebral artery bursts and lets blood flow into the brain, as the artery can be weakened by high blood pressure or birth defects.
- 80% are ischemic. Ischemia (thrombosis) occurs when a cerebral artery is blocked, and a blood clot (thrombus) is formed which prevents the brain from being irrigated. Diabetics and hypertensive patients are the main subjects since these diseases contribute to the thickening of the wall of the cerebral arterioles, sometimes up to the occlusion.

Stroke treatment with sonothrombolysis

Thrombolysis is used to treat the second type of stroke. It consists of breaking down blood clots chemically by injecting an anticoagulant drug (tissue plasminogen activator or tPA) intra-arterially.

Experimental studies have shown that emitting ultrasound through the cranium can increase the effectiveness of thrombolysis, i. e., accelerate the effect of the drug injected and thus the effectiveness of treatment administered to the patient with ischemia. This is called sonothrombolysis. To confirm these results and assess the risk and practicability of sonothrombolysis in humans, a clinical study was undertaken in patients with severe ischemic stroke [DAFFERTSHOFER et al., 2005]. Despite encouraging initial results, the occurrence of secondary cerebral hemorrhage in almost all (13 out of 14) patients treated with low-frequency ultrasound (300 kHz) tPA still raises doubts and raises questions about the experimental protocol to be adopted (transducer size, emission frequency, duration of emission, etc.).

The use of a numerical tool to simulate the propagation of ultrasound waves through the brain makes it possible to understand what causes these secondary cerebral hemorrhages and to explore alternative solutions to avoid them in the future.

Numerical simulation for the safety control of sonothrombolysis

The modelling of the acoustic properties of the skull, phase velocity, density and acoustic absorption, uses density data provided by X-ray images of cross-sectional sections of the skull from which a realistic 3D skull model can be reconstructed.

In order to carry out numerical simulations of ultrasonic wave propagation through the skull, a finite difference diagram is used to implement the wave equation in a fluid, taking absorption into account. To verify the validity of the modeling, the propagation of a plane wave emitted by the transducer array was simulated and compared to experimental signals with success [AUBRY et al., 2003].

The study was based on a comparison of two clinical studies conducted in patients treated with severe stroke : the first one named CLOTBUST combined an anticoagulant with ultrasound at a frequency of 2 MHz using a scanner-doppler [ALEXANDROV et al., 2004], The second, TRUMBI, accelerated the action of the anticoagulant by providing low-frequency ultrasound (300 kHz) [DAFFERTSHOFER et al., 2005]. In the first case, the results showed a beneficial effect of ultrasound in dissolving the clot, while the second case had to be interrupted because of adverse side effects (typical hemorrhages). Using the numerical tool briefly presented above, we tried to understand the phenomena involved in this treatment by sonothrombolysis. Once the absorption, density and velocity maps have been reconstructed to generate the 3D model of the skull, the finite difference code mentioned in the previous paragraph is used to solve the wave equation in an absorbent medium. Experimental conditions are reproduced as close as possible to reality : position and size of the transmitters, focal length, frequency and transmission time. By simulating the two clinical devices, we have identified acoustic cavitation phenomena (gas bubbles forming in areas of fluid depression) in the brain that may be responsible for secondary cerebral hemorrhage observed in the TRUMBI protocol. These zones of acoustic cavitation do not appear in the CLOTBUST study, at 2 MHz the ultrasonic energy is strongly absorbed during the skull crossing. Numerical simulations have shown the predominant role of skull shape in the appearance of stationary waves and the formation of *hot spot* (pressure peak). It seems therefore necessary to remain below the cavitation threshold, but it is necessary to know what the impact on the sonothrombolysis phenomenon

FIGURE 1.11 – Position of the negative pressure peak (red dot) and distribution of the ultrasonic field through the temporal windows a) right and b) left.

would be. After extensive literature review and discussions with clinicians who participated in the trial campaign, contradictions emerged regarding the pressure levels generated and emission parameters. The conclusions of my analysis on this subject are the subject of an article published in *Ultrasound in Medicine and Biology* in 2009 [BARON et al., 2009] (see Chapter 4 p.53).

1.2.2 Ultrasonic stimulation of bone regeneration

In 2012, I decided to do a new job that I had mentioned in my CNRS recruitment project. This involves understanding the mechanisms involved in ultrasonore stimulation of bone healing. Most of my work focuses on ultrasound as a diagnostic vector (mechanical characterization), I wanted to explore the potential of ultrasound as a therapeutic vector. When ultrasound is mentioned in the biomedical environment, ultrasound is immediately mentioned as an imaging tool. Ultrasound is also used in clinical routines to destroy kidney stones or tumor tissue. There is a clinically observed phenomenon that remains poorly understood : ultrasound stimulation of bone healing. The ultrasounds involved are low Intensity Pulsed UltraSound (LIPUS). The effect of ultrasound on tissue regeneration was demonstrated in the 1950s. Since the 1980s, several publications have studied this phenomenon in different processes of adaptation of the bone to its environment : growth [DUARTE, 1983] ; targeted remodeling [CHAN et al., 2006] ; healing [SCHORTINGHUIS et al., 2003]. In 1994, the FDA approved the use of this modality in clinical applications. An Exogen (Bioventus) home treatment device is now available on the market. However, although observed clinically and on animal models [HECKMAN et al., 1994; MAYR et al., 2000] and studied for more than 30 years, the ultrasound stimulation of bone healing remains poorly understood and the underlying physical mechanisms remain unclear. It is with the intention of filling this gap that I initiated a project in collaboration with Carine Guivier-Curien (MCF, IRPHE UMR 7342 CNRS Aix-Marseille Université) to develop a relevant numerical model that could provide answers on this theme.

Bone is a living material that has the ability to adapt to environmental stresses and repair itself in the event of a fracture through the bone remodeling process : a smart balance between the actions of osteoclasts (which destroy the bone) and osteoblasts (which build the bone), all driven by osteocytes (Figure 1.12).

In the case of a fracture, it is placed in diaphysis of the long bones (femur, tibia, radius etc.). So we always focus on the cortical bone. However, while in my previous work

Fig. 3. A schematic sketch representing the central role of osteocytes in bone remodelling. Osteocytes sense the mechanical load and subsequently produce signaling molecules like nitric oxide and prostaglandins that can regulate the activity of the effector cells, the osteoclasts and the osteoblasts, which subsequently leads to adequate bone mass and architecture. OB, osteoblast; OCL, osteoclast.

FIGURE 1.12 – From [KLEIN-NULEND et al., 2013]

I considered vascular porosity and its contribution to bone mechanics, the issue of bone remodelling also requires taking into account a second level of porosity. The bone will therefore be considered as a medium with double porosity (Figure 1.13) :

- vascular porosity : $\varnothing 100 \mu\text{m}$ contains blood vessels and nervesfs (see § 1.1.3.a) ;
- lacuno-canalicular porosity : $\varnothing 10 \mu\text{m}$ contains the osteocytes cbone cells, the cornerstone of mechanotransduction.

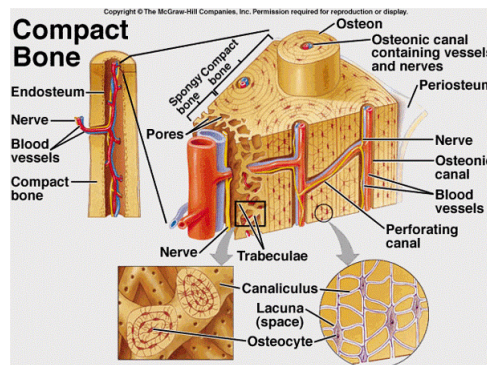

FIGURE 1.13 – Cortical bone as a medium with double porosity.

The lacuno-canalicular network is at the heart of our problem. Indeed, among the strong hypotheses formulated in the literature, the principle of ultrasonic stimulation of bone healing would be based on the generation of fluid shear stresses within the interstitial fluid bathing the osteocytes, which would trigger the osteocyte response and activation of bone remodeling.

The objective is to identify the *mechanical message* that osteocytes perceive as a result of LIPUS ultrasound stimulation. For this purpose, a two scale numerical model was developed with the collaboration of Vu-Hieu Nguyen and Salah Naili (MSME UMR 8208 CNRS UPEC UPEM, Créteil) under the commercial software Comsol Multiphysics. The challenge is to take into account a multiphysical and multi-scale phenomenon.

Two numerical models are implemented :

- the first one is 2D and represents the scale of the tissue (Figure 1.14 left),
- the second is 3D and represents an osteocyte lacuna and its idealized canalicules within the extracellular matrix (Figure 1.14 right)

FIGURE 1.14 – Models with mesoscopic (left) and microscopic scales (right). MPE : Poroelastic matrix.

At the tissue or mesoscopic scale - First of all, a 2D model is considered to simulate an ultrasonic stimulation equivalent to that induced by Exogen ($f = 1$ MHz, pressure = 67 kPa, duty cycle = 20 %, pulse duration = 1 ms, \varnothing transducer = 10 mm) over a single cycle of 1 ms and to measure the effects of ultrasound interaction with bone tissue (Figure 1.14 left). Bone tissue is represented here by a biphasic medium : a fluid (assimilated to water) in the vascular porosity (Havers canals) reconstructed from RX images and a poroelastic matrix (MPE) incorporating the contribution of lacunocanalicular porosity. The characteristics of this anisotropic and poroelastic material are taken from the literature [COWIN et al., 2009; NGUYEN et NAILI, 2012; SCHEINER et al., 2015]. The propagation of ultrasound through this poroelastic matrix is represented by a Biot model. The propagation of waves in porous media in the temporal domain has been implemented in Comsol in weak formulation by Vu-Hieu Nguyen. The surrounding soft tissues are modelled by a fluid domain surrounding the bone.

A pressure gradient in the interstitial fluid of the lacunocanalicular duct network between the endoste (bone to medular canal interface) and the periosteum (bone to surrounding soft tissue interface) is measured at the simulation output of the transducer axis (Figure 1.15). This value will be used as input data in the osteocyte model.

At the osteocyte scale or microscopic scale - A 3D model representing a single osteocyte included in the extracellular matrix is considered. There are three media (Figure 1.14 right) :

- in blue, the osteocyte composed of an ellipsoidal cell body and cylindrical tentacular ramifications modelled by an elastic solid (Young modulus $E = 4.47$ kPa, Poisson ratio $\nu = 0.3$)
- in yellow, the assumed linear and isotropic elastic extracellular matrix assumed to be linear and isotropic ($E = 16.6$ GPa, $\nu = 0.38$) The interstitial fluid that fills the space between the osteocyte and the matrix is presumed Newtonian (density $\rho = 997$ kg/m³, viscosity $\mu = 885 \times 10^{-4}$ kg. m⁻¹. s⁻¹).

The mesoscopic model provides an assessment of the pressure gradient induced by ultrasonic stimulation in the interstitial fluid. The microscopic model gives an estimate of the shear stresses generated by this pressure gradient and their distribution within the interstitial fluid.

FIGURE 1.15 – Acoustic pressure and interstitial fluid pressure (Pa). The pressure gradient of the interstitial fluid is evaluated between the 2 yellow dots.

Multiscale and multiphysics model - The pressure gradient in the interstitial fluid induced by ultrasonic stimulation was estimated at $30 \text{ Pa}/\mu\text{m}$. This pressure gradient would induce a maximum fluid shear stress of 6 Pa, consistent with recent publications [ANDERSON et al., 2005; VERBRUGGEN et al., 2016]. However, several factors have yet to be analysed :

- the simulation was carried out on an excitation cycle of 1 ms, but the treatment is usually 15 minutes or 900,000 cycles! a cumulative effect of cycle repetition can therefore be expected ;
- the properties of the bone matrix are those of a mature bone, but the protocol intervenes at different stages of healing and ultrasound therefore interact with tissues whose properties vary over time ;
- the geometry of the osteocyte is represented here by an ellipsoid of circular cross-section, but recent studies on human bone show a flatter shape in a more flattened direction [VARGA et al., 2015] ;
- the interstitial fluid behavior was assumed to be Newtonian.
- etc.

These limitations will be explored in the coming years (see § 2.1 p.25).

This work was presented at an international congress in July 2016 (European Society of Biomechanics Congress 2016, Lyon, France). The progress of this project was presented at 2 international congresses Interpore 2017 and ESUCB 2017 (European Symposium on Ultrasonic Characterization of Bone 2017).

Introduction

The work of the last 5 years has led to the multi-scale characterization of non-pathological child bones. The objective of this research was to provide a reference database to improve the diagnosis of bone pathologies and adapt therapeutic treatments. The idea was to give a point of comparison between a healthy bone and a bone with a pathology. Of course, there are still many things to explore, but we can consider that we have provided the first characteristic values defining the *quality* of children bone. These results can now be used to treat clinical problems related to bone remodelling such as fracture, bone distraction or bone metastases.

As mentioned in the previous chapter, ultrasound can be used as a diagnostic vector but also as a therapeutic vector : ultrasound modalities therefore have the potential for *theranostic*.

Although observed clinically, the effects of ultrasound on the bone regeneration process, for example in a fracture, remain poorly understood. There is no model that can explain the physical mechanisms that govern the activation of bone remodelling by ultrasound stimulation. The objective of this project is to understand these mechanisms in order to adapt the therapeutic device and eventually couple it with an ultrasonic evaluation system of the mechanical quality of the regenerated bone. The use of ultrasound is particularly strategic in paediatrics because of its non-irradiating and non-ionizing characteristics. In addition, ultrasonic devices are portable and low-cost. Thus, as is the case with Exogen (see § 1.2.2), treatment in the patient's bed or at home can be considered, which may be particularly recommended for young patients.

Designing an ultrasound theranostic device adapted to paediatric practice and capable of individualising treatment and diagnostic follow-up in real time : this is the challenge to which I have decided to contribute. In this chapter, we discuss the interaction of ultrasound with biological tissue **living** : that is, ultrasound alters the cellular processes of targeted tissue. This is an important paradigm shift. After studying how ultrasound **re-act** with bone tissue, in this case the question and answer are ultrasound and bone is *inerte*; I propose to analyze how ultrasound **act** on bone tissue, in this case the question is ultrasound and the answer is cellular, bone is *living*. **The cornerstone of this project is the understanding of the ultrasonic mechanotransduction of bone cells.** On this principle, several problems can be tackled on localized lesions : stimulation of fractural healing, stimulation of regeneration of large volume with biomaterial (hydrogel), treatment of bone metastases. In all cases, the aim is to stimulate or rebalance the bone remodeling process by means of ultrasonic mechanical stress.

2.1 Ultrasonic mechanotransduction of bone regeneration

Numerical model of ultrasonic stimulation of bone healing ultrasound stimulation

Improvement of the numerical model

As pointed out earlier the work started on ultrasonic stimulation of bone healing is a preliminary work that has highlighted the relevance of the development of a numerical model.

Objectives : To better understand the interactions of ultrasonic waves with bone tissue during healing. Numerical modeling (Comsol Multiphysics) and experimentation (mechanical and ultrasonic).

FIGURE 2.1 – Histology of a bone callus [CLAES et HEIGELE, 1999] and synchrotron images of the lacunocanalicular network (Creatis Lyon).

Many points are under consideration, some of which are as follows :

Mesoscopic scale

- Geometry and Materials - The first 2D model developed considers a section of long bone in a plane perpendicular to the axis of the bone. This geometry is associated with a material whose properties correspond to healthy and mature bone. In order to consider a more realistic bone callus geometry (Figure 2.1 left), I was inspired by the idealized model described by BAILÓN-PLAZA et VAN DER MEULEN [2001]; CLAES et HEIGELE [1999]. It is a 2D model in a plane containing the bone axis that takes into account the presence of a bony callus and distinguishes different tissues in its bosom (Figure 2.2).

FIGURE 2.2 – Geometry and composition of the bone callus.

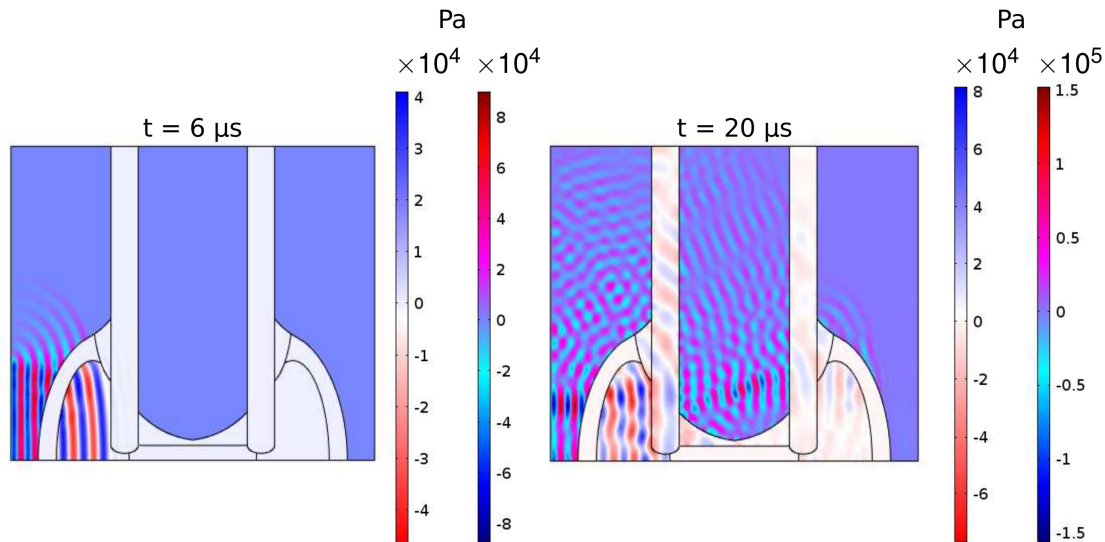

FIGURE 2.3 – Propagation of US waves in the bone callus.

The distribution of these different tissues represents the evolution of healing. One of the hypotheses made in the literature is that ultrasound stimulation occurs preferably at the beginning of the healing process and is not very much in the consolidation phase. To explore this hypothesis, I will consider different distributions of scar tissue representative of different healing phases. The interaction of LIPUS-type ultrasonic waves on these evolutionary configurations can be studied and the effects of ultrasonic stimulation at which stage are most pronounced. I will then use histological sections or high-resolution imaging on animal models (proposed by Kay Raum, Charité - Universitätsmedizin Berlin) to reconstruct the geometry and composition of the bone callus. Other characteristic properties of biological tissues can also be integrated to enrich the model and explore other mechanisms. The absorption of healing tissue, bone and surrounding soft tissues as well as the piezoelectricity of the bone will be taken into account in the near future.

- Pulsed waves - Another important aspect that requires digital developments is the consideration of the 15-minute processing time, i. e. the repetition of 900,000 cycles and the possibility of a cumulative effect.
- Cell Dynamics - It may also be considered to couple this model with cell differentiation models [GONZÁLEZ-TORRES et al., 2010; ISAKSSON et al., 2007; PRENDERGAST et al., 1997]. However, the time scales are different, 15 minutes for ultrasound treatment compared to several weeks for cell dynamics. The numerical model must therefore be rethought in this direction. This is the subject of a reflection with Jean-Louis Milan, senior lecturer in my team and specialist in the modelling of cellular mechanics. Dynamique cellulaire -

Microscopic scale

- Geometry and mechanics of the osteocyte - The osteocyte model that I developed with Carine Guivier-Curien (IRPHE UMR 7342 CNRS Aix-Marseille Université) is very simplified (cf. § 1.2.2). For example, recent morphometric studies carried out on human bone can be used to improve it, which define more precisely the dimensions of the osteocyte deficiency [VARGA et al., 2015]. However, these studies were not carried out on child bones. It would be interesting to do that. To do this, I contacted Felix Ricoh (U1006 INSERM / Aix-Marseille University) who is a specialia-

list in atomic force microscopy (AFM) on cells. Drawing inspiration from the work of LIN et XU [2011] we plan to make AFM images of the lacuno-canalicular network of the child bone and also to evaluate the mechanical properties (Young's modulus) of the osteocyte and the extracellular matrix according to the 3 directions of space.

- Morphometry of the lacunocanalicular network - Another aspect to be taken into account is obviously the effect of the lacunocanalicular network (Figure 2.1), the osteocyte is not isolated in the extracellular matrix but connected to several dozen other osteocytes. During the presentation of my work at the IBDW/ESUCB (International Bone Densitometry Workshop and European Symposium on Ultrasonic Characterization of Bone) congress in June 2017, Françoise Peyrin (CREATIS INSA Lyon) proposed me to provide me with high-resolution images of the lacunocanalicular network. We have received these images and are exploiting them. This offers the possibility to make a morphometric study using the iMorph software and tools developed by Pierric Mora (see § 1.1.3. a.) and to study the behaviour of the fluid in this network using the Comsol Multiphysics software.
- Evaluation of the permeability of the lacuno-canalicular network - The value of the permeability of this porous network remains subject to controversy and a major challenge for the modelling that I am developing. Permeability is a key parameter for understanding mechanotransduction, as it reflects both the structure of the environment and the mechanisms of living organisms. A traditional method of experimental permeability measurement is based on Darcy's law. This involves measuring the volume of fluid passing through a porous layer and dividing it by the pressure gradient generated through the layer. To date, this measure is inaccessible in the lacuno-canalicular network. The permeability is thus estimated by theoretical or experimental approaches coupled with numerical/analytical models and varies between 10^{-17} and 10^{-25} m² [CARDOSO et al., 2013]. Recent advances in X-ray imaging provide a better estimate of the morphometry of the 3D lacuno-channel network and thus improve flux modeling. The iMorph software developed by Jérôme Vicente is already used for estimating permeability in foams and clays and could be adapted to the estimation of permeability of the lacuno-channel network. I am also in contact with Jean-Philippe Berteau, who is based at the City University of New York in the department of Professor Stephen Cowin, who passed away this year. Professor Cowin's team is one of the specialists in poroelasticity of bone and the evaluation of its permeability. I took part in the symposium in Rotterdam last May (Interpore 2017) to commemorate his memory. I met Luis Cardoso, professor at the City College of New York and head of the Department of Biomedical Engineering, who is a close collaborator of Stephen Cowin. Collaborating with them on ultrasound stimulation of bone healing would be an opportunity to seize.

Once the model is validated, we can then proceed with an optimization of the ultrasonic parameters. Indeed, the parameters used by Exogen are *historical*. A few studies *in vitro* or *in silico* have explored the influence of excitation frequency or delivered intensity, but to date the optimization of ultrasonic stimulation parameters for bone healing remains to be carried out.

To continue this work, I intend to propose very soon a thesis subject in co-supervision with Vu-Hieu Nguyen (MCF-HDR). I am also in contact with Guillaume Haiat who is interested in ultrasonic stimulation for the integration of dental implants.

2.1.1 Ultrasonic stimulation of bone regeneration of distracted bone in the presence of a hydrogel

This project has also found a place in the DEFI CNRS REPOUSSE carried out by Martine Pithioux (ISM UMR 7287 CNRS Aix-Marseille University) since January 2016 on the regeneration of large bone volume supported by the implantation of a biomimetic periosteal hydrogel (osteoprogenital membrane surrounding the bone) and ultrasonic stimulation of the repair process. In this project, ultrasound no longer only interacts with regenerating bone tissue but also with biomimetic material. The aim is to optimize the structure of the biomaterial to make it sensitive to ultrasonic stimulation and thus guide cellular processes : colonization, proliferation, differentiation and to adapt ultrasonic parameters to promote bone regeneration. Based on the network of collaborations initiated by this project, a funding request has been submitted for the ANR 2018 campaign.

Numerical model

The numerical model will be strongly inspired by the one developed to study the interaction of ultrasound with a bone fracture without biomaterial (see § 2.1). It remains to define the mechanical and structural properties of biomaterials in order to integrate them in a relevant way. Concerning the design of the biomimetic hydrogel, it is envisaged to design a porous structure with controlled gradient, I will be able to use the models that I developed on the propagation of ultrasonic waves in media with gradient properties (see § 1.1.2).

In-vitro experimental model

A first simple microfluidic model will be designed in collaboration with Laurent Malaquin of LAAS (UPR 8001 CNRS Toulouse) to get an idea of the phenomena induced by the interaction of millimetre wavelength ultrasonic waves with micrometric fluid channels. Literature on the subject is scarce.

Subsequently, an idealized osteocyte deficiency model should be realized by 3D fabrication (LiPhy UMR 5588 CNRS Université Grenoble Alpes and INSA Lyon).

The challenge is to couple a submicrometric resolution and a Young's module matrix comparable to that of the extracellular matrix (15-20 GPa). To do this, we plan to proceed in 2 steps, a first mould will be made with LiPhy (UMR 5588 CNRS Université Grenoble Alpes) in order to reproduce the osteocyte ellipsoidal deficiency and the cylindrical canaliculi, then this mould will be coated in a ceramic matrix and then dissolved to create an osteo-canalicular cavity. A first step has already been explored at LiPhy (Figure 2.4).

Initially, this cavity will be filled with fluid (water) and subjected to ultrasonic excitation of the LIPUS type. The measurements would be carried out externally. In parallel, in collaboration with Thierry Leïchle from LAAS (UPR 8001 CNRS Toulouse), we are thinking about miniaturized devices that can be implanted in the cavity.

Another aspect that we would like to explore with Laurent Malaquin and Thierry Leïchlé is the piezoelectric characteristic of bone that could be used to make it an active element of measurement and excitation.

Later, we will also explore the interactions of LIPUS ultrasound with the hydrogel developed by Romain Debret and Jérôme Sohier at LBTI (UMR 5305 CNRS Université Claude Bernard Lyon 1) within a bioreactor.

FIGURE 2.4 – 3D fabrication of idealized osteocytes by Olivier Stefan (LiPhy UMR 5588 CNRS Université Grenoble Alpes).

Animal model

As has been reported several times in the literature, [PADILLA et al., 2014], the phenomena induced by ultrasonic stimulation *in vitro* are very different from the phenomena *in vivo*. This is why it is particularly interesting to compare the numerical results with an animal model for validation and optimization. As mentioned above, our team develops an animal model (Sprague-Dawley rat) to understand the process of bone healing during a distraction (= lengthening). We are in contact with Bioventus, which commercializes the Exogen system so that they can provide us with a device that we could test on distracted rats and study the effects of ultrasonic stimulation on wound healing. Once this step has been validated, I plan to start a patient study in collaboration with the orthopaedic surgeons of the APHM who are members of our team (Pr Franck Launay).

2.1.2 Ultrasonic theranostic device

The next step is to couple a diagnostic device capable of estimating the repair stage of the bone lesion (fracture, distraction, metastasis). This is the subject of a project on which I am collaborating with Philippe Lasaygues (LMA UPR 7051 CNRS Marseille) on ultrasound tomography applied to the child's bone. On this subject, we supervised together the end-of-study internship of Jules Plisson (student engineer at ENSIM, Le Mans) from April to August 2017. I am developing a numerical model (Comsol Multiphysics) based on the characteristics of its experimental US tomography antenna protocol developed at the LMA. The idea is to optimize the experimental configuration and to couple the acquisition method with an inversion method developed in the geophysical field by Dimitri Komatitsch (LMA UPR 7051 CNRS Marseille). This will not only improve the detection of lesions, but will also make it possible to characterize them. This will result in a more quantitative diagnosis of bone quality and will make it possible to adapt the treatment to the best of your ability. The numerical model will also provide a better understanding of experimental signals, which will contribute to improving the signal processing routines used. After validation *in vitro*, the model will make it possible to take into account all the complexity of the *in vivo* configuration (presence of soft tissue, paired bone, osteosarcoma). Coupling this imaging modality with ultrasound stimulation of bone regeneration is the subject of a letter of intent to the ANR.

2.2 Ultrasonic mechanotransduction of bone metastases

Improving bone healing in fractures is one illustration of the **mechanotransduction** phenomena induced by ultrasonic application. This principle can be applied in the case of regeneration of large volumes of bone in the presence of biomaterials (see § 2.1.1) but also to treat other pathologies resulting in local lesions linked to dysfunctions of bone remodeling.

It is on the basis of this reflection that I proposed a project which obtained funding from the Mission pour l' Interdisciplinarité du CNRS : SUBITO pour Stimulation Ultrasonore Basse Intensité pour la Thérapie Osseuse : application au traitement des tumeurs.

Objectives : Characterize the interactions of ultrasound waves with metastatic bone : from tissue to the cell. Numerical modeling (Comsol Multiphysics) and experimentation on cellular cultures (mechanical and ultrasonic).

This translational and interdisciplinary project will focus on the treatment of bone tumours by low intensity ultrasound stimulation (LSU) applied before and/or after resection. To do this, we need to understand the multiphysical and multi-scale mechanisms that underlie the tissue and cellular responses of bone to ultrasound to control them and design an innovative therapeutic tool that can be used in both adult and pediatric oncology. The project brings together acousticians (Philippe Lasaygues, LMA UPR 7051 CNRS), physicists (Felix Rico and Nicolas Buzhinsky, BioAFMLab, U1006 INSERM Aix-Marseille University), biomechanists (Carine Guivier-Curien, IRPHE UMR 7342 CNRS Aix-Marseille University) and biologists (Jean-Claude Scimeca et David Momier, iBV UMR 7277 CNRS Inserm Université Côte d'Azur). It includes a numerical modelling component and an experimental component *in vitro*.

2.2.1 Metastases and bone remodelling

Bone tumours interfere with bone (re)modelling and cause significant bone fragility resulting in severe skeletal events (fractures, spinal compression, bone marrow aplasia). Combating the weakening of bone resistance and promoting bone reconstruction after resection are key issues in the treatment of cancer. The effect of ultrasound on bone metastases as a therapeutic vector is poorly understood and deserves to be explored. A recent article analyzes the effects of LIPUS ultrasound stress on cancer cells and concludes on the beneficial potential of ultrasound in this configuration [SAWAI et al., 2012]. This trend also appears to be confirmed by the thesis work of Sophie Tardoski (Universté Claude Bernard - Lyon 1) [TARDOSKI, 2015].

2.2.2 Ultrasonic mechanotransduction : from tissue to cell

The model I am developing for ultrasound stimulation of bone healing can be adapted to study the interaction between ultrasound and bone metastases. This model will integrate (i) the propagation of waves in bone, a poroelastic material ; in soft tissues, viscous fluids and in biological fluids (marrow and blood) ; (ii) fluid-structure interactions at the cellular scale. It will provide an evaluation of the mechanical stimulus applied to bone cells according to ultrasonic parameters (frequency, intensity, cycle, duration). The biological reaction thus stimulated will be studied *in vitro* on cell culture. The project will explore the adaptation of the SUBI protocol for bone regeneration to the treatment of bone

tumours. Original protocols will be implemented combining the emission of US and co-culture of bone cells with tumour cells. Cell culture will be carried out on human cells of different types : Osteoclasts and osteoblasts : cells responsible for bone resorption and apposition respectively ; a mammary carcinoma line (MDA-MB-231) and its subclone with bone tropism (MD-231BO). The objective is to establish a link between ultrasound parameters and the response of bone and tumour cells. We will measure viability/proliferation (counting, MTT/XTT) and cell genotype/phenotype (transcriptome/proteome quantification, immuno-chemical markings). In parallel, we will carry out a mechanical characterization of the adhesion conditions of tumour cells subjected to ultrasonic stimulation by atomic force microscopy. It is also envisaged to study the effect of US in addition to bisphosphonate (Bps) therapy in breast cancer patients (the iBV partner already has bio-materials loaded with BPs that can be used as a culture medium). The challenge is two-fold : to link the ultrasound parameters imposed at the tissue level with the constraints perceived by bone cells on a microscopic scale and to optimize ultrasound parameters to promote bone reconstruction without causing cancer cells to proliferate.

Conclusion

Twelve years after my thesis, I am still working to use ultrasound for living organisms and contribute to the development of a theranostic clinical application. These few pages describe ultrasonic wave interactions with bone tissue, a complex, heterogeneous, heterogeneous, anisotropic, multi-scale and **living** material. Ultrasound is discussed as a tissue-scale diagnostic tool (characterization) and ultrasound as a therapeutic vector, triggering cellular reactions (mechanotransduction). The experiments summarized here, from the diagnosis of osteoporosis to ultrasound mechanotransduction of bone and the characterization of growing bone, have brought about a paradigm shift by introducing the purpose of clinical application and shifting priorities. For the hospital practitioner, the priority is to treat. For the researcher, the priority is to understand. Can we cure without understanding? Of course! but the ambition is to understand for **better** treatment : a better characterization of bone lesions will allow a better therapeutic management, more adapted to the patient; an enlightened description of the ultrasonic mechanotransduction will ensure a relevant dosage of the stimulation by ultrasound; the control of these elements will then open the field of possible and one will be able to envisage other applications. Over the years, I have collaborated with clinicians, biologists, physicists, biomechanics and acousticians whose disciplines, when they meet, advance knowledge.

To understand in order to better cure such is the challenge of my research today.

3.1 Curriculum Vitae

CNRS

- 2010 - **Chargée de Recherche**
 Groupe Interdisciplinaire de Biomécanique des systèmes Ostéoarticulaire et Cardiovasculaire (GIBoc) Institut des Sciences du Mouvement - Etienne-Jules Marey (UMR 7287) - CNRS/Aix-Marseille Université.
Recherche : caractérisation mécanique de l'os en croissance. Interaction des ondes élastiques ultrasonores avec des milieux hétérogènes et en particulier les tissus biologiques : theragnostic.
Mots-clés : biomécanique, propagation d'ondes, milieux hétérogènes, multi-échelles, tissus biologiques, simulation numérique.
Congé parental du 19 janvier au 19 juillet 2013 (6 mois).

Université

- 2008 - 2010 **Maître de conférences en mécanique à l'Université Pierre et Marie Curie (Paris 6)**
 Equipe Modélisation, Propagation et Imagerie Acoustique - Institut Jean le Rond d'Alembert (UMR 7190) - CNRS/UPMC Paris 6.
Propagation d'ondes élastiques guidées dans un tube anisotrope et hétérogène : application à la caractérisation de la fragilité osseuse.

PostDoctorat

- 2007 - 2008 **Attachée Temporaire d'Enseignement et de Recherche**
 Laboratoire de Modélisation et Simulation Multi échelle (UMR 8208) - CNRS/Paris Est.
Réponse d'une plaque continûment variable immergée dans un fluide : application à la caractérisation ultrasonore de l'os cortical.
 Collaboration : Salah Naili.
- 2006 - 2007 **Attachée Temporaire d'Enseignement et de Recherche**
 Institut Langevin - Ondes et Images (UMR 7587) - CNRS/Paris 7.
Contrôle de l'innocuité de la sonothrombolyse dans le traitement des accidents vasculaires cérébraux ischémiques par simulation numérique.
 Collaboration : Jean-François Aubry, Mickael Tanter.
- 2005 - 2006 **Post-doc CNRS**
 Laboratoire d'Imagerie Biomedicale (UMR 7371) - CNRS/UPMC.
Etude de l'impact de la porosité sur le comportement élastique de l'os cortical en vue de l'évaluation de la fragilité osseuse. Elaboration d'un modèle numérique de l'os cortical : étude de l'interaction de l'os et des ondes ultrasonores.
 Collaboration : Maryline Talmant, Quentin Grimal, Pascal Laugier.

Doctorat

2002 - 2005	Thèse en mécanique université Bordeaux 1. Institut de Mécanique et d'Ingénierie (UMR 5295) - CNRS/Bordeaux 1. <i>Le développement en série de Peano du matricant pour l'étude de la propagation des ondes élastiques en milieux à propriétés continûment variables</i> Directeur : Marc Deschamps; encadrants : MM. O. Poncelet et A. L. Shuvalov. http://tel.archives-ouvertes.fr/docs/00/11/39/51/PDF/These.pdf

(Received 16 March 2007; revised 12 June 2007; accepted 21 June 2007)

Finite-difference time domain (FDTD) numerical simulations coupled to real experimental data were used to investigate the propagation of 1 MHz pure bulk wave propagation through models of cortical bone microstructures. Bone microstructures were reconstructed from three-dimensional high resolution synchrotron radiation microcomputed tomography (SR- μ CT) data sets. Because the bone matrix elastic properties were incompletely documented, several assumptions were made. Four built-in bone matrix models characterized by four different anisotropy ratios but the same Poisson's ratios were tested. Combining them with the reconstructed microstructures in the FDTD computations, effective stiffness coefficients were derived from simulated bulk-wave velocity measurements. For all the models, all the effective compression and shear bulk wave velocities were found to decrease when porosity increases. However, the trend was weaker in the axial direction compared to the transverse directions, contributing to the increase of the effective anisotropy. On the other hand, it was shown that the initial Poisson's ratio value may substantially affect the variations of the effective stiffness coefficients. The present study can be used to elaborate sophisticated macroscopic computational bone models incorporating realistic CT-based macroscopic bone structures and effective elastic properties derived from μ CT-based FDTD simulations including the cortical porosity effect. © 2007 Acoustical Society of America. I. INTRODUCTION

Quantitative ultrasound has received considerable interest in recent years for its potential to assess different bone properties that are relevant to predict bone fragility.

Axial transmission is a generic term to designate a variety of techniques devised to assess cortical bone using a linear arrangement of ultrasound emitters and receivers placed on top of the overlying soft tissue. A part of the ultrasonic energy is guided along the cortex and can be radiated at the interface between soft tissue and bone. Various technical implementations of the technique have been proposed at different frequencies in the range 250 kHz–1.25 MHz.^{1–4}

Several wave types contribute to the total pressure field sensed by the receivers. The first arriving signal (FAS) is of special interest for *in vivo* assessment of cortical bone because it arrives prior to all other contributions, and therefore, can be easily determined from time-of-flight measurements of the signals received at different positions parallel to the interface.⁵ The nature of the wave associated with the first arriving signal was found to change with increasing cortical thickness to wavelength ratio (Cort.Th/ λ) from an S_0 Lamb mode for Cort.Th/ $\lambda \ll 1$ to a lateral wave for Cort.Th/ $\lambda \gg 1$.⁶

Recently, axial transmission approaches have been described that work in a low frequency range and exploit a later

arriving signal, a slow guided wave mode, in addition to the FAS.^{4,7,8} This guided wave mode is well described by the theory for guided waves in plate [fundamental antisymmetric (or flexural) guided wave].²

Clinical trials revealed the ability of these techniques in discriminating normal and osteoporotic subjects.^{1,8,9} Clinical performances were enlightened by *in vitro* experiments. Experimental studies on excised human radii demonstrate the sensitivity of FAS velocity to porosity and degree of mineralization⁵ and also to intrinsic elastic properties.¹⁰ In addition, the velocity of the fundamental antisymmetric guided wave shows an exquisite sensitivity to cortical thickness.^{11,12}

Another approach used to give insight into clinical performances is the modeling of ultrasound propagation in axial transmission configuration. Bone finite-difference time domain (FDTD) studies, using either a generic model of the structure (plate or tube models)^{6,12} or bone structures reconstructed from three-dimensional x-ray tomography data, provided valuable insights into the relationships between ultrasound propagation characteristics (e.g., velocity of FAS or flexural mode) and bone properties such as cortical thickness and porosity. However, in these previous works, the models ignore the true local material properties, generic values were used instead.

We assume that the prediction capabilities of the computed tomography (CT) based finite-difference simulations may be enhanced with further refinements such as incorporating in the model individualized material properties.

^{a)}Electronic mail: norabelic@yahoo.fr

Bone is a poroelastic medium with a porous network filled with a fluid-like medium (marrow) embedded in an elastic tissue matrix. Cortical porosity mainly consists in an oriented network of Haversian canals of typically $50\ \mu\text{m}$ diameter approximately aligned with the long axis of the bone and of resorption cavities around $50\text{--}200\ \mu\text{m}$ in diameter. At a smaller scale, small transverse canaliculi and osteocytes lacunae (typically less than $10\ \mu\text{m}$ diameter) also contribute to cortical porosity. Each Haversian canal is surrounded by a layered cylindrical structure, called osteon, of typically $200\ \mu\text{m}$ diameter and between the osteons is the highly mineralized interstitial tissue. The wavelength in axial transmission is much longer than the typical size of these structures and the material properties required as input into the bone computational models are effective properties, the values of which are determined by the anisotropic elastic properties of the bone tissue matrix and by the oriented cortical porosity. First, the presence of pores inside the cortex induces a decrease of whole bone stiffness and density compared to stiffness and density of the bone matrix.¹³ Second, due to its preferential orientation, the porous network contributes to the mechanical anisotropy of bone.¹⁴ Progress in CT-based FDTD models requires knowing the effective individual material properties in which the effects of both cortical porosity and anisotropic elasticity are properly taken into account.

Scarce data on porosity-related anisotropic stiffness can be found in literature. Several experimental studies have investigated the impact of porosity on the longitudinal Young's modulus.^{15–18} As these studies were reduced to axial direction, they did not provide any information on the contribution of porosity to the anisotropy. A few studies, based on experiments or micromechanics models have examined the dependence of effective anisotropic stiffness coefficients on tissue properties and especially on porosity. Dependence on porosity of four elastic moduli of cortical bone assumed to be transversally isotropic has been reported in a single experimental study.¹³ Micromechanics provided comprehensive models of effective elastic properties of bone using various hypotheses to describe elastic properties of the bone matrix and the pore network.^{14,19} In particular, Sevostianov *et al.*¹⁴ have depicted the effect of porous network on overall stiffness coefficients of cortical bone assuming an isotropic bone matrix and identifying the effect of pore distribution. In the related field of composite media with unidirectional pores, a similar analysis was performed by Ichitsubo *et al.*²⁰ with an anisotropic matrix.

In this study, we report on microcomputed tomography (μCT) based FDTD simulations whereby the effective elastic properties are directly computed for individualized porous network of 19 cortical bone microstructures reconstructed from high resolution synchrotron radiation microtomography (SR- μCT). The bone matrix was modeled as a homogeneous anisotropic medium. As the elastic properties of the bone matrix were only partially documented in our samples, four built-in models were used for each specimen. The computational bone model for ultrasonic propagation in bone and the basis of the SR- μCT -based FDTD simulations are described in Sec. II. In Sec. III the results of the effective elastic prop-

erties are examined as a function of porosity for the different bone models. We close with a discussion of the limitations and potential extension of the current study.

II. MATERIALS AND METHODS

A. Samples

In this study we use a subset of 19 samples from a collection of human radii with soft tissue removed and previously assessed by different experimental techniques such as SR- μCT and scanning acoustic microscopy (SAM), which provided accurate data for cortical bone microstructure and estimates of material properties (density, stiffness) that were used to build the cortical bone models developed in the present paper.

Assessment of the microstructure was reported in Ref. 5. Small portions were cut in the postero-lateral zone of the distal radius. The dimensions were typically 10 mm long in the direction parallel to the bone axis and 8 mm long in the circumferential direction. These volumes were imaged by SR- μCT ²¹ at the European Synchrotron Radiation Facility (ESRF, Grenoble, France). The radiographs [two-dimensional (2D) projections] were recorded on a 1024×1024 charge-coupled device-based 2D detector and the voxel size was set to $10 \times 10 \times 10\ \mu\text{m}^3$. From sets of 2D projections under different angles of view, three-dimensional reconstructions of the microstructure were obtained by tomography algorithm. The amount of mineral was $1082 \pm 16\ \text{mg}/\text{cm}^3$ in the whole collection of samples.

Among the 19 samples considered in this study, 10 were previously studied by scanning acoustic microscopy at 50 MHz with a spatial resolution of $23\ \mu\text{m}$ and a spatial sampling rate of $20\ \mu\text{m} \times 20\ \mu\text{m}$.²² The section adjacent to the samples investigated by SR- μCT was scanned and a mapping of the acoustic impedance was provided. It was shown that the setup resolved Haversian canals larger than $25\ \mu\text{m}$. As a consequence, these measurements were representative of the impedance of the bone matrix at a scale of $20\ \mu\text{m}$. The acoustical impedance averaged over the whole set of specimens was found to be $8.1 \pm 0.5\ \text{MRa}$.

B. Configuration of the simulation

Propagation of transient 1 MHz plane waves in the 3D reconstructed bone microstructures was computed using a FDTD code, SIMSONIC, developed in the laboratory and detailed elsewhere,^{6,23} which computes a numerical solution to the 3D linear elastic wave propagation. The algorithm is based on Virieux scheme,²⁴ and uses first-order derivative in space and time.

The code requires the simulation box to be defined as right angle volume. Therefore, parallelepipedic volumes were extracted from the 3D SR- μCT reconstructed volumes (Fig. 1). The volume of the blocks analyzed in simulation with a spatial step of $20\ \mu\text{m}$ varies from 9 to $36\ \text{mm}^3$, depending on the thickness of the sample.

A combination of symmetric boundary conditions (tangential velocities equal on both sides of the boundary and normal velocities null on the boundary) and/or antisymmetric boundary conditions (tangential velocities null on the bound-

FIG. 1. Three-dimensional porous network (pores are in grey) in a parallel-pipedic block extracted from the μ CT reconstructed bone structure. On the right-hand side are shown a transverse and longitudinal cross section through the three-dimensional porous network. The preferential orientation of the pores is along the bone axis.

ary and normal velocities equal on both sides of the boundary) on the simulation domain was applied to ensure the propagation of compression and/or shear plane bulk waves. Perfectly matched layers (PML) on sides and edges of the simulation domain were used to avoid unphysical reflections.²⁵

SimSonic provides the transient signals associated with transmission of 1 MHz bulk compression or shear waves through the reconstructed volumes. Typical signals are shown in Fig. 2. Plane bulk waves velocities were deduced from time of flight measurements by detection of first signal maximum.

C. Derivation of effective stiffness

Effective stiffness coefficients were derived from velocities of simulated pure bulk wave propagating in principal directions and from effective mass density. For cortical bone the general degree of anisotropy is that of orthotropic material symmetry,²⁶ which is characterized by nine independent stiffness coefficients. The stiffness matrix can be expressed as follows using the abbreviated subscript notation:²⁷

FIG. 2. (Color online) Velocity evaluation from the first maximum signal detection.

$$C = \begin{pmatrix} c_{11} & c_{12} & c_{13} & 0 & 0 & 0 \\ c_{12} & c_{22} & c_{23} & 0 & 0 & 0 \\ c_{13} & c_{23} & c_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{66} \end{pmatrix} \quad \begin{array}{l} X \leftrightarrow 1 \\ \text{with } Y \leftrightarrow 2, \\ Z \leftrightarrow 3 \end{array} \quad (1)$$

where the X direction corresponds to the radial direction (i.e. thickness direction), the Y direction is the circumferential direction, and the Z direction is along the bone axis. But, as described by Katz,²⁸ the Haversian cortical bone is transverse isotropic in nature because of the locally uniaxial architecture of osteons. Consequently, numerous studies^{29–31} assumed the cortical bone as a transverse isotropic elastic solid medium, which reduces the number of independent coefficients of the stiffness matrix to five. Considering transverse isotropy with (XY) as the isotropic plane,^{32–34} the stiffness coefficients of C verify $c_{13}=c_{23}$, $c_{22}=c_{11}$, $c_{44}=c_{55}$, and $c_{66}=(c_{11}-c_{12})/2$.

When the waves propagate along principal directions of symmetry, the diagonal terms of the stiffness matrix c_{11} , c_{12} , and c_{33} are related to the phase velocity of compression-bulk wave which propagates along the X , Y , and Z direction, respectively, with

$$V_x = \sqrt{\frac{c_{11}}{\rho}}, \quad V_y = \sqrt{\frac{c_{22}}{\rho}}, \quad V_z = \sqrt{\frac{c_{33}}{\rho}}. \quad (2)$$

The stiffness coefficients c_{44} and c_{55} are related to the phase velocity of shear wave which propagate in Z direction and c_{66} in the transverse plane according to

$$V_{yz} = \sqrt{\frac{c_{44}}{\rho}}, \quad V_{xz} = \sqrt{\frac{c_{55}}{\rho}}, \quad V_{xy} = \sqrt{\frac{c_{66}}{\rho}}. \quad (3)$$

The effective stiffness coefficients were deduced from Eqs. (2) and (3) calculating the effective mass density ρ with the following rule of mixture:

$$\rho = \rho^0(1 - p) + p\rho_w, \quad (4)$$

where ρ^0 is the mass density of the tissue matrix, ρ_w is the mass density of the fluid filling the pores (water), and p is the porosity.

D. Numerical bone models

Maps of the mass density and of the stiffness coefficients were used as input data in the software. The cortical bone was modeled as a two-phase medium constituted by the bone matrix and the fluid filling the pores. Each phase was supposed to be homogeneous within and between the samples. The spatial variation of density and stiffness in the simulation volume (spatial step of 20 μ m) relies on the presence of the pores. Both components were clearly delineated by segmentation of the original reconstructed SR- μ CT data and were defined by fixed mass density and stiffness coefficients.

TABLE I. Four bone matrix models.

	c_{33}^0 (GPa)	c_{11}^0 (GPa)	c_{33}^0/c_{11}^0	c_{13}^0/c_{11}^0	c_{55}^0/c_{11}^0	c_{66}^0/c_{11}^0
Model 1	34.3	34.3	1	0.43	0.29	0.29
Model 2	34.3	30.6	1.12	0.42	0.34	0.29
Model 3	34.3	27.3	1.26	0.42	0.38	0.31
Model 4	34.3	22.9	1.5	0.41	0.45	0.30

Ideal nonviscous fluid (water) was assumed to fill the pores. The mass density was ($\rho_f=1 \text{ g/cm}^3$), and the stiffness coefficients were calculated from the following Lamé's constants values ($\lambda=2.25 \text{ GPa}$, $\mu=0 \text{ GPa}$).

Simulations in each bone sample microstructure were conducted with four different models of bone matrix shown in Table I. For the isotropic case (model 1), two independent stiffness coefficients are required (c_{33}^0 , c_{13}^0) to define the elasticity of the bone matrix, and in the three transversely isotropic models (models 2–4), five independent stiffness coefficients are needed (c_{11}^0 , c_{33}^0 , c_{55}^0 , c_{13}^0 , and c_{12}^0). Here, the subscript zero is used to denote the intrinsic stiffness of the tissue matrix.

In all the models, the axial stiffness c_{33}^0 was taken close to 34 GPa, the overall mass density ρ^0 of the bone matrix mass 1.91 g/cm^3 . These values were derived from SR- μ CT and SAM data averaged over the samples that were investigated with these techniques. In Ref. 22, the mass density of the solid matrix was related by a second-order polynomial fit to the mineral amount. According to this, the mass density in our study was approximated to a value of 1.91 mg/cm^3 , considering the mean value of mineralization previously measured and neglecting the intersample variations. The axial stiffness $c_{33}^0=34.3 \text{ GPa}$ was derived from acoustic impedance ($Z=8.1 \text{ MRa}$) values measured at 50 MHz, with a resolution of $23 \mu\text{m}$ well adapted to spatial grid of the simulation ($20 \mu\text{m}$). The axial stiffness was derived using the relation

$$c_{33}^0 = \frac{Z^2}{\rho^0} \quad (5)$$

between acoustical impedance and density, with $\rho^0=1.91 \text{ g/cm}^3$. Because the standard deviation of the acoustic impedance over the samples was small and the variations of the mean value of the acoustic impedance were weak between the different regions investigated, a fixed value of c_{33}^0 was adopted within and between specimens. We choose to couple the numerical simulations to experimental data obtained on the same set of specimens investigated by both scanning acoustic microscopy and μ CT. This might have resulted in stiffness values slightly higher than values reported in the literature.^{13,35} We do not expect the trends reported here to be accurate in an absolute sense. However, since our main conclusion is based on the comparative performance of the models, the general trends reported here are expected to hold in a relative sense. All four models are built around the same value of c_{33}^0 . It would be interesting to carry out a parametric study on the influence of this absolute value.

With models 2–4, transversely isotropic bone matrices with various degrees of anisotropy were explored. The value of the anisotropy ratio $\text{AR}_0=c_{33}^0/c_{11}^0$ was chosen in the range 1–1.5. The value of c_{11}^0 was therefore determined from the selected anisotropy ratio value. Moreover, for the three transversely isotropic matrix (models 2–4), the shear stiffness coefficient c_{55}^0 was fixed to 10.4 GPa .³⁶

The other stiffness coefficients, c_{13}^0 and c_{12}^0 , were derived from the relationship between Poisson's ratio and stiffness, assuming the bone matrix to be either isotropic (model 1) or transversely isotropic (models 2–4), with the following relationships:

$$\nu_L^0 = \frac{c_{13}^0}{c_{11}^0 + c_{12}^0}, \quad \nu_T^0 = \frac{c_{33}^0 c_{12}^0 - (c_{13}^0)^2}{c_{33}^0 c_{11}^0 - (c_{13}^0)^2}. \quad (6)$$

The longitudinal ν_L^0 and the transverse ν_T^0 Poisson's ratios were equal and set to a value of 0.3, a commonly used value in the literature.^{37–39} Model 2 was built with $\text{AR}^0=1.12$, a value reported in Hofmann *et al.*³⁶ In model 3, a ratio of anisotropy $c_{33}^0/c_{11}^0=1.26$ was adopted, according to Turner's report.³⁷ In addition, we kept in this model the value of the longitudinal shear modulus given in Ref. 36 providing c_{55}^0 .

Model 4 was used to enlarge the range of anisotropy ratio and AR^0 reaches the value of 1.5, the value of c_{33}^0 and c_{55}^0 remaining the same as in models 2 and 3.

E. Pore size and porosity

Figure 2 shows a typical 3D reconstruction of the porous network. To perform numerical simulation, the original grey scale reconstructions were segmented to yield binary mappings of the porous network. The segmentation threshold laid between the two well-separated distributions of pixel values

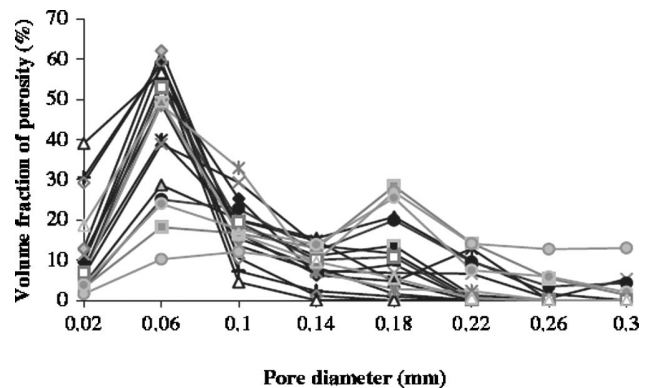

FIG. 3. Distribution of pores diameter through the 19 samples.

FIG. 4. Effective compression and shear bulk wave velocities deduced from FDTD simulations as a function of cortical porosity (model 2). The grey stars represent V_x and V_{zx} .

corresponding to the bone tissue and to the empty pores. The porosity was defined for each specimen as the ratio of the volume of pores to the total bone volume. The pore area related to different pore diameters was estimated in each reconstructed tomographic cross section, and then the pore areas were summed over the cross sections and multiplied by the spatial step increment between two consecutive slices to obtain the porosity. The distribution of the porosity as function of pore diameters was deduced from the morphological analysis of the 19 reconstructed microstructures. In addition, structural parameters such as mean pore density (number of detected pores per mm^2) and mean pore diameter (the equivalent diameter was determined from the area of the individual canals) were extracted.

III. RESULTS

A. Pore size and porosity

Each of the 19 samples had a porosity falling in the range 2%–15%. The distribution of diameters for the 19 specimens illustrated in Fig. 3 shows a bimodal distribution with two pore classes, the 60- and the 180- μm -diam groups, as contributors to the porosity (Fig. 3). The spatial resolution of SR- μCT was not sufficient to resolve the smallest pores (osteocytes lacunae, canaliculi) of a few microns in diameter. A higher resolution ($<10\ \mu\text{m}$) is needed to consistently visualize all cortical pores in human bone.⁴⁰

The average porosity in these samples was about 7%, the average pore number density was $15\ \text{mm}^{-2}$, and the mean

FIG. 5. Effective diagonal stiffness coefficients as a function of porosity (model 2).

pore diameter was about $80\ \mu\text{m}$. These results are consistent with previous morphological studies on human cortical bone.^{22,41}

B. Effective velocities and stiffness coefficients as a function of cortical porosity

Velocities of compression and shear bulk plane waves along the three principal axes of symmetry were computed for the 19 bone specimens and the 4 models. Figure 4 presents results for model 2. All the effective compression and shear bulk wave velocities decrease when porosity increases. However, the decrease was less pronounced for propagation along the long axis of the bone compared to the transverse directions. For a 10% increase in porosity, waves that propagate in the transverse plane undergo a decrease of 12% (470 m/s) for compression waves and 17% (370 m/s) for shear waves, while waves that propagate in the Z direction are reduced by 4% (160 m/s) for compression waves and 11% (260 m/s) for shear waves.

Similar trends of velocity variation versus porosity were observed for the four bone matrix models (Table II).

As a consequence of the decrease of both the effective mass density [Eq. (4)] and bulk wave velocities (Fig. 4) with the porosity, all the effective diagonal stiffness coefficients decline with the porosity as illustrated for model 2 in Fig. 5.

In all the bone models, a quadratic law between stiffness coefficients and porosity (ap^2+bp+c) was a better fit than a linear regression, although the first coefficient of the polynomial was small (see Table III).

TABLE II. Absolute (relative variation) of compression and shear waves velocities for a 10% increase of porosity (from 0 to 10%).

(m/s)	Compression waves in the transverse plane V_x and V_y	Compression wave in the axial direction V_z	Shear wave in the transverse plane V_{xy}	Shear waves in the axial direction V_{zx} and V_{yz}
Model 1	530 (12%)	190 (4.5%)	380 (17%)	250 (11%)
Model 2	470 (12%)	160 (4%)	370 (17%)	260 (11%)
Model 3	420 (11%)	150 (3.5%)	355 (17%)	200 (9%)
Model 4	350 (10%)	130 (3%)	320 (11%)	270 (11%)

TABLE III. Quadratic law variations of the diagonal stiffness coefficients vs porosity $c_{ii}=a(p\%)^2+bp\%+c$.

$AR^0=1.12$	c_{11}	c_{22}	c_{33}	c_{44}	c_{55}	c_{66}

R^2	0.97	0.98	0.96	0.80	0.88	0.88

C. Porosity contribution to effective anisotropy

The influence of porosity on effective stiffness is weaker in the axial direction (i.e., for c_{33} and for c_{44} and c_{55}) compared to the transverse directions (i.e., for c_{11} and c_{22} and for c_{66}), a result that contributes to the increase of the effective anisotropy as a function of porosity compared to the original elastic anisotropy of the bone matrix.

The effective anisotropy ratio ($AR=c_{33}/c_{11}$) normalized by the intrinsic anisotropy ratio of the bone matrix ($AR^0=c_{33}^0/c_{11}^0$) is plotted as a function of porosity for the four different bone models in Fig. 6. Normalized anisotropy ratios are consistently found to be greater than one and increasing with the porosity. The data indicate that the porosity contributes to the overall effective elastic anisotropy of bone structure. The higher the porosity, the higher its contribution to the bone elastic anisotropy. A 10% increase of porosity (from 0 to 10%) results in a relative increase of anisotropy ranging between 16% (for $AR^0=1.5$) and 20% (for the isotropic case) for the four bone matrix models studied.

Furthermore, the effective shear anisotropy ratio ($AR'=c_{55}/c_{66}$) increases with the porosity: For a 10% increase of porosity, the AR' is 16% greater for the isotropic case (model 1), 14% greater for models 2 and 3, and 12% greater for model 4.

The relative contribution of porosity to structural anisotropy of cortical bone is all the more important because the bone matrix is weakly anisotropic.

On the other hand, the other anisotropy ratios assessed by FDTD simulations (c_{ii}/c_{11}) were found to remain almost unchanged with the porosity.

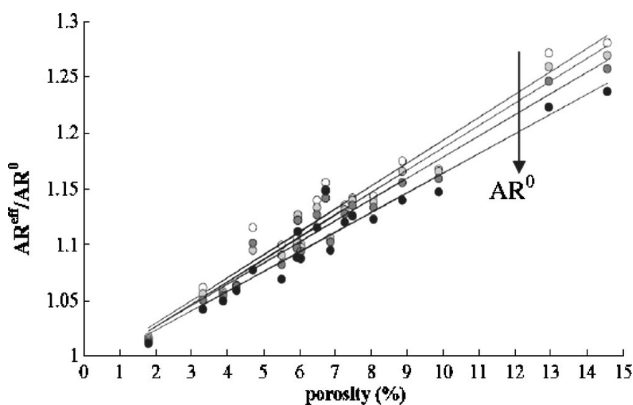

FIG. 6. Normalized effective anisotropy ratio (AR/AR_0) as a function of porosity for the different bone matrix models. Open circles correspond to the isotropic case (model 1), the light grey circles to model 2 ($AR^0=1.12$), the dark grey circles to model 3 ($AR^0=1.26$), and the closed circles to model 4 ($AR^0=1.5$).

IV. DISCUSSION

Our results suggest that the porous network introduces or reinforces transverse isotropy, as expected owing to its preferential orientation parallel to the bone axis. Indeed, it is noteworthy that the effect of porosity is similar for c_{11} and c_{22} , and for c_{44} and c_{55} . As pictured by Fig. 5, the differences between c_{11} and c_{22} and between c_{44} and c_{55} induced by the porous network were subtle: for example, $(c_{11}-c_{22})/c_{11} \leq 2 \times 10^{-4}$ for $p \leq 10\%$ and $(c_{11}-c_{22})/c_{11} \approx 4 \times 10^{-2}$ for $p \geq 10\%$. Therefore, if either isotropic (model 1) or transversely isotropic symmetry (models 2–4) is assumed for the tissue matrix, the introduction in the bone model of the oriented porous network resulted in a structure with effective transversely isotropic elastic properties. The result is consistent with the well-known effective macroscopic transverse isotropy of human cortical bone.^{34,42–44}

However, two additional conditions, $c_{13}=c_{23}$ and $c_{66}=(c_{11}-c_{12})/2$, required by this symmetry could not be checked here because mixed-indices stiffness coefficients were not evaluated. The evaluation of the mixed-indices stiffness coefficients c_{12} , c_{13} , and c_{23} requires one either to rotate the sample or to record angular variation of transmitted bulk wave. In the first case, it would be necessary to modify the software to implement capabilities of working with material of more general anisotropy than orthotropy, and in the second case it would be necessary to implement a more sophisticated signal processing. As these tasks were not under the scope of this study, the stiffness coefficients c_{12} , c_{13} , and c_{23} were not evaluated. However, note that under the reasonable assumption of a macroscopic transverse anisotropy, c_{12} can be simply derived from the knowledge of c_{11} and c_{66} with $c_{66}=(c_{11}-c_{12})/2$.

Coupling μ CT-based models of bone microstructure with FDTD simulations is a powerful means to compute the effect of porosity on effective stiffness and elastic anisotropy of bone. The high spatial resolution reached by SR- μ CT allows an accurate determination of the porous network. However, the bone computational model also requires input data for the stiffness of the bone tissue matrix. Because the complete set of real data (five stiffness coefficients and mass density) for the bone matrix was not known, some hypotheses were made. The Poisson's ratios are not easy to determine experimentally and therefore are not known with accuracy, and an *a priori* value of 0.3 for the Poisson's ratios was assumed, following a commonly adopted assumption in many studies, especially finite element analyses,⁴⁵ despite the rather wide range of values, between 0.12 and 0.63, reported in literature.^{31,42} Thus, one limitation of our study is related to the assumption adopted regarding the values of the

FIG. 7. Influence of the longitudinal Poisson's ratio on the dependence of the axial velocity on the cortical porosity. The stars represent the data obtained for $\nu_L=0.4$ and the circles represent the data related to $\nu_L=0.3$. The colors from white to black correspond to increasing AR^0 (model 1, model 2, and model 4).

Poisson's ratios, as mentioned in Raum *et al.*²² Here, in a first step we have investigated the influence of the longitudinal Poisson's ratio value on the axial velocity as a function of porosity for model 1 (model 1 is isotropic, the longitudinal and transverse Poisson's ratios are equal), model 2, and model 4. For these bone models, the computations have been run with an input Poisson's ratio value of 0.4 instead of 0.3. The new Poisson's ratio value was properly taken into account by modifying the value of the stiffness coefficients c_{12}^0 and c_{13}^0 according to Eq. (6).

The influence of the Poisson's ratio value on the axial velocity is presented in Fig. 7. The increase of Poisson's ratio from 0.3 to 0.4 induces a stronger impact of porosity on axial velocity and a better differentiation of the behavior between the different anisotropy models. For a longitudinal Poisson's ratio of 0.3 and a 10% increase of porosity, the axial velocity decreases by 190 m/s (4%) for model 1, 165 m/s (4%) for model 2, and 130 m/s (3%) for model 4. When the longitudinal Poisson's ratio is fixed to 0.4, the impact of a 10% increase of porosity on the axial velocity is of 430 m/s (10%) for model 1, 300 m/s (7%) for model 2, and 200 m/s (5%) for model 4. Consequently, an accurate estimation of the Poisson's ratios or of the related stiffness coefficients, especially the mixed-indices ones, at the matrix level is critical for a reliable prediction of relative variation of ultrasound velocities as function of porosity. Advances in this field have been published recently.^{31,45}

The present study permits a direct assessment of the effect of porosity on the stiffness coefficients of cortical bone. However, the morphology of the porous network is complex and requires several parameters to be fully characterized, including the size of the pores, pore density (number of pores per unit of area), spatial distribution of the pores, and shape of the pores.⁴⁶ The question arises as to whether these properties are determinant factors of the effective stiffness and the elastic anisotropy of cortical bone. Simplified models of porous networks were numerically built in order to better understand these effects for fixed values of porosity.

Preliminary results (not shown here) suggest that the influence of morphological parameters is small. For example, with a simplified model with a periodic spatial distribution of cylindrical inclusions embedded in the bone matrix, with their axis parallel to the axis of the bone, only subtle difference of 2% in the axial compression velocity could be observed. However, more work is required to explore the consequences of morphological variations in the cortical porosity on effective elastic properties.

The results of the present study can be used to elaborate sophisticated macroscopic computational bone models incorporating realistic CT-based macroscopic bone structures and effective elastic properties derived from μ CT-based FDTD simulations taking into account the effect of cortical porosity. These macroscopic computational bone models are of considerable interest as they can be used in order to evaluate the effect of porosity and of macroscopic bone structure on measured velocities in axial transmission. The frequency bandwidth (around 1 MHz) in this study is in the range of that typically used in some of the clinical settings. However, as mentioned in Sec. I, other devices are working at lower frequencies (around 250 kHz). Work on velocity frequency dispersion in cortical bone is sparse. Studying the frequency dependence of stiffness coefficients is potentially important. Therefore, specific attention must be paid in future works to the determination of phase velocity and amplitude in different frequency ranges.

V. CONCLUSION

The effect of oriented cortical bone porosity on ultrasound plane bulk wave velocities and elastic stiffness coefficients was investigated using transient numerical simulation of ultrasound plane bulk waves in 3D reconstructed microstructure of cortical bone samples. The effective stiffness coefficients were found to decrease with increasing porosity. The preferential orientation of the pore network along the bone axis induced an additional anisotropy (16%–20%) of the effective medium compared to the initial anisotropy of the bone tissue matrix. With initial Poisson's ratios values of 0.3, the variation of the effective anisotropy ratio was found to be fairly the same whatever the original anisotropy of the bone matrix was. However, the Poisson's ratio of the elastic bone matrix was found to be a critical determinant of the evaluation of relative variation of effective velocities and in turn of effective stiffness coefficients as a function of porosity.

Abstract—Two clinical trials have used ultrasound to improve tPA thrombolysis in patients with acute ischemic stroke. The Combined Lysis of Thrombus in Brain Ischemia Using Transcranial Ultrasound and Systemic tPA (CLOTBUST) trial reported accelerated recanalisation of the middle cerebral artery (MCA) in patients with symptoms of MCA infarction, which were monitored with 2-MHz transcranial Doppler. In CLOTBUST, there was no increased bleeding as evidenced by cranial computed tomography. The Transcranial Low-Frequency Ultrasound-Mediated Thrombolysis in Brain Ischemia (TRUMBI) trial, which employed magnetic resonance imaging (MRI) before and after tPA thrombolysis, was discontinued prematurely because of an increased number of secondary hemorrhages, possibly related to the use of low frequency 300-kHz ultrasound. The purpose of our work is to help identify possible mechanisms of intracerebral hemorrhage resulting from sonothrombolysis by applying a simulation tool that estimates the pressure levels in the human brain that are produced with different sonothrombolysis devices. A simulation software based on a finite difference time domain (FDTD) three-dimensional (3D) scheme was developed to predict acoustic pressures in the brain. This tool numerically models the wave propagation through the skull and reproduces both ultrasound protocols of CLOTBUST and TRUMBI for analysis of the distribution of acoustic pressure in the brain during stroke treatment. For the simulated TRUMBI trial, we analyzed both a “high” and “low” hypothesis according to published parameters (for high and low amplitude excitations). For these hypotheses, the mean peak rarefactional pressures in the brain were 0.26 ± 0.2 MPa (high hypothesis) and 0.06 ± 0.05 MPa (low hypothesis), with maximal local values as high as 1.2 MPa (high hypothesis) and 0.27 MPa (low hypothesis) for configurations modelled in this study. The peak rarefactional pressure was thus higher than the inertial acoustic cavitation threshold in the presence of a standing wave in large areas of the brain, even outside the targeted clot. For the simulated CLOTBUST trial, the maximum peak negative pressure was less than 0.07 MPa. This simulated pressure is below the threshold for both inertial and stable acoustic cavitation but likewise lower than any acoustic pressure that has been reported as sufficient for effective sonothrombolysis. Simulating the pressure field of ultrasound protocols for clinical trials of sonothrombolysis may help explain mechanisms of adverse effects. Such simulations could prove useful in the initial design and optimization of future protocols for this promising therapy of ischemic stroke. INTRODUCTION

Stroke is now the second leading cause of death in industrialized countries. The great majority of strokes are ischemic (85%). This is generally due to a blood clot, which occludes a cerebral artery and causes brain necrosis in the territory of the supplying vessel. The key point in the treatment of ischemic stroke is the rapidity of the reperfusion to avoid irreversible damage of brain tissue

and sequelae for the patient (Caplan 1999). So far, intravenous recombinant tissue plasminogen activator (tPA) is the only effective and approved treatment available for acute ischemic stroke, despite controversial results concerning the balance between its established beneficial thrombolytic effect and its potential neurotoxicity (Benchenane et al. 2004).

Several *in vitro* and *in vivo* (animal models) studies have revealed that ultrasonic exposure of clots (with $I_{SPTA,3}$ ranging from 700 to 1750 mW/cm²) accelerates the effect of fibrinolytic agents over a wide range of frequencies (from 20 kHz to 2 MHz) (Kudo 1989; Lauer et al. 1992; Kornowski et al. 1994; Francis et al. 1995;

Behrens *et al.* 1999; Alexandrov *et al.* 2004; Daffertshofer *et al.* 2004). Mechanisms of ultrasound-accelerated tPA thrombolysis include reversible disaggregation of cross-linked fibrin fibers (Braaten *et al.* 1997), microcavity formation in the shallow layer of thrombus (Kondo *et al.* 1999) and increased uptake and penetration of tPA into clots (Francis *et al.* 1995). Cavitation, bubble formation in the rarefactional pressure zones, plays an important role in the production of such bioeffects (Blinc *et al.* 1993; Everbach and Francis 2000; Behrens *et al.* 2001; Meunier *et al.* 2007). Thermal effects may also contribute to ultrasound-assisted thrombolysis (Shaw *et al.* 2006)

Two clinical trials of sonothrombolysis for treatment of ischemic stroke have been reported. CLOTBUST (Combined Lysis of Thrombus in Brain Ischemia Using Transcranial Ultrasound and Systemic tPA) (Alexandrov *et al.* 2004) was a multicenter randomized clinical trial on 126 patients who had acute ischemic stroke due to occlusion of the middle cerebral artery (MCA). All patients were treated with intravenous tPA within 3 h after the onset of symptoms. Target patients received along with tPA, 2-MHz, pulsed wave transcranial Doppler monitoring for a duration of 2 h. A complete reperfusion or dramatic clinical recovery was observed for 49% of the patients in the target group (tPA + US) and for only 30% of the control group. No secondary effects linked with ultrasound exposure were identified.

Another clinical trial on sonothrombolysis, the TRUMBI trial (Transcranial Low-Frequency Ultrasound-Mediated Thrombolysis in Brain Ischemia), was stopped prematurely because of the occurrence of a higher number of intracerebral hemorrhages after tPA treatment combined with transcranial sonication at 300 kHz (Daffertshofer *et al.* 2005). Unlike the CLOTBUST study, rigorous MRI monitoring was performed in all patients and not just in those where control imaging after thrombolysis was warranted clinically. This led to detection of MRI evidence of hemorrhage in 93% of the target patients and 42% of the control patients in TRUMBI. Among these hemorrhages, all were classified as hemorrhagic transformation in the tPA only group versus 61% in the tPA plus ultrasound group. Five hemorrhages in the target group were symptomatic hemorrhages, possibly linked to ultrasound exposure.

The reasons for the different outcomes in these two clinical trials of sonothrombolysis are unclear. Indeed, experimental studies using animal models (Daffertshofer *et al.* 2004) were unable to demonstrate harmful secondary effects of ultrasound insonification using TRUMBI parameters. One report has suggested that hemorrhages in TRUMBI were related to abnormal permeability of the human blood-brain barrier that was induced by wide-field low-frequency insonation (Reinhard *et al.* 2006). Wang and coworkers (Wang *et al.* 2008) hypothe-

size that in TRUMBI a pulse length of 765 mm combined with a very wide beam can cause overlap many times as the wave runs its course back and forth across the brain, reflecting off the skull. Therefore, the instantaneous intensity of ultrasound in the brain tissue may multiply constructively at some localized sites of brain tissue, resulting in MIs that are larger than the maximum limit set by the Food and Drug Administration (FDA).

The purpose of our work is to better understand the brain pressure amplitude distribution involved in these studies through numerical simulations. This approach may allow localization of potential areas of acoustic cavitation and, thus, help explain mechanisms of adverse effects of sonothrombolysis.

MATERIALS AND METHODS

Ultrasound parameters from clinical studies of sonothrombolysis

All the pressure levels involved in the clinical studies (CLOTBUST or TRUMBI) have been deduced from data collected in various publications. Namely, peak negative pressure had to be deduced from the derated $I_{\text{SPTA},.3}$.

$$I_{\text{SPTA},.3} = P_-^2 / 2\rho c \quad (1)$$

ρ is the mass density and c is the ultrasound wave's velocity. The derating factor is fixed to 0.3 dB/cm-MHz and the derated intensities are noted with the index ".3" (AIUM/NEMA 1992). Due to the frequencies used in the clinical studies, the derated $I_{\text{SPTA},.3}$ has to be taken into account carefully in the CLOTBUST study whereas the value of $I_{\text{SPTA},.3}$ is very close to that of $I_{\text{SPTA},.3}$ in the TRUMBI protocol.

Assuming that the nonlinear effects are negligible in this configuration, we considered

$$P_{p2p} = 2P_- \quad (2)$$

P_{p2p} is the peak-to-peak acoustic pressure.

CLOTBUST study. The emitter was a 10 mm-diameter single element delivering a 2-MHz pulsed wave with duty cycle of 15% and short emission duration of 15 μs . The focusing was set in the ipsilateral hemisphere. The focal length depends on the targeted region: proximal (between 30 mm and 45 mm) or distal (more than 45 mm). At 45 mm away from the transducer, the derated spatial-peak time-averaged intensity, $I_{\text{SPTA},.3}$ was measured at 739 mW/cm^2 (Moehring *et al.* 2000) and a $I_{\text{SPPA},.3}$ of 4.9 W/cm^2 . The corresponding pressure in water is, thus, equal to 0.385 MPa.

TRUMBI study. The diamond pattern transducer (50 mm diameter) emitted an unfocused pulsed ultrasound wave at 300 kHz modulated in frequency (± 1.5 kHz) to

limit standing waves. The targeted zone was the contralateral brain hemisphere corresponding to a distance around 100 mm.

The emission parameters reported in (Daffertshofer et al. 2005) include a 5% duty cycle (corresponding to an emission duration of 500 μ s) and a spatial-peak time-average intensity ($I_{SPTA,3}$) of 700 mW/cm² in water with a pulse repetition frequency of 100 Hz.

Taking into account the duty cycle, the spatial-peak pulse-average intensity ($I_{SPPA,3}$) was 14 W/cm², corresponding to a mechanical index (MI) in water of 1.18. However, the authors claim that the mechanical index was less than 0.2. Wang (2008) recently estimated the MI used in the TRUMBI study and concluded that the value given in (Daffertshofer et al. 2005) was wrong: the MI was 1.18 and the pressure was higher than the one expected by the authors of the TRUMBI study. However, a closer look at the description of the emission parameters given in (Daffertshofer et al. 2005) could be interpreted in another way: the 5% duty cycle has been added in order to “further reduce thermal effects” and was, thus, not taken into account in the evaluation of the 700 mW/cm² $I_{SPTA,3}$ in water, so that technically speaking, it corresponds to an $I_{SPPA,3}$ of 0.7 W/cm². This corresponds to the back-calculation of a mechanical index of 0.25.

To summarize, data given in (Daffertshofer et al. 2005) are not coherent: either the given MI is equal to 1.18 or it is equal to 0.2. Since it is unclear which interpretation of the published data is correct, both parameters will be evaluated in this study, according to two separated hypothesis.

High hypothesis. The MI is equal to 1.18. It corresponds to an $I_{SPPA,3}$ of 14 W/cm². This hypothesis is supported by Wang et al (2008) and corresponds to the published $I_{SPTA,3}$ (Daffertshofer et al 2005). The corresponding pressure in water is, thus, equal to 0.65 MPa.

Low hypothesis. The MI is equal to 0.2. It corresponds to an $I_{SPPA,3}$ of 0.7 W/cm². This hypothesis is supported by the designers of the TRUMBI device and corresponds to the published MI value (Daffertshofer et al 2005). The corresponding pressure in water is, thus, equal to 0.15 MPa.

A frequency modulation was used in the TRUMBI study to avoid standing waves: 300 \pm 1.5 kHz but no reference to the exact frequency modulation was given. Different frequency modulation options have, thus, been tested: ramp or sinusoidal modulation. Furthermore, in order to study the influence of the frequency modulation, various frequency ranges have been modelled (300 kHz; 300 \pm 1.5 kHz; 300 \pm 15 kHz; 300 \pm 150 kHz).

Ultrasonic parameters of both CLOTBUST and TRUMBI studies are summarized in Table 1.

The mechanical index (MI)

In order to evaluate the likelihood of cavitation-related biological effects, the most relevant indicator was established to be the mechanical index (MI) (Apfel and Holland 1991). Indeed acoustic cavitation activity occurs in areas of rarefactional pressure and depends on the ultrasound frequency. The MI is defined as follows:

$$MI = \frac{P_-}{\sqrt{f}} \quad (3)$$

with P_- the in situ peak rarefactional pressure in megapascal and f the ultrasound center frequency in megahertz.

In this study, as the simulation is taking into account the absorption in the tissues, the computed pressure corresponds to the in situ peak rarefactional pressure P_- . Equation 3, thus, enables to directly calculate the simulated MI.

To avoid adverse biologic effects related to acoustic cavitation, the FDA (FDA-510K) imposes the diagnostic devices to ensure a MI less than 1.9 (Dalecki 2004).

No adverse biologic effect induced by ultrasound alone on mammals has been recorded for MI < 0.3 (AIUM/NEMA 1992). Nevertheless, this threshold may be lowered in the presence of tPA and clot and in a standing wave field.

Importantly, this definition of MI is only valid for single cycle pulses. As in previous publications (Daffertshofer et al. 2005; Wang et al. 2008), the MI will be used later in this article to analyse previous results. Significant work has been done on the influence of pulse duration and pulse repetition frequency on the safety of ultrasound-induced lung hemorrhage (O'Brien Jr 2007). Church and O'Brien Jr. introduced recently a modified MI taking into account the pulse length (Church and O'Brien Jr 2007). Basically, the threshold for cavitation decreases with pulse length and reaches a plateau for 10 cycles: the modified MI is three times higher than the classical one in water. All the MIs given in this article refer to conventional calculations (for one cycle pulses). As all pulses have much more than 10 cycles, such MIs do not reflect the exact biologic effects of ultrasound but only serve as reference for the readers in addition to the pressure levels.

The skull acoustical model

From high resolution computed tomography (CT) images, a three-dimensional (3D) portion of the skull is reconstructed. CT images were acquired with a GE Genesis CT scanner (GENESIS Medical Imaging, Inc., Huntley, Illinois, USA) (3 mm slice thickness, 1 mm between slices, slice resolution: 0.69 mm \times 0.69 mm) at the Curie Institute Hospital (Paris, France). The Curie Institute institutional review board approved the imaging protocol and data was anonymized before transmission

Table 1. Parameters for the two trials

	CLOTBUST	TRUMBI
Number of patients	126	26
Transducer diameter (mm)	10	50
Focused/unfocused	yes	no
Distance of the target (mm)	Proximal (30-45) Distal (>45)	100
Frequency (MHz)	2	0.3
Emission duration (μ s)	15	500
Pulse repetition frequency (MHz)	0.1	0.0001
I_{SPPA} (W/cm ²)	4.9	14 (high hypothesis) 0.7 (low hypothesis)
Peak negative pressure in water	0.385	0.65 (high hypothesis) 0.15 (low hypothesis)

CLOTBUST = Combined Lysis of Thrombus in Brain Ischemia Using Transcranial Ultrasound and Systemic tPA; TRUMBI = Transcranial Low-Frequency Ultrasound-Mediated Thrombolysis in Brain Ischemia.

to the Laboratoire Ondes et Acoustique. All measurements and simulations were performed on one female skull. Patient data protection regulations for this study do not allow disclosure of ethnic group or age. As previously described in (Aubry *et al.* 2003), the acoustical properties of the skull are then deduced from the raw CT data.

The brain acoustical model

The brain is considered as soft tissue with an acoustical behavior close to that of water (Wells 1977):

$$\rho_{\text{brain}} = 1000 \text{ kg/m}^3; c_{\text{brain}} = 1500 \text{ m/s} \quad (4)$$

The brain is an absorbing medium, the absorption coefficient depends on the ultrasound frequency and was set to (Goss *et al.* 1978).

$$\text{abs}_{\text{brain}} = 0.5 \text{ dB/cm/MHz} \quad (5)$$

Thus, in our simulations the brain is modelled by a homogeneous absorbing medium.

Simulation code

Three-dimensional (3D) finite simulations have been performed in order to evaluate pressure field distributions and pressure levels in the brain. Simulations were performed with a C++ finite differences program developed at the Laboratoire Ondes et Acoustique (UMR CNRS 7587, Paris, France). The scalar heterogeneous wave equation with loss absorption (eqn 6) was discretized with a second order in space and second-order centered in time scheme. A fourth order approximation Higdon absorption boundary (Higdon 1991) condition was used on computation volume borders to avoid unphysical reflections (reflections are typically 40 dB lower than

the incident wave field over a wide range of incidence angles).

$$\left(1 + \tau(\vec{r}) \frac{\partial}{\partial t}\right) \left[\rho(\vec{r}) \nabla \cdot \left(\frac{1}{\rho(\vec{r})} \nabla p(\vec{r}, t) \right) \right] - \frac{1}{c(\vec{r})^2} \frac{\partial^2 p(\vec{r}, t)}{\partial t^2} = S(\vec{r}, t) \quad (6)$$

where $c(\vec{r})$ is the speed of sound, $\rho(\vec{r})$ the density and $\tau(\vec{r})$ the absorption coefficient in the medium either in the skull bone or in the brain. The pressure field p and the source term S depend on both space and time.

Simulations were conducted at 2-MHz and 300-kHz central frequency. The simulation grid was set to one tenth of a wavelength. In order to meet the Von Neumann stability criteria (Press *et al.* 1992), the temporal step is given by $\Delta t < \frac{\Delta x}{\max_{\vec{r}} (c_0(\vec{r}))\sqrt{3}}$, where Δx is the spatial

step of the grid. An example of the 3D pressure field in the region of interest located in front of the transducer is given on Fig. 1. One can see the appearance of vibration nodes and antinodes in the 3D wave field distribution. For sake of clarity, only two-dimensional (2D) views will be displayed in the results. In both studies, we assumed that the clinicians located the transducers optimally, perpendicularly to the temporal window. Such a configuration was reproduced at best in the simulation process.

Definition of the targeted area

Each clinical study had its own procedure to target the clot once it was located.

Trumbi. The transducer was positioned on the temporal bone window on the contralateral side of the head with a clot-probe distance around 100 mm (Dafertshofer *et al.* 2005).

Clotbust. The transducer was positioned on the temporal bone window ipsilateral to the clot. Typically, the clot-probe distance was around 45 mm (Alexandrov *et al.* 2004).

According to each set-up, the location of the targeted region has been estimated in respect to the location of the probe. Even though no model of clot has been introduced in the simulations, pressure levels obtained in the expected location of a clot were analyzed for each study. Such regions-of-interest (1 cm \times 1 cm \times 1 cm) will be later referred to as ‘‘expected location of the clot’’. Parameters described in this section are summarized in Table 1.

Cavitation threshold

In order to determine in which areas of the brain inertial cavitation might occur, the pressure field simulated in the brain has been mapped. The areas where the pressure

Fig. 1. Three-dimensional simulation of the acoustic field after propagation through the skull bone (in a dB scale with a 60 dB dynamic). The transducer is located on the right side of the image.

went beyond the threshold for inertial acoustic cavitation in a standing wave field have been plotted. The inertial acoustic cavitation threshold applied to our analysis was derived from (Azuma et al. 2005). In Azuma's study the acoustic cavitation threshold was measured in degassed water, in a standing wave field established inside a human skull, at 617-kHz frequency. The back-calculated peak rarefactional pressure was 0.27 MPa. By considering that the cavitation threshold increases as the square root of the frequency, the corresponding threshold at 300 kHz is equal to 0.19 MPa. It is important to note here that the cavitation threshold in a standing wave field is much smaller than the threshold in a progressive wave field. This is mainly due to the fact that nanobubbles can be trapped in antinodes and create bigger bubbles by coalescing (Azuma et al. 2005). Those microbubbles inertially collapse as soon as they reach their resonant size.

RESULTS

The TRUMBI study

Several points are crucial in analyzing the interaction between the biologic medium and the ultrasound field: the

location and the amplitude of the peak rarefactional pressure and the possibility of standing waves formation.

Peak rarefactional pressure. In the whole area of the brain in front of the transducer, the mean peak rarefactional pressure is equal to 0.26 ± 0.2 MPa in the case of the high hypothesis and 0.06 ± 0.05 MPa in the case of the low hypothesis.

Table 2 summarizes the simulated pressure levels at the expected location of the clot and the maximum pressure levels achieved in the brain (on the so-called "hot spot") with the corresponding MI: the maximum peak rarefactional pressure in the brain is equal to 1.2 MPa for the high hypothesis and 0.27 MPa for the low hypothesis. At the expected location of the clot, the maximum peak rarefactional pressure is equal to 1 MPa for the high hypothesis and 0.22 MPa for the low hypothesis.

The location of the corresponding maximum pressure levels achieved in the brain can be seen in Fig. 2 (black dots). The location of these "hot spots" is highly dependent on the skull shape and on the position of the probe. The pressure field distribution in the brain for two different locations of the probe has been represented:

Table 2. Simulation results for the TRUMBI set-up

	Left temporal window (parallel to the skull)	Right temporal window (parallel to the skull)
Maximum peak rarefactional pressure (MPa) High hypothesis/low hypothesis	1.2/0.27	1.1/0.25
MI _{max} High hypothesis/low hypothesis	2.2/0.49	2/0.45
Pressure at the expected location of the clot (MPa) High hypothesis/low hypothesis	1/0.22	0.8/0.18
MI _{clot} High hypothesis/low hypothesis	1.8/0.40	1.5/0.33

TRUMBI = Transcranial Low-Frequency Ultrasound-Mediated Thrombolysis in Brain Ischemia; MI = Mechanical Index.

Fig. 2. Maximum peak rarefactional pressure (black spot) location and shape of the ultrasound field through (a) the right and (b) the left temporal windows.

probe located on the right temporal window (Fig. 2a) and on the left temporal window (Fig. 2b). The maximum peak rarefactional pressure is not located in the same area: between the emitter and the clot for the right window configuration and near the bone at the opposite side from the emitter for the left window configuration. Moreover, in Fig. 2a, the acoustic beam is reflected with an angle whereas in Fig. 2b the reflected wave travels parallel to the incident wave yielding to completely different pressure field distribution in the brain. In the latter case, a standing wave is likely to occur all the way in front of the transducer.

Standing waves. In order to have a closer look at potential standing wave formation, the acoustic pressure is presented as a function of time in Fig. 3 for our high hypothesis. In the case of the low hypothesis, the patterns are identical and only the pressure amplitudes differ. It corresponds to the configuration with the transducer

located on the right temporal window. Each plot represents the pressure recorded at the location of the maximum pressure amplitude observed in the brain (a, “hot spot”) and at the expected location of the clot (b, “clot”). The distance of the “hot spot” from the emitter surface is 65 mm. The distance of the clot (targeted region) from the emitter surface is equal to 100 mm. One can see that the amplitude is varying with time, indicating interferences between direct waves and waves reflected on the contralateral skull.

Cavitation. Figure 4 represents in grey the areas where the pressure went beyond the threshold for inertial cavitation in a standing wave. The inertial acoustic cavitation threshold applied to our analysis was set to 0.19 MPa (derived from [Azuma *et al.* 2005]). During sonication, each time the simulated pressure levels went beyond the cavitation threshold, the corresponding pixel was definitely turned to from a black pixel to a grey one.

Fig. 3. Evolution of the acoustic pressure waveform as a function of time for one emission burst of 500 μs for two locations: at the maximum pressure amplitude location (left) and at the expected location of the clot (right).

The zone where the acoustic cavitation is liable to take place is not confined to the clot for both the low hypothesis (Fig. 4a) and the high hypothesis (Fig. 4b): such areas exist in tissues located in front of the transducer all along the brain. This observation may be related to the occurrence of atypical hemorrhages outside the targeted region.

Frequency modulation. Different frequency modulation options have been tested (Fig. 5) in order to take into account the frequency modulation used in the TRUMBI study. Areas where the acoustic pressure is higher than 0.19 MPa (Azuma et al. 2005) are displayed in grey color. Figure 5a is the reference, without modulation. Different frequency modulation options have been tested: ramp (left: Fig 5b, d and f) or sinusoidal modulation (right: Fig. 5c, e and g). Furthermore, in order to study the influence of the frequency modulation, various frequency ranges have been modelled (300 ± 1.5 kHz [Fig. 5b and c]; 300 ± 15 kHz [Fig. 5d and e]; 300 ± 150 kHz [Fig. 5f and 5g]). One can see that whatever the modulation, when frequency is shifted, the locations of the maximum pressure amplitude are shifted: nanobubbles are not trapped at the same location for a long time anymore but the pressure levels remains higher than 0.19 MPa in all cases.

The CLOTBUST study

The maximum peak negative pressure recorded in the simulation is equal to 0.07 MPa in the whole brain. The MI in the brain is thus less than 0.05. At the location of the maximum peak negative pressure (hot spot), the pressure is not affected by standing waves: the pressure reaches a plateau at 0.07 MPa during all the duration of the burst and vanishes at the end of the burst.

At the expected location of the clot, the peak negative pressure is 0.05 MPa, without any standing wave pattern.

Standing waves are confined in the vicinity of the contralateral skull, within a 1 cm band. Nevertheless, in the standing wave area, the pressure field is one order of magnitude smaller than the hot spot. The main values of maximum peak negative pressure concerning both studies are summarized in Table 3.

DISCUSSION

For the CLOTBUST study, the simulated maximum negative peak pressure is 0.07 MPa: the simulated MI in the brain is less than 0.05. In fact, the pressure is so low after attenuation of the skull bone that it has been questioned whether any thrombolytic effect at all can be expected (Pfaffenberger et al. 2005). According to several *in vitro* studies (Blinc et al. 1993; Everbach and Francis 2000; Behrens et al. 2001; Meunier et al. 2007), stable acoustic cavitation seems to be the key process of low-frequency sonothrombolysis. As underlined by Vykhodtseva and colleagues (Vykhodtseva et al. 1995), it is very difficult to measure the stable and inertial cavitation thresholds in living tissues because they depend on numerous parameters: propagation medium, ultrasound frequency, duty cycle, pulse duration and standing wave. In a recent paper (Datta et al. 2006), Datta and colleagues demonstrated the sensitivity of cavitation thresholds to the medium. The likelihood of cavitation effects is higher when the ultrasound field is applied to plasma containing tPA and a clot, than when it is applied to plasma alone (Table 4). According to all experimental measurements of cavitation thresholds in tissues published in the literature, our simulations show that stable cavitation is not likely to occur in the brain with the CLOTBUST acoustical setup. Stable cavitation cannot explain the efficiency of the CLOTBUST approach. Nevertheless, there is little evidence that cavitation plays

Fig. 4. Two-dimensional representation of the cavitation area (in grey) through one insonation for a 50 mm-emitter and with frequency modulation of the signal (ramp ± 1.5 kHz). (a) Low hypothesis. (b) High hypothesis.

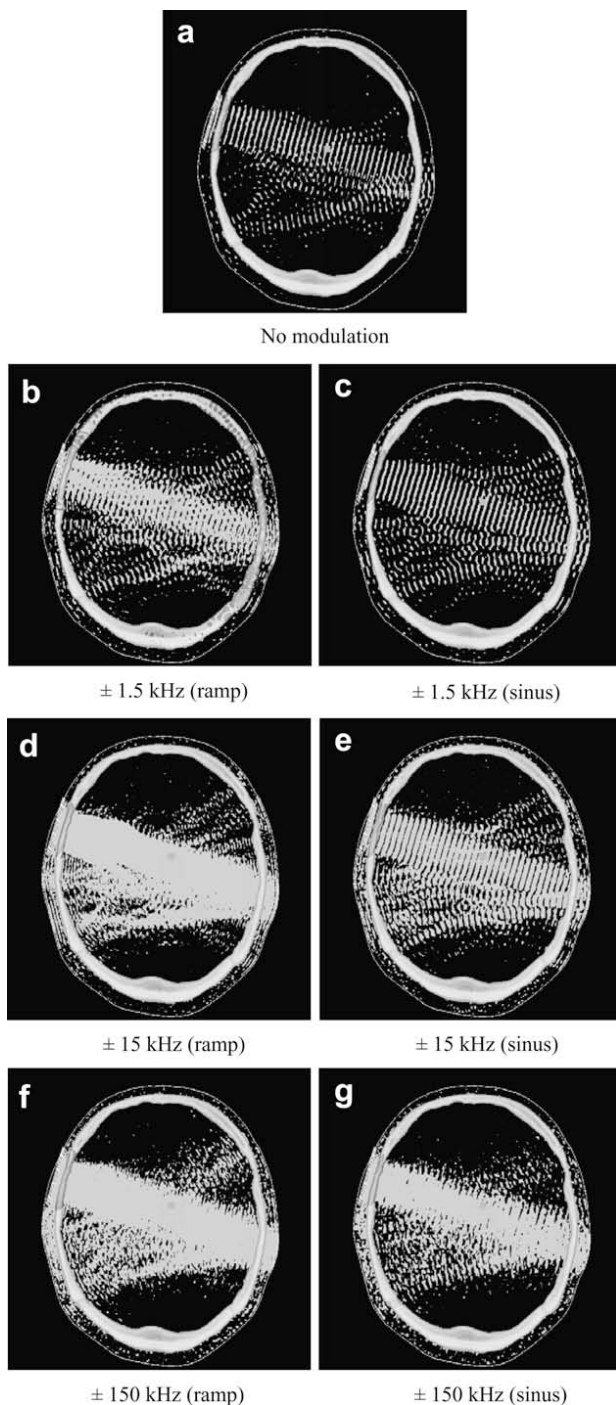

Fig. 5. Comparison of pressure repartition in different cases of frequency modulation.

such an important role *in vivo* and one should be cautious when extrapolating *in vitro* results to the clinical situation.

Several reports have hypothesized that high pressure amplitudes were used in the TRUMBI study (Azuma *et al.* 2005; Wang *et al.* 2008). Such reasoning was correct regarding the TRUMBI acoustical data available: MI and I_{SPTA} given in (Daffertshofer *et al.* 2005) were not

compatible. Considering that the MI was not equal to 0.2 but that $I_{SPTA,3}$ was truly equal to 700 mW/cm^2 yielded high pressure levels generated in water (high hypothesis). In this article, a new analysis of the TRUMBI acoustical data has been proposed. We hypothesized a mix-up between the Spatial Peak-Temporal Average intensity and the Spatial Peak-Pulse Average intensity: $I_{SPTA,3}$ is not equal to 700 mW/cm^2 but $I_{SPPA,3}$ is. In that case, the MI meets 0.2. Such a low hypothesis is highly plausible.

Whatever the pressure level, as first highlighted by Azuma (2005) the simulations performed in this article confirmed the possibility of standing wave formation when using the TRUMBI set-up on a human skull. Moreover, pressure field distributions in the brain could be plotted (Fig. 2). Standing waves are likely to occur not only near the bone (Fig. 2.a) (Azuma *et al.* 2005) but also all along the way in front of the transducer (Fig. 2b). As the emission duration in the TRUMBI protocol ($500 \mu\text{s}$) corresponds to several crossings of the brain, the ultrasound wave is reflected more than four times in the brain so that complex pressure fields can be obtained in the brain (Fig. 2). These pressure fields are highly dependent on the position of the transducer: the transducer was positioned at best perpendicularly to the bone for both left and right bone window configurations (Fig. 2a and b), as was performed clinically by the physician for each study. Even though human skulls are almost symmetrical, the pressure fields differ significantly, most probably due to slightly different angles between the probe and the skull. Interestingly, these figures highlight two remarkable different phenomena that are likely to occur in the brain during TRUMBI sonication.

Figure 2a. The plane wave emitted by the transducer has been focused towards the hot spot because of a lens effect induced by the shape of the skull: right after crossing the skull, the wave front is no longer planar, but cylindrical. Figure 6 highlights that in this configuration the maximum peak rarefactional pressure is precisely in the area where the atypical secondary hemorrhage occurred for the pathologic case reported in (Daffertshofer *et al.* 2005)

Figure 2b. The wave is reflected perpendicularly to the skull interface located at the opposite side of the transducer, yielding to a standing wave pattern all the way in front of the transducer.

The skull bone is usually considered as a barrier for ultrasonic waves. Simulating the pressure fields generated by the TRUMBI set-up highlights a particular property of the skull: at low frequency, absorption is weak in the bone and in the brain, so that the skull potentially acts as a sur-pressure generator by either creating an acoustical lens (Fig. 2a) or acting as a resonator (Fig. 2b). These two examples are not exhaustive and other ways to generate

Table 3. Simulation results for CLOTBUST and TRUMBI set-ups

	CLOTBUST	TRUMBI (high hypothesis)	TRUMBI (low hypothesis)
Frequency	2 MHz	300 kHz	300 kHz
$I_{SPTA,3}$	700 mW/cm ²	700 mW/cm ²	35 mW/cm ²
Expected pressure in water	0.385 MPa	0.65 MPa	0.15 MP
Simulated maximum pressure in the brain	0.07 MPa	1.2 MPa	0.27 MPa

CLOTBUST = Combined Lysis of Thrombus in Brain Ischemia Using Transcranial Ultrasound and Systemic tPA; TRUMBI = Transcranial Low-Frequency Ultrasound-Mediated Thrombolysis in Brain Ischemia.

hot spots in the brain can be envisioned: any constructive interference due to reflections on any part of the skull bone, like the orbital shelf or the anterior clinoid. The curvature of the skull plays an important role and may explain the discrepancy between the results of this study and the previous ones carried out *in vitro* or on animal models (Daffertshoffer et al. 2004).

Simulations demonstrate that due to the complex skull geometry and due to the length of the emission (500 μ s), standing waves are likely to occur at the targeted location and outside the targeted location with pressure levels higher than 0.27 MPa (low hypothesis). On the contrary CLOTBUST simulations show that standing waves are confined to a 1cm band close to the contralateral skull with pressure levels 10 times lower than in the targeted location.

The simulations could thus, explain the atypical secondary hemorrhages observed in the TRUMBI study for two reasons: the possibility of inertial cavitation in a large area of the brain is demonstrated in Fig. 4 but possible tPA extravasation might also occur. A recent paper (Reinhard et al. 2006) points out the abnormal permeability of the human blood-brain barrier (BBB) which can be induced by wide-field low-frequency inso-

nation. The observed excessive bleeding rate with low-frequency sonothrombolysis might thus be attributable to primary BBB disruption by ultrasound. (Hynynen et al. 2006) evaluated the threshold for BBB disruption to 0.4 MPa, using 260-kHz focused ultrasound bursts and ultrasound contrast agent. This threshold is far below the maximum peak pressure amplitude simulated in the brain for the TRUMBI set-up with the high hypothesis and on the order of magnitude of the one simulated with the low hypothesis. Ultrasound could, thus, induce BBB opening in areas remote from the brain infarction so that tPA could diffuse in the brain parenchyma. As tPA is a known neurotoxic agent which can induce hemorrhages (Benchenane et al. 2004; Kaur et al. 2004), this might also explain the occurrence of secondary hemorrhages in TRUMBI.

One of the main differences between the clinical trials studied in this article is the ultrasound frequency. In the CLOTBUST trial, the frequency is seven times higher than in the TRUMBI trial, thus, the attenuation through the skull is much higher and explains mostly the difference in the pressure level. Sonothrombolysis devices are often characterized by the value of their I_{SPTA} in the absence of skull bone. Nevertheless, even though both studies claimed to have the same $I_{SPTA,3}$ (739 mW/cm² for CLOTBUST and 700 mW/cm² for TRUMBI), the simulated maximum pressure levels in the brain are significantly different: 0.07 MPa for CLOTBUST and 1.2 MPa (high hypothesis) or 0.27 MPa (low hypothesis). Basically, the skull attenuation is eight times lower in TRUMBI compared with CLOTBUST. In order to evaluate the safety and the efficiency of sonothrombolysis systems, the mean $I_{SPTA,3}$ (or mean peak negative pressure) expected in the brain appears to be more relevant than $I_{SPTA,3}$ value (or mean peak negative pressure) in water. We have shown that such pressure levels can be estimated with finite differences simulations. Moreover, simulation could be of value for optimizing the efficacy and the safety of new sonothrombolytic devices. For example, in order to reduce standing waves Daffertshoffer et al. (2005) proposed to apply a 0.5% frequency modulation. Our simulations have shown, however, that this approach was not sufficient to significantly

(Received 27 June 2008; revised 19 August 2009; accepted 22 December 2009)

Non-destructive evaluation of heterogeneous materials is of major interest not only in industrial but also in biomedical fields. In this work, the studied structure is a three-layered one: A laterally heterogeneous anisotropic solid layer is sandwiched between two acoustic fluids. An original method is proposed to solve the wave equation in such a structure without using a multilayered model for the plate. This method is based on an analytical solution, the matricant, explicitly expressed under the Peano series expansion form. This approach is validated for the study of a fluid-loaded anisotropic and homogeneous plane waveguide with two different fluids on each side. Then, original results are given on the propagation of elastic waves in an asymmetrically fluid-loaded waveguide with laterally varying properties. This configuration notably corresponds to the axial transmission technique to the ultrasound characterization of cortical bone *in vivo*.

I. INTRODUCTION

A lot of natural media have unidirectional varying elastic properties. The mantle crust, the oceans, and cortical bone are some of these functionally graded media. Scientists focused on the advantages presented by this type of materials in terms of mechanical behavior, and since the 1980s, they developed industrial functionally graded materials (FGMs) particularly exploited in high-technology and biomedical applications. Consequently, the non-destructive evaluation of these materials is a key issue. Surface and guided waves play a major role in non-destructive testing and evaluation of complex structures. Several studies are dedicated to the leaky Lamb wave propagation in fluid-loaded plates (Chimenti and Nayfeh, 1990; Chimenti and Rokhlin, 1990; Deschamps and Poncelet, 2000). In all these studies, the media are homogeneous or multilayered. In this work, we introduce a general method to take into account the continuity of the property variation in an anisotropic waveguide. This method is based on the knowledge of an analytical solution of the wave equation, the matricant, explicitly expressed via the Peano series (Peano, 1888). The accuracy of the numerical evaluation of this solution and its validity domain are perfectly managed (Baron, 2005; Youssef and El-Arabawi, 2007). Because it deals with an analytical solution, all the wave propagation parameters are controlled. This represents an advantage with respect to numerical methods such as finite-element and finite-difference methods for which the problem treated is a global one, making difficult to analyze and interpret the experimental data, which result from the interaction and coupling of numerous physical phenomena. To the best of our knowledge, this is the first method to evaluate the mechanical behavior of a fluid-loaded anisotropic waveguide with

continuously varying properties without modeling the FGM plate by a multilayered plate. Consequently, in the context of real materials with continuously varying properties (such as bone, bamboo, or manufactured FGM), this method could allow assessing the solution to a more realistic model with a controlled accuracy and without an increase in the computation-time.

In this work, we first present the method and its setup with fluid-structure interaction; then we proceed to the validation of the method by comparing our results to the dispersion curves obtained from classical schemes on homogeneous waveguides (isotropic and anisotropic). Two advantages of the method are underlined: (i) An asymmetric fluid-loading may be taken into account without modifying the scheme for the numerical solution, and (ii) the influence of the property gradient on the ultrasonic response of the waveguide may be investigated via the frequency spectrum of the reflection coefficient modulus. Finally, we get onto the relevancy of this model applied to the ultrasound characterization of cortical bone by the axial transmission technique.

II. BACKGROUND

Contemporary work efforts over the last 2 decades illustrate some of the technology interest on guided waves to non-destructive evaluation. Namely, Rose (2002) gave a review of ultrasonic guided wave inspection potential. A lot of papers deal with the interaction between guided waves and a solid plate immersed in a fluid or embedded between two different fluids. Guided modes in an infinite elastic isotropic plate in vacuum were first treated by Rayleigh (1885) then by Lamb (1917). The Lamb wave problem is reserved, strictly speaking, for wave propagation in a traction-free homogeneous isotropic plate. To deal with guided modes in a fluid-loaded plate, we use the term “leaky Lamb waves” as the energy is partly radiated in the fluids on both sides of the plate. For the basic Lamb problem—plate in vacuum—the

^{a)} Author to whom correspondence should be addressed. Electronic mail: naili@univ-paris12.fr

solutions of the dispersion equation are real whereas in the case of a plate bounded by media on both sides, the dispersion equation has complex solutions. In 1961, Worlton (1961) gave an experimental confirmation of the theoretical work of Lamb (1917), by obtaining experimentally the dispersion curves of aluminum and zirconium plates, asserting that water loading has little effect on the behavior of waves in plates. In 1976, Pitts *et al.* (1976) presented some numerical test results on the relationship between real part of the reflection coefficient poles and the phase velocity of leaky Lamb modes in a homogeneous isotropic brass plate in water. Folds and Loggins (1977) proposed analytical expressions of the reflection and transmission coefficients for plane waves at oblique incidence on a multilayered isotropic plate immersed in water based on Brekhovskikh's (1980) analysis. They found good agreement with their theoretical results and experimental data. Few years later, Fiorito *et al.* (1979) developed a resonance formalism for the fluid-loaded elastic plate and gave some theoretical and numerical results for an isotropic steel plate immersed in the water. This formalism was generalized to the interactions of acoustic plane waves with an asymmetrically fluid-loaded elastic plate by Franklin *et al.* (2001). Nayfeh, Chimenti, and Rokhlin produced a lot of works on wave propagation in anisotropic media and particularly in fiber composite plates immersed in a fluid (Chimenti and Nayfeh, 1986, 1990; Chimenti and Rokhlin, 1990; Nayfeh and Chimenti, 1988, 1989; Rokhlin and Wang, 2002). Based on their formalism, Deschamps and Poncelet (2000) placed the emphasis on the difference between what they called transient Lamb wave-solutions of the characteristic equation of the plate for complex frequency and real slowness (time attenuation), and heterogeneous Lamb waves for which the slowness is complex and the frequency is real (spatial attenuation). These two ways of resolution of the dispersion equation have two different physical meanings—space or time attenuation—and consequences of this difference are developed in their paper (Deschamps and Poncelet, 2000). A critical point is the validity of the Cremer's coincidence hypothesis: The real couples (angular frequency ω and phase velocity v_φ), such that the reflection coefficient is minimum, may be identified as velocity dispersion of plate waves. Experimentally checked in a lot of configurations, it appears to be not well satisfied in several cases (for instance, graphite-epoxy plates when the ratio between fluid and plate mass densities is not "small") (Chimenti and Nayfeh, 1986; Nayfeh and Chimenti, 1988). The results obtained by Deschamps and Poncelet (2000) on fluid-loaded plate show a good correlation between dispersion curves obtained in complex frequency and the minima of the reflection coefficient, which suggests that the Cremer's coincidence principle is still valid considering time attenuation. All these studies show the evidence that the wave propagation in fluid-loaded elastic plate emerges as a very delicate problem, which needs cautious treatment.

III. GENERAL FORMULATION OF THE PROBLEM

We consider a three-dimensional multilayer system composed of one elastic solid layer sandwiched between two

acoustic fluid layers. Let $\mathbf{R}(O, \mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3)$ be the Cartesian frame of reference where O is the origin of the space and $(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3)$ is an orthonormal basis for this space. The coordinate of the generic point \mathbf{x} in \mathbf{R} is specified by (x_1, x_2, x_3) . The acoustic fluid layers occupy an open unbounded domain. Both fluids f_1 and f_2 are supposed perfect, of respective mass densities ρ_{f_1} and ρ_{f_2} ; the constant speeds of sound in each fluid are c_{f_1} and c_{f_2} , respectively. The thickness of the solid layer is denoted by d and its mass density by ρ . The interfaces between the fluids and the solid layer are infinite planes parallel to the $(\mathbf{x}_1, \mathbf{x}_2)$ -plane. The \mathbf{x}_3 -axis is oriented downward and the origin O is located at the interface between the upper fluid f_1 and the solid layer. Therefore, we assume that the structure is a two-dimensional one and that the guided waves travel in the plane $x_2=0$; in the following parts, this coordinate is implicit and is omitted in the mathematical expressions. Moreover, the solid layer will be so-called plate.

The elastic plate is supposed to be anisotropic and is liable to present continuously varying properties along its thickness (\mathbf{x}_3 -axis). These mechanical properties are represented by the stiffness fourth-order tensor $\mathbf{C}=\mathbf{C}(x_3)$ and the mass density $\rho=\rho(x_3)$.

A. System equations

1. The wave equation in the fluid f_n (for $n=1$ or 2)

In the fluid f_n and the context of the linear acoustic theory, the linearized Euler's equation and the constitutive equations are written as

$$-\frac{\partial p^{(n)}}{\partial x_j} = \rho_{f_n} \frac{\partial^2 u_j^{(n)}}{\partial t^2},$$

$$p^{(n)} = K_{f_n} \operatorname{div} \mathbf{u}^{(n)}, \quad (1)$$

where $\mathbf{u}^{(n)}$ and $p^{(n)}$, respectively, represent the displacement vector and the pressure in the fluid f_n ; its compressibility and the speed of sound in the fluid at equilibrium are, respectively, K_{f_n} and $c_{f_n} = \sqrt{K_{f_n}/\rho_{f_n}}$. The operator div is the divergence.

The solutions of system (1) for the fluid f_n are sought under the form

$$\mathbf{f}_n(x_1, x_2, t) = \mathbf{A}_n(x_3) \exp \iota(k_1 x_1 + k_3^{(n)} x_3 - \omega t), \quad (2)$$

where k_1 and $k_3^{(n)}$ are the wavenumbers, respectively, along the \mathbf{x}_1 -axis and \mathbf{x}_3 -axis in the fluid f_n ; the angular frequency is noted ω and ι is the imaginary unit.

We consider an incident wave reaching the plate at an angle θ_1 from the \mathbf{x}_3 -axis in the fluid f_1 . The incident displacement-field is defined in the following form, assuming that its amplitude is normalized:

$$\mathbf{u}_I^{(1)} = \begin{pmatrix} \sin \theta_1 \\ 0 \\ \cos \theta_1 \end{pmatrix} \exp \iota(k_1 x_1 + k_3^{(1)} x_3 - \omega t), \quad (3)$$

with $k_1 = (\omega/c_{f_1}) \sin \theta_1$ and $k_3^{(1)} = (\omega/c_{f_1}) \cos \theta_1$. From this, the expressions of the reflected displacement-field $\mathbf{u}_R^{(1)}$ in f_1 and of the transmitted displacement-field $\mathbf{u}_T^{(2)}$ in f_2 are deduced as follows:

$$\mathbf{u}_R^{(1)} = R \begin{pmatrix} \sin \theta_1 \\ 0 \\ -\cos \theta_1 \end{pmatrix} \exp i(k_1 x_1 - k_3^{(1)} x_3 - \omega t),$$

$$\mathbf{u}_T^{(2)} = T \frac{c_{f_2}}{c_{f_1}} \begin{pmatrix} \sin \theta_1 \\ 0 \\ \cos \theta_1 \end{pmatrix} \exp i(k_1 x_1 + k_3^{(2)} x_3 - \omega t). \quad (4)$$

where $R=R(x_1, x_3; t)$ and $T=T(x_1, x_3; t)$, respectively, represent the reflection and transmission coefficients, which will be expressed explicitly in the sequel. The incident, reflected, and transmitted pressure fields, respectively, noted $p_I^{(1)}$, $p_R^{(1)}$, and $p_T^{(2)}$, are deduced from expressions (3) and (4), and the second equation of the system (1)

$$p_I^{(1)} = -i\omega \times \rho_{f_1} c_{f_1} \times \exp i(k_1 x_1 - k_3^{(1)} x_3 - \omega t),$$

$$p_R^{(1)} = -i\omega \times \rho_{f_1} c_{f_1} \times R \times \exp i(k_1 x_1 - k_3^{(1)} x_3 - \omega t),$$

$$p_T^{(2)} = -i\omega \times \rho_{f_2} c_{f_2} \times T \times \exp i(k_1 x_1 + k_3^{(2)} x_3 - \omega t). \quad (5)$$

B. The wave equation in the plate waveguide

The body forces in the solid plate are neglected. The balance equation of linear momentum associated with the constitutive law of linear elasticity (Hooke's law) gives the following equations:

$$\frac{\partial \sigma_{ij}}{\partial x_j} = \rho \frac{\partial^2 u_i}{\partial t^2},$$

$$\sigma_{ij} = \frac{1}{2} C_{ijkl} \left(\frac{\partial u_k}{\partial x_\ell} + \frac{\partial u_\ell}{\partial x_k} \right), \quad (6)$$

where u_i (for $i=1, \dots, 3$) and σ_{ij} (for $i, j=1, \dots, 3$), respectively, represent the components of the displacement-field \mathbf{u} and of the stress $\boldsymbol{\sigma}$. In system (6), Einstein's convention of summation on repeated indices is used. The solutions are sought for the vectors of displacement \mathbf{u} and traction σ_{i3} (for $i=1, \dots, 3$) (assumed to be harmonic in time t and space along the \mathbf{x}_1 -axis) under the form

$$\mathbf{f}(x_1, x_3; t) = \mathbf{A}(x_3) \exp i(k_1 x_1 - \omega t). \quad (7)$$

C. Fluid-loading interface conditions

The conditions at both interfaces $x_3=0$ and $x_3=d$ are the continuity of the normal displacement and the continuity of the normal stress. We consider that the fluids f_1 and f_2 are perfect; consequently, the shear stresses are zero at the interfaces [$\sigma_{13}(x_1, 0; t) = \sigma_{13}(x_1, d; t) = 0$ and $\sigma_{23}(x_1, 0; t) = \sigma_{23}(x_1, d; t) = 0$]. The following relations are obtained:

$$u_3(x_1, 0; t) = u_3^{(1)}(x_1, 0; t), \quad u_3(x_1, d; t) = u_3^{(2)}(x_1, d; t),$$

$$\sigma_{33}(x_1, 0; t) = -p^{(1)}(x_1, 0; t), \quad \sigma_{33}(x_1, d; t) = -p^{(2)}(x_1, d; t), \quad (8)$$

with

$$u_3^{(1)} = \mathbf{u}_I^{(1)} \cdot \mathbf{x}_3 + \mathbf{u}_R^{(1)} \cdot \mathbf{x}_3, \quad u_3^{(2)} = \mathbf{u}_T^{(2)} \cdot \mathbf{x}_3 \quad \text{and}$$

$$p^{(1)} = p_I^{(1)} + p_R^{(1)}, \quad p^{(2)} = p_T^{(1)}. \quad (9)$$

D. A closed-form solution: The matricant

Introducing expression (7) in Eq. (6), we obtain the wave equation under the form of a second-order differential equation with non-constant coefficients. For particular forms of profiles, this equation has analytical solutions expressed with special functions (Bessel or Hankel functions) (Vlasie and Rousseau, 2004). But, in the general case, there is no analytical solution to the problem thus formulated. The most current methods to solve the wave equation in unidirectionally heterogeneous media are derived from the Thomson–Haskell method (Haskell, 1953; Thomson, 1950). These methods are appropriate for multilayered media (Hosten and Castaigns, 2003; Kennen, 1982; Lévesque and Piché, 1992; Wang and Rokhlin, 2001). But, for continuously varying media, these techniques mean to replace the continuous profiles of properties with step-wise functions. Thereby, the studied problem becomes an approximate one, even before the resolution step; the accuracy of the solution as its validity domain is hard to evaluate. Moreover, the multilayered model of the waveguide creates some “virtual” interfaces likely to induce artifacts. In order to deal with the exact problem, that is to keep the continuity of the properties' variation, the wave equation is re-written under the form of an ordinary differential equation system with non-constant coefficients for which an analytical solution exists: the matricant (Baron, 2005).

1. Hamiltonian form of the wave equation

We consider that the plate presents material symmetries that allow decoupling the pressure–shear vertical (P-SV) waves, polarized in the propagation plane ($\mathbf{x}_1, \mathbf{x}_3$) and the shear horizontal (SH) waves polarized along \mathbf{x}_2 -axis. The incident medium f_1 is a perfect fluid; only the P-SV waves travel in the plate. Applying a spatio-temporal Fourier transform on (x_1, t) of the displacement-field [noted $\hat{\mathbf{u}}(k_1, x_3; \omega)$ after Fourier transform] and on the traction field [noted $\hat{\sigma}_{i3}(k_1, x_3; \omega)$ for $i=1, \dots, 3$] and using the Voigt notation (C_{ijkl} for $i, j, k, \ell=1, \dots, 3$ is replaced with c_{IJ} for $I, J=1, \dots, 6$), Eq. (6) leads to Stroh's (1962) sextic plate formalism (Hamiltonian formulation of the wave equation)

$$\frac{\partial \hat{\sigma}_{13}}{\partial x_3} = \rho(\omega)^2 \hat{u}_1 - ik_1 \hat{\sigma}_{11}, \quad \frac{\partial \hat{\sigma}_{33}}{\partial x_3} = \rho(\omega)^2 \hat{u}_3 - ik_1 \hat{\sigma}_{13}, \quad (10)$$

$$\hat{\sigma}_{11} = ik_1 c_{11} \hat{u}_1 + c_{33} \frac{\partial \hat{u}_3}{\partial x_3}, \quad \hat{\sigma}_{13} = c_{55} \left(\frac{\partial \hat{u}_1}{\partial x_3} + ik_1 \hat{u}_3 \right),$$

$$\hat{\sigma}_{33} = ik_1 c_{13} \hat{u}_1 + c_{33} \frac{\partial \hat{u}_3}{\partial x_3}. \quad (11)$$

According to Eqs. (10) and (11), $\hat{\sigma}_{11}$ is function of \hat{u}_1 and $\hat{\sigma}_{33}$. The wave equation becomes a matrix system expressed using the Thomson–Haskell parametrization of Stroh's (1962) sextic plate formalism

$$\frac{d}{dx_3} \begin{pmatrix} i\omega \hat{u}_1 \\ i\omega \hat{u}_3 \\ \hat{\sigma}_{13} \\ \hat{\sigma}_{33} \end{pmatrix} = i\omega \begin{pmatrix} 0 & s_1 & 1/c_{55}(x_3) & 0 \\ -s_1 c_{13}(x_3)/c_{33}(x_3) & 0 & 0 & 1/c_{33}(x_3) \\ \rho(x_3) - s_1^2 \zeta(x_3) & 0 & 0 & -s_1 c_{13}(x_3)/c_{33}(x_3) \\ 0 & \rho(x_3) & -s_1 & 0 \end{pmatrix} \begin{pmatrix} i\omega \hat{u}_1 \\ i\omega \hat{u}_3 \\ \hat{\sigma}_{13} \\ \hat{\sigma}_{33} \end{pmatrix}, \quad (12)$$

that is,

with the relations

$$\zeta(x_3) = c_{11}(x_3) - \frac{c_{13}^2(x_3)}{c_{33}(x_3)}, \quad k_1 = \omega s_1, \quad (14)$$

where s_1 is the x_1 -component of the slowness. The matrix \mathbf{Q} includes all the information about the heterogeneity of the waveguide because it is expressed from the plate mechanical properties ($\rho(x_3), C(x_3)$) and from two acoustical parameters (s_1, ω).

2. Explicit solution: The Peano expansion of the matricant

The wave equation thus formulated has an analytical solution expressed between a reference point $(x_1, 0, x_3^0)$ and some point of the plate $(x_1, 0, x_3)$ in the propagation plane. This solution is called the matricant and is explicitly written under the form of the Peano series expansion (Gantmacher, 1959; Peano, 1888; Pease, 1965):

$$\mathbf{M}(x_3, x_3^0) = \mathbf{I} + (i\omega) \int_{x_3^0}^{x_3} \mathbf{Q}(\xi) d\xi + (i\omega)^2 \times \int_{x_3^0}^{x_3} \mathbf{Q}(\xi) \left(\int_{x_3^0}^{\xi} \mathbf{Q}(\xi_1) d\xi_1 \right) d\xi + \dots, \quad (15)$$

where \mathbf{I} is the identity matrix of dimension (4,4). If the matrix components $\mathbf{Q}(x_3)$ are bounded in the study interval, these series are always convergent (Baron, 2005). The components of the matrix \mathbf{Q} are continuous in x_3 and the study interval is bounded (thickness of the waveguide); consequently the hypothesis is always verified. We underline that the $i\omega$ -factorization leads up to a polynomial form of the matricant. The $i\omega$ -polynomial coefficients are matrices independent of ω .

3. Boundary conditions: Fluid-structure interaction

Using the propagator property of the matricant through the plate thickness, the state-vector [defined in Eq. (13)] at the second interface $\eta(d)$ is evaluated from the state-vector at the first interface $\eta(0)$ as follows:

$$\eta(d) = \mathbf{M}(d, 0) \eta(0). \quad (16)$$

The fluid-structure interaction sets the conditions of zero shear stresses (see Sec. III C), used after a spatio-temporal Fourier transform on (x_1, t) . Equation (16) becomes

$$\begin{pmatrix} i\omega \hat{u}_1(k_1, d; \omega) \\ i\omega \hat{u}_3(k_1, d; \omega) \\ 0 \\ \hat{\sigma}_{33}(k_1, d; \omega) \end{pmatrix} = \begin{pmatrix} M_{11} & M_{12} & M_{13} & M_{14} \\ M_{12} & M_{22} & M_{23} & M_{24} \\ M_{13} & M_{23} & M_{33} & M_{34} \\ M_{14} & M_{24} & M_{34} & M_{44} \end{pmatrix} \times \begin{pmatrix} i\omega \hat{u}_1(k_1, 0; \omega) \\ i\omega \hat{u}_3(k_1, 0; \omega) \\ 0 \\ \hat{\sigma}_{33}(k_1, 0; \omega) \end{pmatrix}. \quad (17)$$

The condition to obtain a nontrivial solution to Eq. (17) leads to the following relation:

$$i\omega \hat{u}_1(k_1, 0; \omega) \times M_{13} + i\omega \hat{u}_3(k_1, 0; \omega) \times M_{32} + \hat{\sigma}_{33}(k_1, 0; \omega) \times M_{34} = 0, \quad (18)$$

where M_{ij} (for $i, j = 1, \dots, 4$) represent the components of the matrix \mathbf{M} . The displacement component $\hat{u}_1(k_1, 0; \omega)$ can be expressed as a linear combination of $\hat{u}_3(k_1, 0; \omega)$ and $\hat{\sigma}_{33}(k_1, 0; \omega)$; thus system (16) of dimension 4 is reduced to a matrix system of dimension 2

$$\eta(d) = \begin{pmatrix} P_1 & P_2 \\ P_3 & P_4 \end{pmatrix} \eta(0) \quad \text{where} \quad \eta(x_3) = \begin{pmatrix} i\omega \hat{u}_3 \\ \hat{\sigma}_{33} \end{pmatrix}, \quad (19)$$

with the relations

$$P_1 = M_{22} - M_{21} \frac{M_{32}}{M_{31}}, \quad P_2 = M_{24} - M_{21} \frac{M_{34}}{M_{31}}, \\ P_3 = M_{42} - M_{41} \frac{M_{32}}{M_{31}}, \quad P_4 = M_{44} - M_{11} \frac{M_{34}}{M_{31}}. \quad (20)$$

Interface conditions (8) are transformed in the Fourier domain (k_1, ω) . The expressions of the displacement and the pressure in the fluids [see Eqs. (3)–(5)], so that the one of the displacement and traction fields in the solid plate [see Eq. (19)], are substituted in the transformed interface conditions.

Setting $\boldsymbol{\eta}(0) = (\alpha_1, \alpha_2)^T \exp i(k_1 x_1 - \omega t)$, where the superscript T designates the transpose operator, we obtain the following matrix equation:

$$\begin{pmatrix} i\omega s_3^{(1)} c_{f_1} & 1 & 0 & 0 \\ -i\omega \rho_{f_1} c_{f_1} & 0 & 1 & 0 \\ 0 & P_1 & P_2 & -i\omega s_3^{(2)} c_{f_2} \exp(i\omega s_3^{(2)} d) \\ 0 & P_3 & P_4 & -i\omega \rho_{f_2} c_{f_2} \exp(i\omega s_3^{(2)} d) \end{pmatrix} \begin{pmatrix} \hat{R} \\ \alpha_1 \\ \alpha_2 \\ \hat{T} \end{pmatrix} = \begin{pmatrix} i\omega s_3^{(1)} c_{f_1} \\ i\omega \rho_{f_1} c_{f_1} \\ 0 \\ 0 \end{pmatrix}, \quad (21)$$

where $\mathbf{s}^{(n)} = \mathbf{k}^{(n)} / \omega$ is the slowness-vector in the fluid f_n ($n = 1$ or 2). The quantities \hat{R} and \hat{T} are, respectively, the reflection and transmission coefficients expressed in the Fourier domain: $\hat{R} = \hat{R}(k_1, x_3; \omega)$ and $\hat{T} = \hat{T}(k_1, x_3; \omega)$. The two first lines of system (21) express the boundary conditions at the first interface ($x_3 = 0$) and the two last lines those at the second interface ($x_3 = d$) introducing the Fourier transform of expressions (3)–(5) in the following relations:

$$\boldsymbol{\eta}(0) - \begin{pmatrix} i\omega \hat{u}_{3R}^{(1)} \\ -\hat{p}_R \end{pmatrix}_{x_3=0} = \begin{pmatrix} i\omega \hat{u}_{3I}^{(1)} \\ -\hat{p}_I \end{pmatrix}_{x_3=0},$$

$$\begin{pmatrix} P_1 & P_2 \\ P_3 & P_4 \end{pmatrix} \boldsymbol{\eta}(0) - \begin{pmatrix} i\omega \hat{u}_{3T}^{(2)} \\ -\hat{p}_T \end{pmatrix}_{x_3=d} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \quad (22)$$

where $\hat{u}_{3R}^{(1)}$, $\hat{u}_{3I}^{(1)}$, and $\hat{u}_{3T}^{(2)}$ are the components along \mathbf{x}_3 -axis of $\hat{\mathbf{u}}_R^{(1)}$, $\hat{\mathbf{u}}_I^{(1)}$, and $\hat{\mathbf{u}}_T^{(2)}$ vectors, respectively. Note the equality between the quantities $u_{3T}^{(2)}$ and $u_3^{(2)}$ where this last is defined in Eq. (9).

4. Expression of the reflection and transmission coefficients

From Eq. (21), we deduce the analytical expressions of the reflection and transmission complex coefficients

$$\hat{R}(s_1, x_3; \omega) = \frac{(P_3 - P_1 Z_2 + P_4 Z_1 - P_2 Z_1 Z_2)}{(P_3 - P_1 Z_2 - P_4 Z_1 + P_2 Z_1 Z_2)},$$

$$\hat{T}(s_1, x_3; \omega) = -\frac{2Z_2(\rho_{f_1} c_{f_1} / \rho_{f_2} c_{f_2})(P_1 P_4 - P_2 P_3)}{(P_3 - P_1 Z_2 - P_4 Z_1 + P_2 Z_1 Z_2)} \times \exp(-i\omega s_3^{(2)} d), \quad (23)$$

with $Z_n = \rho_{f_n} / \sqrt{1/c_{f_n}^2 - s_1^2}$ (for $n = 1$ or 2) and $k_1 = \omega s_1$.

IV. VALIDATION OF THE METHOD

The aim of this section is to check that the Peano expansion of the matricant is well-adapted to study fluid-loaded waveguides. We take into account the fluid-structure interaction in different configurations of homogeneous plates com-

TABLE I. Elastic properties of transversely isotropic plate (with $c_{23} = c_{22} - 2c_{44}$).

ρ (g cm ⁻³)	c_{11} (GPa)	$c_{22} = c_{33}$ (GPa)	$c_{12} = c_{13}$ (GPa)	c_{44} (GPa)	$c_{66} = c_{55}$ (GPa)
1.85	23.05	15.1	8.7	3.25	4.7

paring the results obtained from the numerical implementation of the Peano expansion of the matricant to results taken from literature.

The numerical evaluation of P_1 , P_2 , P_3 , and P_4 requires us to truncate the Peano series and to numerically calculate the integrals. Thus, the error can be estimated and controlled (Baron, 2005). We retained 70 terms in the series and evaluate the integrals over 100 points using Simpson's rule (fourth-order integration method). These choices ensure the convergence of the solution and the accuracy of the results for a reasonable computation-time (never exceeding few minutes on a desktop computer). Expressions (23) give the frequency spectrum (modulus and phase) of the reflection coefficient for different incidences (s_1 varies from zero-normal incidence to $1/c_{f_1}$ corresponding to the critical incidence in the fluid f_1).

A lot of works detailed the relationship between the poles and the zeros of the reflection coefficient and the leaky Lamb wave dispersion curves (Chimenti and Rokhlin, 1990; Deschamps and Poncelet, 2000). The results of Sec. IV A compare the dispersion curves obtained by seeking the poles of reflection coefficient (23) and the results taken from literature or from closed-form solution.

A. Validation for a homogeneous and isotropic or anisotropic fluid-loaded plate

The method is tested by plotting the dispersion curves (variation of the phase velocity versus frequency-thickness product) for an isotropic aluminum plate immersed in water. The data in the paper of Chimenti and Rokhlin (1990) are used. The results obtained (not shown) by the present method are in perfect agreement with the results presented by them (Chimenti and Rokhlin, 1990).

As mentioned by Chimenti and Rokhlin (1990), there are few differences between the zeros' loci and the poles' loci for a plate immersed in a fluid whose the mass density is lower than the plate mass density. As underlined by several authors, fluid-load does have just a weak influence on guided wave traveling in the plate immersed in water.

Taking into account the anisotropy does not change the scheme for the numerical solution of wave equation with the matricant. We consider a transverse isotropic plate immersed in water ($\rho_f = 1$ g cm⁻³, $c_f = 1.485$ mm μ s⁻¹) whose properties are reported in Table I. For that configuration, Nayfeh and Chimenti (1989) developed a method to obtain an analytical expression of the reflection coefficient. By using the data from this paper, the results obtained (see Fig. 1) with the present method are in perfect agreement with theirs. The curves presented in Figs. 1(a) and 1(b) are superimposed and need to be presented separately.

FIG. 1. Dispersion curves for a transversely isotropic plate immersed in water; comparison between (a) analytical results from Nayfeh and Chimenti (1989) and (b) results obtained via the Peano series expansion of the matrixant.

B. Validation for an asymmetrically loaded homogeneous isotropic plate ($f_1 \neq f_2$)

The formalism presented here to solve the wave equation in an unidirectionally graded medium presents two main advantages: Without changing the scheme to obtain the numerical solution we can take into account (i) an asymmetric loading and (ii) the unidirectional continuous heterogeneity.

The mechanical behavior of the plate is different for symmetric and asymmetric loadings. For example, in the symmetric loading case, there is a unique critical frequency and a unique phase velocity value v_ϕ in the plate, which corresponds to the propagation velocity in the fluid ($v_\phi = c_{f_1} = c_{f_2}$), for which the displacements and the stresses at the interfaces are quasi-null; whereas in the asymmetric loading ($f_1 \neq f_2$), there are two critical frequencies and two values of the phase velocity in the plate for which the structure does not respond (Dickey *et al.*, 1995). The validation is done on an isotropic aluminum plate with the following properties: $\rho = 2.79 \text{ g cm}^{-3}$; the longitudinal and transverse wave velocities are, respectively, $v_L = 6.38 \text{ mm } \mu\text{s}^{-1}$ and $v_T = 3.10 \text{ mm } \mu\text{s}^{-1}$. The characteristic properties of the fluid f_1 correspond to those of water (see Sec. IV A); the characteristic properties of the fluid f_2 correspond to glycerine: $\rho_{f_2} = 1.26 \text{ g cm}^{-3}$ and $c_{f_2} = 1.920 \text{ mm } \mu\text{s}^{-1}$. This configuration is the same as the one studied by Franklin *et al.* (2001). The modulus of the reflection coefficient versus the incident angle is plotted in Fig. 2 for a fixed frequency-thickness product ($f \times d = 4.7 \text{ MHz mm}$).

This figure shows the perfect agreement between our results and the ones presented by Franklin *et al.* (2001).

FIG. 2. Reflection coefficient modulus for an asymmetrically fluid-loaded aluminum plate (water and glycerine) versus incident angle: in dark lines results published in Franklin *et al.* (2001), and in gray crosses the reflection coefficient modulus calculated from Eq. (23). The vertical lines (dashed) represent the two critical angles for longitudinal waves and transverse waves. The dashed curve corresponds to the resonant amplitudes (Franklin *et al.*, 2001).

V. RELEVANCY OF THE METHOD FOR ULTRASOUND CHARACTERIZATION OF CORTICAL BONE

Cortical bone is a kind of hard tissue found at the edges of long bones and supports most of the load of the body. Several studies demonstrated the heterogeneous nature of the cortical bone, particularly they show evidence the gradual variation of the volumetric porosity (ratio between pores and total volume) along the cortical thickness. Yet, the porosity is intrinsically linked to the macroscopic mechanical behavior of the cortical bone (Baron *et al.*, 2007). Therefore, the continuous variation of porosity induces a continuous variation of material properties. Taking into account the gradient should prove itself to be essential in the context of diagnosis and therapeutic monitoring of osteoporosis. Indeed, the gradient characterization would allow assessing geometrical (cortex thickness) and material (elastic coefficients variation) information, which are fundamental parameters to evaluate the bone fragility. For several years, the quantitative ultrasonography (by axial and transverse transmissions) proved itself to be a hopeful alternative technique to evaluate the fracture risk (Marin *et al.*, 2006). However, the inter-individual and inter-site variations of bone mechanical properties make the standardization of the protocol of fracture risk evaluation by ultrasound very delicate.

The focus is set on a configuration closed to the axial transmission device for *in vivo* conditions. In this context, the relevancy of studying the head wave propagation has been demonstrated (Bossy *et al.*, 2004a, 2004b; Camus *et al.*, 2000). As a consequence all the reflection coefficients presented in this paper were calculated for an incident angle corresponding to the grazing-angle for longitudinal waves [critical angle of longitudinal wave propagation in the plate at the first interface ($x_3=0$)].

The surrounding media in the *in vivo* configuration of ultrasound characterization of cortical bone are the muscle for the upper fluid f_1 ($c_{f_1} = 1.54 \text{ mm } \mu\text{s}^{-1}$ and $\rho_{f_1} = 1.07 \text{ g cm}^{-3}$) and the marrow for the lower fluid f_2 ($c_{f_2} = 1.45 \text{ mm } \mu\text{s}^{-1}$ and $\rho_{f_2} = 0.9 \text{ g cm}^{-3}$) (Burlew *et al.*, 1980; Hill *et al.*, 1986). We are interested in the influence of the continuous gradient of the mechanical properties on the ultrasonic response in the configuration of *in vivo* cortical bone characterization.

A. Determination of a realistic range of variation of elastic bone properties

In order to define numerical values for a realistic value of the gradient of the different material properties, it is necessary to determine the limiting values reached by each elastic property. Our approach consists in considering *in vitro* measurements published in [Dong and Guo, 2004](#) and performed in 18 samples. It is assumed that these limiting values for elastic properties are relevant for physiologic ranges of variations.

We assume that cortical bone is transversely isotropic. Transverse isotropy has been shown experimentally by different authors ([Dong and Guo, 2004](#); [Reilly and Burnstein, 1974](#); [Rho, 1996](#)) to be a realistic approximation of cortical bone degree of anisotropy.

[Dong and Guo \(2004\)](#) measured the homogenized bone properties by performing tensile and torsional tests with a mechanical testing system on 18 different human femoral bone specimens. The authors measured the values of the longitudinal and transverse Young's moduli (E_L and E_T , respectively) as well as the values of the longitudinal shear modulus G_L . From these measurements and by assuming constant values of Poisson's ratio, the values of the different components of the stiffness-tensor corresponding to the values of E_L , E_T , and G_L measured in [Dong and Guo, 2004](#) were obtained following the relationships given in the Appendix.

The value of the longitudinal Poisson's ratio ν_L is taken equal to 0.37 for all computations because it corresponds to the average value found in [Dong and Guo, 2004](#). The value of the transverse Poisson's ratio ν_T is taken equal to 0.45 following Eq. (A3) of the Appendix. The values of the stiffness coefficients corresponding to the mean values of the bone mechanical properties are referred to as "reference" set of parameters in what follows. The maximum and minimum values of the stiffness coefficients are obtained by considering, respectively, the maximum and minimum values of E_L and E_T within the range of variation measured in [Dong and Guo, 2004](#), which is a simple way to obtain a realistic range of variation for the stiffness coefficients in cortical bone. Furthermore, the elastic properties deduced from the approach reported above were constrained to verify the thermodynamical stability conditions given in the Appendix by Eq. (A4).

We choose reference value of mass density ρ equal to 1.722 g cm^{-3} , following the value taken in [Macocco et al., 2006](#). In order to derive a realistic range of variation for mass density, we assume that the reference value is given by a porosity of 7%, which corresponds approximately to the mean porosity at the radius ([Baron et al., 2007](#)). The porosity was assumed to vary between 3% and 15% ([Bousson et al., 2001](#); [Dong and Guo, 2004](#)) and a rule of mixture leads to the range of variation of mass density.

B. Modeling a gradient of material property

The impact of a controlled gradient vector δ of any investigated material property S on the response of the structure studied is assessed. The scalar S corresponds to one of the stiffness coefficients c_{ij} of \mathbb{C} or to mass density ρ . In each

FIG. 3. Schematic representation of the two types of spatial variation considered for the material property S corresponding to the stiffness coefficient and to mass density. The solid lines in the solid layer indicate the spatial dependence of S . The dotted line in the solid layer indicates homogeneous material properties corresponding to the reference material properties. The variation of type 1 shown in (a) corresponds to a constant value at the bone-soft tissues' interface. The variation of type 2 shown in (b) corresponds to a constant value in the middle of the bone.

set of simulations, all the material properties are constant and equal to their reference value while S is subjected to the defined gradient.

The gradient vector $\delta = \text{grad } S = \delta \mathbf{x}_3$ is assumed to be independent of x_1 in all cases, where \mathbf{x}_3 is a unit vector along x_3 -axis and grad is the gradient operator acting on a scalar field. The quantity δ is always taken positive because the porosity is known to be higher in the endosteal part ($x_3=d$) than in the periosteal part ($x_3=0$) of the bone. Moreover, only the simple situation of affine spatial variations of S is considered, corresponding to a constant value of δ . This affine spatial variation of S is chosen because the actual physiological spatial dependence of S remains unknown. Two different affine spatial dependencies of the studied material property are considered and are illustrated in Fig. 3. Associated gradient δ will be referred to as type 1 or 2.

Type 1. The gradient of type 1 is such that the physical property S takes the same value S_M at the upper interface $x_3=0$ of the solid plate for all values of the gradient δ . The quantity $S(x_3)$ is therefore given by

$$S(x_3) = S_M + \delta \times x_3, \quad (24)$$

where S_M is given by the maximal value of the material property S considered. The maximal value δ_M of δ is chosen so that $S(d)$ is equal to S_m , where S_m is given by the minimal value of S . The gradient δ_M is given by

$$\delta_M = \frac{(S_m - S_M)}{d}. \quad (25)$$

Type 2. The gradient of type 2 is such that the physical property S takes the same value at the middle $x_3=d/2$ of the solid plate for all values of gradient δ . Furthermore, the

TABLE II. Mean value, maximum, and minimum values of the homogenized longitudinal and transversal Young moduli, of the four elastic constants and of mass density affecting the ultrasonic propagation in the framework of the model. These values are taken from [Dong and Guo \(2004\)](#).

Mechanical quantity	E_L (GPa)	E_T (GPa)	c_{11} (GPa)	c_{13} (GPa)	c_{33} (GPa)	$c_{55}=G_L$ (GPa)	ρ (g cm ⁻³)
Mean value (reference)	16.6	9.5	23.1	8.7	15.1	4.7	1.722
Minimum	13.4	6.5	17.6	5.1	9.1	3.3	1.66
Maximum	20.6	12.8	29.6	15.9	25.9	5.5	1.753

mean value of the property S is identical for all δ . The quantity $S(x_3)$ is given by

$$S(x_3) = \frac{(S_m + S_M)}{2} + \delta \times \left(x_3 - \frac{d}{2} \right). \quad (26)$$

The maximal value of δ is also given by Eq. (25), so that all values of $S(x_3)$ are again always comprised between S_m and S_M . Again, the maximal value δ_M of δ is given by Eq. (25).

Gradient of type 2 leads for all magnitudes of δ to a constant value of the spatial average of the gradient.

For both types of spatial variations, five different values of δ regularly distributed between 0 and δ_M are arbitrarily considered in the thickness.

Table II recalls the maximum, minimum, and mean measured values of E_L , E_T , and G_L as given by [Dong and Guo \(2004\)](#). Table II also shows the maximum, minimum, and mean values of the four components (c_{11} , c_{13} , c_{33} , and c_{55}) of the stiffness-tensor C affecting wave propagation derived from Eq. (A3) of the Appendix.

In Table III, the minimal and maximal values of each variable corresponding to the realistic range of variation obtained (i) by considering the reference values of Table II and (ii) by verifying that the thermodynamical stability conditions are fulfilled. Values resulting from the stability conditions are marked with an asterisk.

In the simulations, the values of S_M and S_m are those reported in Table III.

C. Results and discussion

First of all, the method allows investigating the influence of the fluids on the ultrasonic response. In the case of the characterization of cortical bone, the two fluids f_1 and f_2 are different, which corresponds to an asymmetrical loading (see Sec. IV B): The fluid f_1 has been considered as muscle ($c_{f_1} = 1540 \text{ m s}^{-1}$ and $\rho_{f_1} = 1.07 \text{ g cm}^{-3}$) and fluid f_2 as marrow ($c_{f_2} = 1450 \text{ m s}^{-1}$ and $\rho_{f_2} = 0.9 \text{ g cm}^{-3}$). The properties of these two fluids are very close to those of water. The frequency spectrum of the reflection coefficient modulus has

been plotted for the *in vivo* configuration and compared with the result obtained for a cortical bone plate immersed in water for the ten profiles of mechanical properties (figure not shown). For homogeneous plates as for linearly graded plates, the two curves are very close; however, the modulus of the reflection coefficient at null-frequency is not null and the minimum values are greater than for water but obtained for the same frequency-thickness products. That is why all the following results have been calculated for a cortical bone plate immersed in water.

The reflection coefficient calculated with the Peano series expansion of the matricant is sensitive to the variation of the properties gradient. As we consider that the osteoporosis entails a trabecularization of cortical bone from the endosteal side, the characterization of the gradient of the properties between the endosteal and periosteal regions may be an element of the diagnosis of the osteoporosis progress and of the therapeutic follow-up.

It is known that the gradient of the properties along the cortical thickness is due to the continuous variation of the porosity growing progressively from the periosteal to the endosteal region. From previous work, we know that the porosity influences all the stiffness coefficients ([Baron et al., 2007](#)). The frequency spectrum of the reflection coefficient has been plotted for the ten profiles presented in Fig. 3 applied to all the stiffness coefficients implied (c_{11} , c_{13} , c_{33} , and c_{55}) and to the mass density ρ (see Table III). The reflection coefficients have been calculated at an incident angle corresponding to the grazing-angle (critical angle for the longitudinal waves in the bone plate). For the two types of gradients, differences appear between all the gradients and the homogenized plates (corresponding to the maximum value for type 1 and to the average value for type 2) particularly on the location of the extrema values of the reflection coefficient modulus (see Fig. 4).

The increase in the gradient of properties shifts the minimum and maximum values forward high frequency-thickness products. However, the results (see Fig. 4) put on evidence that the behavior of the reflection coefficient modulus is sensibly the same for frequency-thickness products be-

TABLE III. The minimal and maximal values of each variable corresponding to the realistic range of variation obtained (i) by considering the reference values of Table II and (ii) by verifying that the thermodynamical stability conditions are fulfilled. Values resulting from the stability conditions are marked with an asterisk.

Material property S	c_{11} (GPa)	c_{13} (GPa)	c_{33} (GPa)	$c_{55}=G_L$ (GPa)	ρ (g cm ⁻³)
Realistic range [S_m, S_M] (reference)	[17.6, 29.6]	[5.1, 11.1*]	[11.8*, 25.9]	[3.3, 5.5]	[1.66, 1.753]

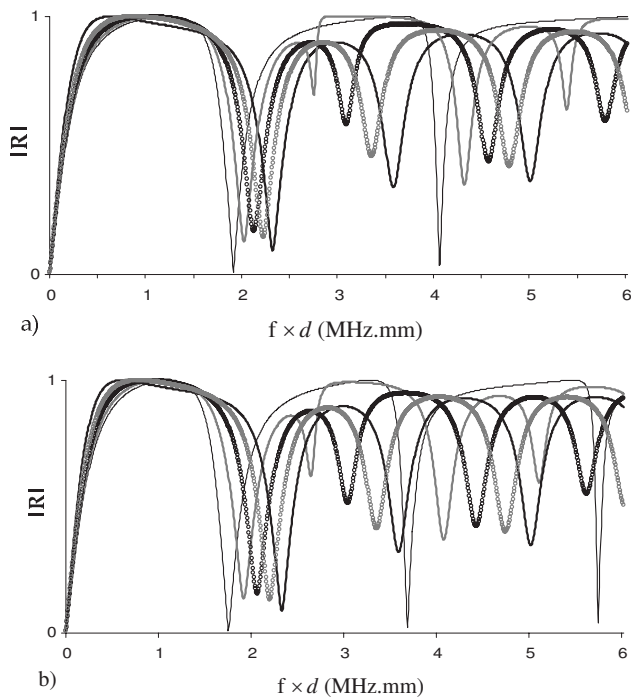

FIG. 4. Frequency spectrum of the reflection coefficient modulus for different properties' variations corresponding to (a) the five profiles of type 1 [Fig. 3(a)] and (b) the five profiles of type 2 [Fig. 3(b)].

tween 0 and 1.5 MHz mm. Beyond this value, the behavior is clearly different. At sufficiently high frequency, the wavelength is smaller and more sensitive to the affine variation of the material properties. It is noteworthy that for a heterogeneous waveguide, the minima of the reflection coefficient magnitude do not reach zero (except for null-frequency) but end at a finite value and the changes in phase (not shown) are not so rapid, which means that total transmission does not take place in this situation.

The influence of the variation of each parameter (stiffness coefficients) on the frequency spectrum of the reflection coefficient has been investigated. This analysis has been led for an incidence angle corresponding to the longitudinal wave critical angle in the plate at $x_3=0$. This incidence corresponds to the generation and the propagation of the head wave.

It appears that each of them has an impact on the reflection wave, but the leading term is c_{11} . The frequency spectrum of the reflection coefficient for a varying c_{11} in an affine way is very close to the frequency spectrum of the reflection coefficient obtained for the affine variation of all the material properties (c_{ij} and ρ) and is the most different to the results from homogenized plates (average value or maximum value) compared to the frequency spectrum calculated for the *one-parameter variation* of the other elastic parameters (c_{13} , c_{33} , and c_{55} , and ρ) (see Fig. 5). It is noteworthy that c_{11} is the stiffness coefficient associated with the axial direction and determining the speed of the head wave. So, it seems that the head wave would be the indicator of the c_{11} gradient. It is important to note that for homogenized plates (extremum value or average) the frequency spectrum of the reflection coefficient is really different from that of the plate with con-

FIG. 5. Frequency spectrum of the reflection coefficient modulus for different properties' variations at grazing-incidence $\theta_1 = \theta_c$: for a homogeneous plate whose properties are those at $x_3=0$ at $\theta_c=21.1^\circ$ (thick gray line), for a homogeneous plate whose properties are the average of the properties through the plate at $\theta_c=23.6^\circ$ (thin gray line), for a plate with all its properties linearly varying at $\theta_c=21.1^\circ$ (black line), and for a plate with an affine variation of the c_{11} only at $\theta_c=21.1^\circ$ (gray lozenges).

tinuously varying properties. We infer that the approximation by a homogeneous plate of cortical bone and all the more so for the osteoporotic cortical bone (for which the gradient would be greater) may induce bad interpretation of the ultrasonic response.

The authors do not know any results in literature about the measurement of the variation of the porosity within the cortical thickness. The assumption of an affine gradient is a first step; other gradients may be investigated and the method presented in this article would be applied in the same way for non-affine gradients (Shuvalov *et al.*, 2005).

VI. CONCLUSION AND PERSPECTIVES

Stroh's (1962) sextic plate formalism has been employed for analyzing the leaky Lamb waves in anisotropic heterogeneous plates immersed in fluids. This formalism and especially the polynomial form of the solution [see Eq. (15)] presents several analytical and numerical advantages. First, the low-frequency asymptotics are naturally assessed evaluating only two or three terms in the series (Shuvalov *et al.*, 2005). The information thus collected is of major interest in the analysis of the elastic behavior of waveguides (Baron *et al.*, 2008). Second, the polynomial form makes the numerical evaluation of the solution faster. Indeed, the polynomial coefficients are independent of the frequency, so they are calculated for a fixed slowness value and stored. When the frequency varies, there is no need to recalculate the polynomial coefficients, it comes to a polynomial evaluation whose coefficients are perfectly known, which is time-saving.

The Peano series of the matricant is a method that keeps the continuity of the profiles and so, the authenticity of the problem. One of the key points for methods based on multi-layered media to deal with FGM is to relevantly discretize the properties' profiles. The choice of the discretization may lead to some errors especially in the evaluation of the resonances.

This elegant mathematical tool is also very adaptative to different physical problems. In the case studied—a fluid-loaded plane waveguide—the anisotropy, the heterogeneity (continuous or discontinuous variation of properties) and the asymmetric fluid-loading are taken into account without changing the resolution scheme.

Further work needs to be done to relate the results presented in this paper to dispersion curves and propagation of transient and heterogeneous waves in a fluid-loaded continuously heterogeneous waveguide.

Furthermore, from this study, the transient response of a fluid-loaded plate is considered. The frequency spectrum of the reflection coefficient is calculated for incidences between the normal and critical incidences for compression waves in the fluid f_1 . Thus, the plate transfer function is calculated in the Fourier domain (x_1 -wavenumber, frequency): $\hat{R}(k_1, x_3; \omega)$. A double inverse Fourier transform on (k_1, ω) is applied on $\hat{R}(k_1, x_3; \omega)$ to transform into the space-time domain; the temporal signals can be obtained at different points along the propagation x_3 -axis: $R(x_1, x_3; t)$.

Lastly, the formalism presented here is well-adapted to deal with wave propagation in anisotropic tubes with radial property gradients (Shuvalov, 2003). The wave equation keeps the same form as Eq. (12), the state-vector is expressed from the displacement and traction components in the cylindrical basis, and the matrix \mathbf{Q} depends on the radial position r ($\mathbf{Q}=\mathbf{Q}(r)$). In cylindrical homogeneous structures, taking into account an anisotropy more important than transverse isotropy is fussy because there is no analytical solution to the “classical” wave equation (second-order differential equation). Stroh’s (1962) formalism, upon which the Peano expansion of the matricant is based, is a promising alternative solution that allows considering altogether the geometry (cylinder), the anisotropy, and the heterogeneity (radial property gradients) of a structure.

APPENDIX: THERMODYNAMICS STABILITY CONDITIONS AND STIFFNESS COEFFICIENTS

Hooke’s law is written under the form $\sigma_{ij}=C_{ijkl}\epsilon_{kl}$ for $(i, j, k, \ell=1, \dots, 3)$, where σ is the stress-tensor, ϵ is the strain-tensor, and C is the fourth-order stiffness-tensor. In the transversely isotropic case, with (x_2, x_3) as isotropic plane, the stiffness-tensor is expressed as a stiffness matrix (using Voigt’s notation)

$$\mathbf{C} = \begin{pmatrix} c_{11} & c_{13} & c_{13} & 0 & 0 & 0 \\ c_{13} & c_{33} & c_{23} & 0 & 0 & 0 \\ c_{13} & c_{23} & c_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{55} \end{pmatrix}. \quad (\text{A1})$$

We introduce the matrix \mathbf{S} , the inverse of the matrix \mathbf{C} . It is expressed by

$$\mathbf{S} = \begin{pmatrix} 1/E_L & -\nu_L/E_L & -\nu_T/E_L & 0 & 0 & 0 \\ -\nu_L/E_L & 1/E_T & -\nu_T/E_T & 0 & 0 & 0 \\ -\nu_L/E_L & -\nu_T/E_T & 1/E_L & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/G_T & 0 & 0 \\ 0 & 0 & 0 & 0 & 1/G_L & 0 \\ 0 & 0 & 0 & 0 & 0 & 1/G_L \end{pmatrix}. \quad (\text{A2})$$

with $E_{L,T}$, the longitudinal (L) and transverse (T) Young’s moduli; $\nu_{L,T}$, the longitudinal (L) and transverse (T) Poisson’s ratios; and $G_{L,T}$, the longitudinal (L) and transverse (T) shear moduli. By inverting Eq. (A1) and identifying it with Eq. (A2), we obtain the following relations:

$$E_L = \frac{c_{11}c_{33} - 2c_{13}^2 + c_{11}c_{23}}{c_{33} + c_{23}}, \quad \nu_L = \frac{c_{13}}{c_{33} + c_{23}},$$

$$E_T = \frac{c_{11}(c_{33}^2 - c_{23}^2) + 2c_{13}^2(c_{23} - c_{33})}{c_{11}c_{33} - c_{13}^2}, \quad \nu_T = \frac{c_{11}c_{23} - c_{13}^2}{c_{11}c_{33} - c_{13}^2},$$

$$G_T = c_{44}, \quad G_L = c_{55}. \quad (\text{A3})$$

Knowing the stiffness coefficient values, we can verify if the thermodynamical stability conditions are satisfied as follows:

$$E_L > 0, \quad E_T > 0, \quad -1 < \nu_T < 1,$$

$$\frac{(1 - \nu_T)E_L}{2} - \nu_L^2 > 0, \quad G_L > 0. \quad (\text{A4})$$

ABSTRACT

As a non-destructive, non-invasive and non-ionizing evaluation technique for heterogeneous media, the ultrasonic method is of major interest in industrial applications but especially in biomedical fields. Among the unidirectionally heterogeneous media, the continuously varying media are a particular but widespread case in natural materials. The first studies on laterally varying media were carried out by geophysicists on the Ocean, the atmosphere or the Earth, but the teeth, the bone, the shells and the insects wings are also functionally graded media. Some of them can be modeled as planar structures but a lot of them are curved media and need to be modeled as cylinders instead of plates. The present paper investigates the influence of the tubular geometry of a waveguide on the propagation of elastic waves. In this paper, the studied structure is an anisotropic hollow cylinder with elastic properties (stiffness coefficients C_{ij} and mass density ρ) functionally varying in the radial direction. An original method is proposed to find the eigenmodes of this waveguide without using a multilayered model for the cylinder. This method is based on the sextic Stroh's formalism and an analytical solution, the matricant, explicitly expressed under the Peano series expansion form. This approach has already been validated for the study of an anisotropic laterally-graded plate (Baron et al., 2007; Baron and Naili, 2010) [6,5]. The dispersion curves obtained for the radially-graded cylinder are compared to the dispersion curves of a corresponding laterally-graded plate to evaluate the influence of the curvature.

Preliminary results are presented for a tube of bone in vacuum modelling the *in vitro* conditions of bone strength evaluation.

1. Introduction

The observation of natural media and particularly of living tissues is a great source of inspiration for scientists. As an example, they develop industrial Functionally Graded Materials (FGM) in the 80s which reproduce a characteristic observed in natural media such as wood, bone or shells. The continuous variation of the mechanical properties of these materials reveals interesting mechanical behavior particularly exploited in high-technology and biomedical applications [48,19,26]. As a consequence, the non-destructive characterization of FGM structures became a key issue: first, to better understand the natural mechanisms observed and second, to guide the conception of groundbreaking FGM. Surface and guided waves are significant information source in non-destructive testing and evaluation of complex structures. A lot of works detailed the behavior of the guided waves in isotropic or anisotropic plates [39,23,46,3]. Also, elastic wave propagation in

cylindrical structures formed from material with lower anisotropy than orthotropy has been the subject of numerous theoretical and experimental investigations widely published [30,50,20]. For anisotropic material, the complexity of the problem relies on the fact that the boundary problem do not permit solution in cylindrical functions except in some particular configurations [29].

In this work, we solve the wave equation in an anisotropic waveguide with one-direction heterogeneity using a general method based on the sextic Stroh's formalism [44]. It takes into account the unidirectional continuous variation of the properties of the waveguide without using a multilayered model. It is based on the knowledge of an analytical solution of the wave equation, the matricant, explicitly expressed *via* the Peano series expansion [6]. The accuracy of the numerical evaluation of this solution and its validity domain are perfectly managed [4,49]. One of the advantages of knowing an analytical solution with respect to purely numerical methods is to control all the physical parameters and to interpret more easily the experimental data which result from the interaction and coupling of numerous physical phenomena.

In this paper, a sample of long bone is considered as an example of anisotropic functionally graded tube. The material is multiscale

E-mail address: cecile.baron@upmc.fr

and the discrete variations of its microscopic properties (bone matrix elasticity, micro-architecture, etc.) [9,8,41] is assumed to induce continuous profiles of macroscopic properties in the radial direction [7,16,5]. Obviously, the mechanical behavior of bone depends on several parameters (microstructure, elasticity and geometry). The curvature is part of them and its influence remains unclear.

We first present the method and its setup for the cylindrical waveguide; this method has been validated by comparing our results to the dispersion curves obtained from classical schemes on homogeneous and functionally graded waveguides. Some advantages of the method are underlined: (i) general anisotropy may be taken into account for cylindrical structures; (ii) the influence of the property gradient on the mechanical behavior of the waveguide may be investigated; (iii) the influence of the curvature on the propagation of elastic waves may be evaluated.

2. Methods

We consider an elastic tube of thickness t placed in vacuum.

The radius r varies from a_0 to a_q , respectively, the inner and outer radius of the tube (Fig. 1). The elastic cylinder is supposed to be anisotropic and is liable to present continuously varying properties along its radius (\mathbf{e}_r -axis). These mechanical properties are represented by the stiffness tensor $\mathbb{C} = \mathbb{C}(r)$ and the mass density $\rho = \rho(r)$.

2.1. System equations

The momentum conservation equation associated with the constitutive law of linear elasticity (Hooke's law) gives the following equations:

$$\begin{cases} \operatorname{div} \boldsymbol{\sigma} = \rho \frac{\partial^2 \mathbf{u}}{\partial t^2}, \\ \boldsymbol{\sigma} = \frac{1}{2} \mathbb{C} (\operatorname{grad} \mathbf{u} + \operatorname{grad}^T \mathbf{u}), \end{cases} \quad (1)$$

where \mathbf{u} is the displacement vector and $\boldsymbol{\sigma}$ the stress tensor.

We are seeking the solutions of wave equation for displacement (\mathbf{u}) and radial traction-vector ($\boldsymbol{\sigma}_r = \boldsymbol{\sigma} \cdot \mathbf{e}_r$) expressed in the cylindrical coordinates (r, θ, z) with the basis $\{\mathbf{e}_r, \mathbf{e}_\theta, \mathbf{e}_z\}$:

$$\begin{aligned} \mathbf{u}(r, \theta, z; t) &= \mathbf{U}^{(n)}(r) \exp i(n\theta + k_z z - \omega t), \\ \boldsymbol{\sigma}_r(r, \theta, z; t) &= \mathbf{T}^{(n)}(r) \exp i(n\theta + k_z z - \omega t); \end{aligned} \quad (2)$$

with k_z the axial wavenumber and n the circumferential wavenumber.

We distinguish two types of waves propagating in a cylindrical waveguide: the *circumferential waves* and the *axial waves*. The *circumferential waves* are the waves traveling in planes perpendicular to the axis direction. They correspond to $u_z(r) = 0$ ($\forall r$), $k_z = 0$ and $n = k_\theta a_q$. The *axial waves* are the waves traveling along the axis

Fig. 1. Geometrical configuration of the waveguide.

direction, the circumferential wavenumber is an integer $n = 0, 1, 2, \dots$. Among the *axial waves*, we distinguish three types of modes numbered with two parameters (n, m) representing the circumferential wavenumber and the order of the branches: longitudinal (L), flexural (F) and torsional (T) modes. The longitudinal modes are axially symmetric ($n = 0$), they are noted $L(0, m)$ and sometimes called the breathing modes [3]. For the two other types of modes, two classifications have been proposed in the literature. Meitzler [28] and Zemanek [50], following Gazis work [14], restricted the T-modes to axially symmetric circumferential fundamental modes $T(0, m)$ and the modes with non-zero n are considered as F-modes $F(n, m)$. An other way is proposed by Nishino and colleagues [34] who considered that the n -parameter of the T-modes is not limited to zero. Consequently they can associate “their” L- and F-modes to the Lamb waves (coupled bulk longitudinal and bulk shear-vertical waves) in the plate and the T-modes to the bulk horizontal-shear waves propagating in the plate. This classification may be relevant in the case of isotropic media but it becomes invalid for anisotropic media for which the flexural waves are longitudinal shear waves [14].

In this paper, only the *axial waves* are investigated and the usual classification of Gazis [14] is used.

2.2. A closed-form solution: the matricant

Introducing the expression (2) in Eq. (1), we obtain the wave equation under the form of a second-order differential equation with non-constant coefficients. In the general case, there is no analytical solution to the problem thus formulated. The most current methods to solve the wave equation in unidirectionally heterogeneous media are derived from the Thomson–Haskell method [45,18]. These methods are appropriate for multilayered structures [22,27,47,21]. But, for continuously varying media, these techniques mean to replace the continuous profiles of properties by step-wise functions. Thereby the studied problem becomes an approximate one, even before the resolution step; the accuracy of the solution as its validity domain are hard to evaluate. Moreover, the multilayered model of the functionally graded waveguide creates some “virtual” interfaces likely to induce artefacts. Lastly, for generally anisotropic cylinders, the solutions cannot be expressed analytically even for homogeneous layers [29,32,43].

In order to deal with the exact problem, that is to keep the continuity of the properties variation, the wave equation is written under the sextic Stroh's formalism [44] in the form of an ordinary differential equations system with non-constant coefficients for which an analytical solution exists: the matricant [4]. Another method relies on the Legendre's polynomial as explained and used in [25,11,13,12].

2.2.1. Hamiltonian form of the wave equation

In the Fourier domain, the wave equation may be written as:

$$\frac{d}{dr} \boldsymbol{\eta}(r) = \frac{1}{r} \mathbf{Q}(r) \boldsymbol{\eta}(r). \quad (3)$$

The components of the state-vector $\boldsymbol{\eta}(r)$ are the three components of the displacement and the three components of the stress traction in the cylindrical coordinates, and the matrix $\mathbf{Q}(r)$ contains all the information about the heterogeneity: it is expressed from stiffness coefficients of the waveguide in the cylindrical coordinates and from the two acoustical parameters: axial or circumferential wavenumbers (k_z , or n) and the angular frequency ω . The detailed expression of $\mathbf{Q}(r)$ is given in Appendix A for the case of a material with orthorhombic crystallographic symmetry but it can be expressed for any type of anisotropy [42].

2.2.2. Explicit solution: the Peano expansion of the matricant

The wave equation thus formulated has an analytical solution expressed between a reference point (r_0, θ, z) and some point of the cylinder (r, θ, z) . This solution is called the matricant and is explicitly written under the form of the Peano series expansion:

$$\mathbf{M}(r, r_0) = \mathbf{I} + \int_{r_0}^r \mathbf{Q}(\xi) d\xi + \int_{r_0}^r \mathbf{Q}(\xi) \int_{r_0}^{\xi} \mathbf{Q}(\xi_1) d\xi_1 d\xi + \dots, \quad (4)$$

where \mathbf{I} is the identity matrix of dimension (6,6). If the matrix $\mathbf{Q}(r)$ is bounded in the study interval, this series is always convergent [4]. The components of the matrix \mathbf{Q} are continuous in r and the study interval is bounded (thickness of the waveguide), consequently the hypothesis is always borne out. The matricant verifies the propagator property [4]:

$$\boldsymbol{\eta}(r) = \mathbf{M}(r, r_0)\boldsymbol{\eta}(r_0). \quad (5)$$

2.2.3. Free boundary conditions

The cylinder is supposed to be in vacuum, so the traction-vector $\boldsymbol{\sigma}_r$ defined in (2) is null at both interfaces. Using the propagator property of the matricant through the thickness of the cylinder, Eq. (5) is written as $\boldsymbol{\eta}(a_q) = \mathbf{M}(a_q, a_0)\boldsymbol{\eta}(a_0)$:

$$\begin{pmatrix} \mathbf{u}(r = a_q) \\ \mathbf{0} \end{pmatrix} = \begin{pmatrix} \mathbf{M}_1 & \mathbf{M}_2 \\ \mathbf{M}_3 & \mathbf{M}_4 \end{pmatrix} \begin{pmatrix} \mathbf{u}(r = a_0) \\ \mathbf{0} \end{pmatrix}. \quad (6)$$

Eq. (6) has non-trivial solutions for $\det \mathbf{M}_3 = 0$. As detailed in Appendix A for an orthotropic material and from Eq. (4), the components of \mathbf{M}_3 are bivariate polynomials in (k_z, ω) . Consequently, to seek out the zeros of $\det \mathbf{M}_3$ corresponds to find the couples of values (k_z, ω) which describe the dispersion curves.

3. Results

To calculate the dispersion curves, we evaluate numerically the matricant $\mathbf{M}(a_q, a_0)$ from the expression (4). This step requires us to truncate the Peano series and to numerically calculate the integrals. Thus, the error can be estimated and controlled [4]. For the calculations in the plate we retained 70 terms in the series and evaluate the integrals over 100 points using the Simpson's rule (fourth-order integration method) and for the tube, we retained 33 terms in the series and evaluate the integrals over 30 points. These choices are not optimized but ensure the convergence of the solution and the accuracy of the results in the range of frequency-thickness products considered for a reasonable computation time (few dozen of minutes on a desktop computer).

3.1. Validation

We compare our results to results from the literature obtained on homogeneous tubes [30,34] (not shown). In the following part, the method is validated calculating the dispersion curves obtained for an isotropic FGM cylinder previously studied in the literature [17,11,13]. The properties of the tube (Young's modulus E , Poisson's ratio ν and mass density ρ) vary from silicon nitride properties at the inner interface ($r = a_0$) to the properties of stainless steel at the outer interface ($r = a_q$). The values of the properties for these two materials are reported in Table 1.

The dispersion curves are compared for an affine profile:

Table 1
Elastic properties of the materials at the two interfaces of the tube.

	E (GPa)	ν	ρ (kg/m ³)
Stainless steel (outer)	207.82	0.317	8166
Silicon nitride (inner)	322.4	0.24	2370

$$\begin{aligned} E(r) &= E_{out} + (E_{in} - E_{out})(r - a_0)/(a_q - a_0); \\ v(r) &= v_{out} + (v_{in} - v_{out})(r - a_0)/(a_q - a_0); \\ \rho(r) &= \rho_{out} + (\rho_{in} - \rho_{out})(r - a_0)/(a_q - a_0). \end{aligned} \quad (7)$$

In Fig. 2, the dispersion curves obtained for an isotropic FGM tube (Table 1) from two different schemes, Peano expansion of the matricant and Legendre polynomials, are in perfect agreement.

3.2. Influence of the ratio t/a_q

As mentioned in [37] and shown in [25], when the outer radius of the tube a_q is large compared to the wall thickness t , the longitudinal modes are very close to the Lamb modes obtained for a plate of the same thickness. Nishino and colleagues detailed the influence of the ratio t/a_q on the similarity of the modes of the cylindrical waveguide with the Lamb's waves [34]. The same trend is observed for the torsional modes as pointed in [34]: for small values of the ratio t/a_q (typically less than 0.5) they are very similar to horizontal-shear waves propagating in a plate of the same thickness. Considering the flexural waves, it is a little more delicate and sometimes cleverly sidestepped. In [25], the comparison is not convincing if superimposing the figures (Figs. 2–4 in [25]) and in Protopappas' paper [37], the comparison is made for particular flexural modes $F(1, 2m + 1)$ ($m = 0, 1, 2$).

Flexural modes are characterized by a three-dimensional polarization vector. As underlined by Rose [40], understanding the physical characteristics of flexural modes is necessary for advanced applications involving wave reflection from defects. For instance it can be difficult experimentally to generate pure longitudinal modes over a given frequency range. So, this point needs clarification.

3.2.1. Homogeneous isotropic tube

In this part, the results are inspired by Nishino's ones for a homogeneous isotropic aluminium tube ($C_L = 6400$ m/s, $C_T = 3040$ m/s, $\rho = 2.7$ kg/m³). Two configurations are represented: (a) $t/a_q = 0.4 < 0.5$; (b) $t/a_q \approx 0.7 > 0.5$.

The results reported in Figs. 3 and 4 are in agreement with previous experimental and numerical studies above-cited. The dispersion curves obtained for the longitudinal and torsional modes are very similar to the plate modes for $t/a_q < 0.5$ except at low frequency-thickness products ($ft < 1$ MHz mm). When t/a_q increases the discrepancy becomes more and more significant in the whole range of frequency-thickness products.

As underlined before the case of flexural modes is more complex. We observe in Fig. 5 that for the first five modes, the branches $F(1, m)$ when m is even are similar to the Lamb's modes, whereas those $F(1, m)$ when m is odd are similar to the SH modes. For higher order modes, it seems that they are partly similar to Lamb's modes and partly similar to SH waves. These results are in accordance with the definition given by Gazis of longitudinal shear waves [14]. Furthermore, the influence of the ratio t/a_q remains identical to what it has been observed for longitudinal and torsional modes.

3.2.2. Heterogeneous anisotropic tube

The same trend is observed for anisotropic homogeneous structures (results not presented) and for anisotropic functionally graded ones. The anisotropic functionally graded structure studied in this paper has the mechanical properties of the cortical bone.

As the great majority of the biological tissue, the cortical bone is a complex medium. It is anisotropic, multi-components, heterogeneous. It can be modeled as a two-phase medium: the bone matrix and the pores full of marrow (assimilated to water). The characteristic size of the pores in the cortical bone is less than a few hundred micrometers. The classical range of frequency used in quantitative

Fig. 2. The results obtained from the Stroh's formalism (grey points) compared with the results published in [11] (black points).

Fig. 3. Influence of the ratio t/a_q for a homogeneous isotropic aluminium tube. The Lamb's modes (black lines) are compared with the longitudinal modes $L(0,m)$ (grey points).

ultrasonography to evaluate bone fragility is [0.2;2.5] MHz. For such frequencies, the wavelength of the ultrasonic waves is larger than the size of the pores and the waves propagate in an effective macroscopic medium whose properties obviously depend on the microscopic properties such as the porosity or the intrinsic material properties of the bone matrix. An increasing number of papers underlined the relevancy of taking into account these heterogeneities across the cortex to improve the ultrasonic method for cortical bone assessment [33,37,16]. It may be particularly relevant in the case of healing bone as proposed by Protopappas and colleagues [37,38]. In their papers, they pointed also the limitations of the

Lamb wave theory when applied to real bones and underlined the relevance of taking into account the tubular geometry and the anisotropy of the long bones.

In our study, at the scale of the wavelength (few millimeters), the cortical bone may be viewed as a functionally graded material as its porosity increases continuously along the cortical thickness from the periosteal part (soft tissue side) to the endosteal one (marrow side). It is noteworthy that the intrinsic material properties of the bone matrix vary also across the cortical thickness [41] and contribute to the continuous gradient of macroscopic properties.

In a first approach, knowing the relationship between the porosity and the effective material properties [7] (neglecting the intrinsic material properties variation), the gradient of materials properties may be deduced from the gradient of porosity. To the best of our knowledge, we do not know exactly how the porosity varies across the cortical thickness and how it influences the macroscopic mechanical properties. Several studies brought some information on that point [9,8].

According to these results, one of the simplest realistic profile of properties to take into account seems to be the affine one.

As shown previously [5], the propagation of ultrasonic waves in the frequency range of clinical measurement is influenced by the gradient of properties encountered in cortical bone modeled as a plate. Therefore, we study the influence of the curvature on the dispersion curves for a transversely isotropic bone material with linearly varying mechanical properties along its radius. A particular attention was paid to assign realistic values to the properties of bone, for this reason we use the data published in [16,5]. The properties profile tested is an affine function:

$$C(r) = C_m + (C_M - C_m)(r - a_0)/(a - q - a_0); \quad (8)$$

the values of C_m and C_M are reported in Table 2.

The dispersion curves of the longitudinal $L(0,m)$, torsional $T(0,m)$ and flexural $F(1,m)$ modes calculated for a radially graded tube of thickness t are compared with the dispersion curves calculated for a plate of the same thickness (Lamb and Shear Horizontal modes). All the results are obtained from the Peano expansion of the matricant (4).

In Figs. 6–8, we can remark the same trend as observed in Figs. 3–5. The dispersion curves of the longitudinal modes L are very similar to Lamb's modes for ratios $t/a_q < 0.5$ except for low frequency-thickness products ($ft < 0.3$ MHz mm) (Fig. 6). Note that

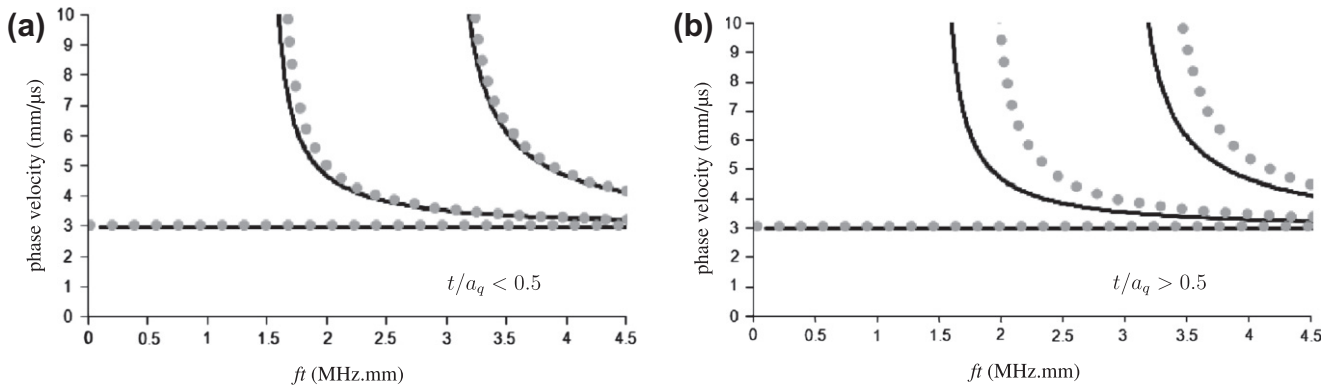

Fig. 4. Influence of the ratio t/a_q for a homogeneous isotropic aluminium tube. The SH modes (black lines) are compared with the torsional modes $T(0,m)$ (grey points).

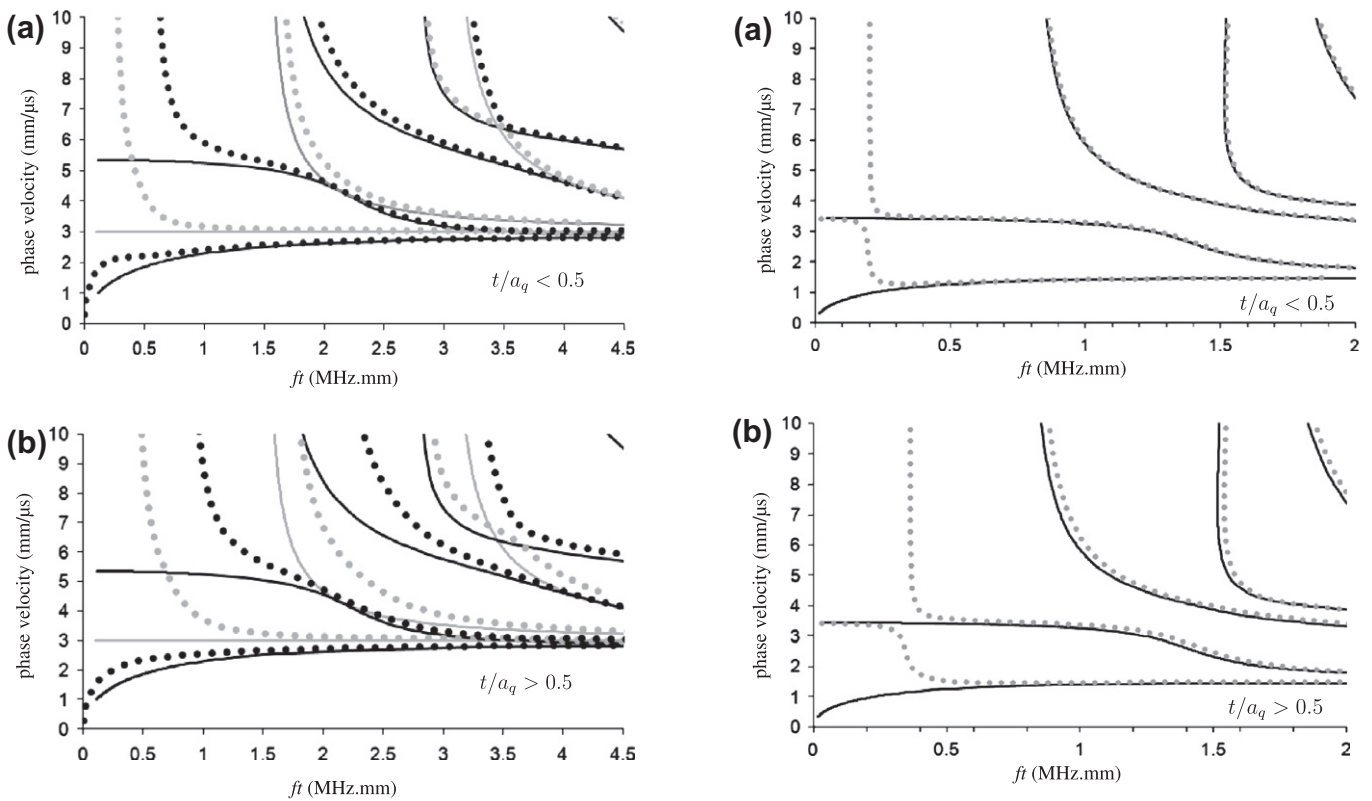

Fig. 5. Influence of the ratio t/a_q for a homogeneous isotropic aluminium tube. The SH modes (grey lines) and Lamb's modes (black lines) are compared with the flexural modes $F(1,2m)$ (grey points) and $F(1,2m-1)$ (black points) with $m = 1, 2, 3, 4$.

Fig. 6. Influence of the ratio t/a_q for a tube with bone properties (Table 2). The Lamb's modes (black lines) are compared with the longitudinal modes (grey circles).

the range is smaller than for the isotropic aluminium tube. The differences become significant when the ratio t/a_q increases. We can also compare the dispersion curves of the torsional modes T to the SH modes in a plate of the same thickness (Fig. 7). They are represented in Fig. 7 for the same range [0–2 MHz mm]. Again, the dispersion curves are very similar for low ratios and the difference increases with t/a_q . Concerning the flexural waves, the anisotropy

makes the comparison between tube modes and plate modes more difficult. Again, in Fig. 8 we observe the coupling between longitudinal and shear waves expressed in the dispersion curves of the flexural modes. The dependence on t/a_q remains the same.

4. Discussion and perspectives

The non-destructive evaluation of cylindrical anisotropic waveguide remains a key issue, particularly for generally anisotropic

materials. The method proposed in the present paper allows to solve the wave equation in an anisotropic tube with radially varying properties. From these results dealing with the direct problem, further work is needed to develop inversion techniques. There are many industrial applications: super heat resistant materials, "smart structures", powder metallurgy and ceramics or the graded-index plastic optical fibers for communications. Among these domains, the improvement of evaluation of biological tissues such as bone and the development of biomimetic materials for bone implants are booming subjects.

4.1. The bone evaluation in prospect

The characterization of bone strength remains a major issue particularly in the context of osteoporosis diagnosis known as a

public health problem. Nowadays it is established that bone fragility does not depend only on bone density but also on geometry, microstructure and elasticity of bone [33,15]. Consequently, a lot of works investigate this way in order to provide relevant criteria of bone strength evaluation. The work presented in this paper is altogether part of that perspective. One of the point is to improve the models used to inverse the experimental data. The goal is to select the relevant characteristic parameters which influence the clinical ultrasonic response and to relate them to the bone fragility. In this study, we take into account the anisotropy of the cortical bone, its tubular geometry and its heterogeneity and we evaluate the influence of the curvature on the ultrasound response representative of the mechanical behavior of the bone.

As a preliminary study on the influence of the curvature on *in vitro* ultrasound characterization of bone, the results presented are promising. But, obviously there are a lot of weaknesses in this study.

First, one of the limitations is the choice of the elastic properties values and their variation across the cortical thickness. These values are different from some data given in other papers [24,2,35,7] but remain in a realistic range deduced from experimental measurements [10] and thermodynamical conditions. Moreover they take into account the known anisotropy of cortical bone. Concerning the linear variation of the elastic properties (stiffness coefficients and mass density), it is a basic model which provides a first insight into the effect of multiscale heterogeneity of long bone. A recent study [16], Haiat and colleagues inputted the same values and the same profiles of properties in their simulations and obtained a good agreement between their results and former studies. Nevertheless, experimental data are needed to better define the way the microscopic properties (properties and intrinsic bone matrix properties) vary across the cortical thickness and contribute to the gradient of macroscopic elastic properties.

Second, the dispersion curves are obtained for a free-stress tube. Consequently, another limitation of this work is the absence of surrounding media which obviously influence the clinical measurements and has to be included in a relevant mechanical model [5,31]. The presence of fluids inside and outside the tube induces significant changes: the appearance of extra fluid modes and some differences in the shape of the tube modes in terms of attenuation and, phase and group velocities [36,1,31]. Moreover the behavior of the fluid-loaded structure depends on the viscosity of the fluids [1]. Further work is needed to consider the effect of soft tissue and marrow modelling the bone as a fluid-loaded tube. The boundary conditions may be taken into account in the same way as we did for the plate [5]. The reflection and transmission coefficients for a fluid-loaded anisotropic tube with radially varying properties will be calculated following the same steps as detailed for the plate. Nevertheless, the present work may provide an interesting tool to give support to *in vitro* studies.

5. Conclusion

In the context of non-destructive evaluation of complex media, the method presented here reveals several advantages to solve the wave equation in graded anisotropic waveguide. First, the formalism used allows to take into account a general anisotropy of the material even in the case of cylindrical geometry. Second, the Peano expansion of the matricant is one of the only method which provides an analytical solution of the exact problem in a functionally graded medium, that is to say without modelling the waveguide as a multilayered medium. Consequently, the accuracy and validity range are managed. Third, the computation time is a few dozen minutes for the structures studied in this paper. Using this method, it has been demonstrated that the trend revealed in the case of isotropic, homogeneous tubes is confirmed in the case of anisotropic heterogeneous tubes: for thickness to outer radius ratios less than 0.5, the plate model seems to be efficient except at low frequency-thickness products. In the particular context of ultrasonic evaluation of bone, further work is needed to analyse the relevance of the anisotropic heterogeneous tube model. A study will begin to compare different types of properties profiles and gain an insight into the parameters of the profiles which influence predominantly the ultrasonic response. Anyway, using the Stroh's formalism, one of the point of this method is the possibility of taking into account the anisotropy of the bone tube which has been proven to widely influence the wave propagation. Furthermore, this study gives some clues on the interaction between the ultrasonic waves and a realistic model of long bone under *in vitro* conditions (tubular geometry, radial heterogeneity and anisotropy): the guided modes are more sensitive to the curvature at low frequency-thickness products (at low frequencies and/or for thin bones). Whereas, the guided waves are more sensitive to the variation of properties at higher frequency-thickness products (at high frequencies and/or for thick bones). Now, this gradient may provide a multiparametric evaluation of the bone fragility by assessing pieces of information on the geometry, the structure and the material at a time and may reveal itself a relevant parameter in the diagnosis an the therapeutic following of the osteoporosis.

But a question remains: are the ultrasounds sensitive to this gradient? an experimental study is insistently needed to gain insight on that point.

Appendix A

Expression of the vector $\eta(r)$ and of the matrix $Q(r)$ for a material with orthorhombic crystallographic symmetry (nine independent stiffness coefficients). The symbol $\hat{\cdot}$ represents the quantities in the Fourier domain.

$$\eta(r) = (\hat{u}_r(r), \hat{u}_\theta(r), \hat{u}_z(r), r\hat{\sigma}_{rr}(r), r\hat{\sigma}_{r\theta}(r), r\hat{\sigma}_{rz}(r))^T,$$

and

$$Q(r) = \frac{1}{r} \begin{pmatrix} -\frac{c_{12}}{c_{11}} & -m\frac{c_{12}}{c_{11}} & & & \\ -m & 1 & & & \\ -ik_z r & 0 & & & \\ i(\gamma_{12} - r^2\rho\omega^2) & -n\gamma_{12} & \dots & & \\ n\gamma_{12} & m^2\gamma_{12} + r^2(k_z^2 c_{44} - \rho\omega^2) & & & \\ k_z r \gamma_{23} & m k_z r (\gamma_{23} + c_{44}) & & & \\ -ik_z r \frac{c_{13}}{c_{11}} & -\frac{1}{c_{11}} & 0 & 0 & \\ 0 & 0 & -\frac{1}{c_{66}} & 0 & \\ 0 & 0 & 0 & \frac{1}{c_{55}} & \\ \dots & -k_z r \gamma_{23} & \frac{c_{12}}{c_{11}} & -m & -ik_z r \\ m k_z r (\gamma_{123} + c_{44}) & -m\frac{c_{12}}{c_{11}} & -1 & 0 & \\ m^2 c_{44} + r^2(k_z^2 \gamma_{13} - \rho\omega^2) & -ik_z r \frac{c_{13}}{c_{11}} & 0 & 0 & \end{pmatrix}$$

with

$$\gamma_{12} = c_{22} - \frac{c_{12}^2}{c_{11}}; \gamma_{13} = c_{33} - \frac{c_{13}^2}{c_{11}}; \gamma_{23} = c_{23} - \frac{c_{12}c_{13}}{c_{11}}.$$

USING THE GRADIENT OF HUMAN CORTICAL BONE PROPERTIES TO DETERMINE AGE-RELATED BONE CHANGES VIA ULTRASONIC GUIDED WAVES

CÉCILE BARON

Aix-Marseille Univ, Institute of Movement Sciences, Marseille, France

(Received 9 November 2011; revised 1 February 2012; in final form 23 February 2012)

Abstract—Bone fragility depends not only on bone mass but also on bone quality (structure and material). To accurately evaluate fracture risk or propose therapeutic treatment, clinicians need a criterion, which reflects the determinants of bone strength: geometry, structure and material. In human long bone, the changes due to aging, accentuated by osteoporosis are often revealed through the trabecularization of cortical bone, *i.e.*, increased porosity of endosteal bone inducing a thinning of the cortex. Consequently, the intracortical porosity gradient corresponding to the spatial variation in porosity across the cortical thickness is representative of loss of mass, changes in geometry (thinning) and variations in structure (porosity). This article examines the gradient of material properties and its age-related evolution as a relevant parameter to assess bone geometry, structure and material. By applying a homogenization process, cortical bone can be considered as an anisotropic functionally graded material with variations in material properties. A semi-analytical method based on the sextic Stroh formalism is proposed to solve the wave equation in an anisotropic functionally graded waveguide for two geometries, a plate and a tube, without using a multilayered model to represent the structure. This method provides an analytical solution called the matricant and explicitly expressed under the Peano series expansion form. Our findings indicate that ultrasonic guided waves are sensitive to the age-related evolution of realistic gradients in human bone properties across the cortical thickness and have their place in a multimodal clinical protocol. INTRODUCTION

It is now widely accepted that bone strength relies on two main factors: bone density and bone quality. Thus, accurate information is needed on the quantity of bone, the way it is organized and the mechanical quality of its constituent materials (elastic properties) to accurately evaluate fracture risk, to optimize treatment (time and dosage) and to reduce adverse effects. Nowadays, bone densitometry as determined by dual-energy X-ray absorptiometry (DXA) is the gold standard technique used to diagnose osteoporosis and to decide on treatment. It provides a value for bone mineral density (BMD), which is compared with that of a reference population to assess whether the patient is “normal,” presents with osteopenia or presents with osteoporosis.

One of the fundamental challenges in bone characterization is to identify the relevant parameters, which have to be correlated to the pathology and accessible through clinical measurements. Moreover, as with all technological developments for biomedical applications, it is essential to respect certain criteria: techniques should be nondestructive, noninvasive and nonradiating. Quantitative ultrasound techniques are good candidates on all these conditions. Yet, they continue to struggle for acceptance against the gold standard of DXA analysis, partly because no single physical parameter has been identified to represent the “structure, geometry, material” triangle. For a long time now, it has been recognized that bone mass alone (bone mineral density) is insufficient to predict risk of fracture (Faulkner 2000; Robbins et al. 2005). It has been reported that BMD alone explains less than half the risk of hip fractures (Marshall et al. 1996). Several studies have revealed cases where the effect of BMD on risk of fracture is atypical. Postmenopausal Chinese women, for example, have significantly

Address correspondence to: Cécile Baron, Institute of Movement Sciences UMR 7287 CNRS/AMU 163, Avenue de Luminy, 13288 Marseille Cedex 09, France. E-mail: cecile.baron@univ-amu.fr

lower hip bone mineral density than white women and are classified at higher risk but in fact they have fewer fractures (Tobias et al. 1994; Xiaoge et al. 2000).

It would appear, then, that bone quantity alone is not sufficient to evaluate bone fragility and that bone geometry and quality are key factors which significantly affect bone strength (Augat et al. 1996; Ammann and Rizzoli, 2003; Moilanen et al. 2007; Gregory and Aspden 2008).

Moreover, even though BMD combines cortical and trabecular bone mass, the majority of what is measured by DXA is trabecular bone. As a consequence, osteoporosis treatments focus primarily on trabecular bone. Yet, while both bone compartments contribute to bone strength (Manske et al. 2009), several recent studies point out that cortical bone is a critical component in determining fracture resistance at the femoral neck (Augat and Schorlemmer, 2006; Holzer et al. 2009; Treece et al. 2010).

At the same time, as imaging techniques become more and more accurate, a newly visible characteristic of bone is emerging: intracortical porosity changes gradually across the thickness of long bones (Bousson et al. 2001; Tatarinov et al. 2005; Haïat et al. 2009; Grimal et al. 2011). When homogenization methods are applied to cortical bone, it can be viewed as a functionally graded material at mesoscopic scale.

Among the changes in cortical bone due to aging, there is a joint process accentuated by osteoporosis: trabecularization of the endosteal part leading to thinning of the cortex. Therefore, the gradient (spatial variation) of intracortical porosity is a parameter representative of increased variation in porosity across a reduced thickness and should be relevant to evaluate the combined effect of thinning and trabecularization. This gradient of intracortical porosity induces gradients of material properties (mass density and stiffness coefficients). Thus, characterizing the gradient of the bone properties across the cortical thickness, will provide information on structure (porosity), geometry (thickness) and material (stiffness).

In this study, we consider the diaphysis of long bone, in particular cortical bone. We model cortical bone as a one-phase material with varying mechanical properties (mass density and stiffness coefficients). Modeling how porosity changes across the cortical thickness and translating this variation in a microscopic property to mesoscopic level are complex tasks. We base ourselves on two studies (Bousson et al. 2000; Grimal et al. 2011) and define a mesoscopic functionally graded material (FGM) model. A semi-analytical method is proposed to solve the wave equation in an FGM waveguide. This method, based on the Stroh formalism, allows us to avoid a multilayered media approximation and to consider a cylindrical geometry in association with an anisotropic material. According to numerous experimental studies

(Reilly and Burnstein 1974; Dong and Guo 2004; Lakshmanan et al. 2007), human cortical bone is assumed to be a transversely isotropic material. Here cortical bone is represented by a transversely isotropic plate or tube in vacuum. The dispersion curves of the guided waves are explored to evaluate the sensitivity of these waves to a realistic variation in intracortical porosity.

MATERIALS AND METHODS

Cortical bone as an anisotropic functionally graded material waveguide

The model takes into account the anisotropy and the heterogeneity of cortical bone: it is considered as transversely isotropic with linearly varying material properties. Moreover, two geometries are investigated for long bone modeled as a plate or as a tube with realistic dimensions.

Functionally graded material properties

Here, every attempt was made to model realistic variation in porosity across the cortical thickness. Based on previous work reported on femoral cortical bone samples from skeletons (Bousson et al. 2000, 2001), we focus on a solely female population (86 subjects) aged from 11 to 96. We use these authors' 3-point measurement of porosity (periosteal, midcortical and endosteal regions) to infer the evolution of porosity across the cortical thickness.

Then, the evolution of intracortical porosity (microscopic scale) is translated into a variation in the elastic properties of the bone at the mesoscopic level by using the regression models (size of the mesodomain $L = 0.5$ mm) proposed by Grimal and colleagues (Grimal et al. 2011). Thereby, the Young's and shear moduli and the Poisson ratios are expressed as a function of porosity.

Porosity varies with position across the thickness of the bone and, consequently, the Young's and shear moduli and Poisson ratios are also dependent on the spatial variable across the thickness (x - variable for the plate and r - variable for the tube), except for ν_{TL} , which is assumed to be constant at 0.3.

Then, we deduce the five independent stiffness coefficients as five spatially-dependent functions from the following equations:

$$\begin{aligned} c_{11} &= \frac{E_T(1-\nu_{TL}\nu_{LT})}{\Delta}; & c_{12} &= \frac{E_T(\nu_{TT}+\nu_{TL}\nu_{LT})}{\Delta}; \\ c_{13} &= \frac{E_T(\nu_{LT}+\nu_{TT}\nu_{LT})}{\Delta}; & c_{33} &= \frac{E_L(1-\nu_{TT}\nu_{TT})}{\Delta}; \\ & & c_{44} &= G_{LT}; \end{aligned} \quad (1)$$

with $\Delta = \nu_{TT}^2 + 2\nu_{LT}\nu_{TL} + 2\nu_{LT}\nu_{TL}\nu_{TT}$.

Fig. 1. Variation in stiffness coefficients over porosity: $c_{11} = c_{22}(\diamond)$, $c_{12}(\square)$, $c_{13} = c_{23}(\Delta)$, $c_{33}(\times)$, $c_{44} = c_{55}(\ast)$, $c_{66}(\bullet)$.

Note the correspondence $1 \rightarrow T$; $2 \rightarrow T$; $3 \rightarrow L$ where L and T are longitudinal and transverse, respectively.

The degree of porosity (from 0% to 30%) does not disturb the crystallographic symmetry of the material at the mesoscopic scale (Baron et al. 2007): the thermodynamic conditions are still valid.

Figure 1 shows that the stiffness coefficients can be supposed to linearly vary according to porosity across the cortical thickness for each age group. A linear regression provides an affine function representing the evolution of

the stiffness coefficients across the cortical thickness. Thus, the elastic properties vary from a maximum value in the periosteal region to a minimum value in the endosteal region (Table 1).

A classical mixture law is used to obtain mass density as a function of spatial variable ξ , where $\xi = x$ for the plate and $\xi = r$ for the tube. We assume that the pores are filled with water, which is considered to be a perfect fluid:

$$\rho(\xi) = \rho_{\text{bone}}(1-p(\xi)) + \rho_{\text{water}}p(\xi); \quad (2)$$

with p the porosity, $\rho_{\text{bone}} = 1.9 \text{ g/cm}^3$ and $\rho_{\text{water}} = 1 \text{ g/cm}^3$.

Choice of waveguide geometry

It was essential to set realistic parameters for the geometry of the model. For a first approximation, long bone can be modeled as a plate, ignoring the curvature effect on guided wave propagation (Lefebvre et al. 2002; Bossy et al. 2004; Protopappas et al. 2006; Baron 2011). However, a more realistic shape for long bone is a tube (Protopappas et al. 2007) and here both geometries were investigated. For the plate, the set of parameters was reduced to the thickness, taken as decreasing with age (Bousson et al. 2001) (Table 2). For the tube, one of the parameters known to influence guided wave propagation is the ratio of thickness over outer radius (Nishino et al. 2001; Baron 2011). Here too, thickness was taken from (Bousson et al. 2001). Previous findings (Carter et al. 1996; Feik et al. 2005) have established that the outer diameter remains the same after 30 years; in this study, it is fixed at 24 mm and the thinning of the cortical wall with age is represented by an increase in the inner diameter to reach the thickness measured by Bousson and colleagues (Bousson et al. 2001).

Ultrasonic guided waves

We consider an elastic waveguide (plate or tube) of thickness t placed in vacuum. The coordinate systems

Fig. 2. Geometrical configuration of the waveguides.

(x, y, z) for the plate and (r, θ, z) for the tube are defined with the z -axis corresponding to the axis of the long bone and x and r representing the spatial variables along the cortical thickness.

The variable x describes the thickness of the plate from 0 to t . The radius of the tube r varies from a_0 to a_q , the inner and outer radius of the tube (Fig. 2), respectively. To simplify the notation, we use the variable ξ where $\xi = x, r$.

The elastic waveguide is considered to be anisotropic and is liable to present continuously varying properties across its thickness (e_x -axis or e_r -axis). These mechanical properties are represented by the stiffness tensor $C = C(\xi)$ and the mass density $\rho = \rho(\xi)$.

System equations

The momentum conservation equation associated with the constitutive law of linear elasticity (Hooke's law) gives the following equations:

$$\begin{cases} \text{div } \boldsymbol{\sigma} = \rho \frac{\partial^2 \mathbf{u}}{\partial t^2}, \\ \boldsymbol{\sigma} = \frac{1}{2} \mathbb{C} (\text{grad } \mathbf{u} + \text{grad}^T \mathbf{u}), \end{cases} \quad (3)$$

where \mathbf{u} is the displacement vector and $\boldsymbol{\sigma}$ the stress tensor.

• For the plate

We assume that the structure is two-dimensional (2-D) and that the guided waves travel in the plane $y = 0$; in the following, this coordinate is implicit and is omitted in the mathematical expressions. Solutions are sought for the vectors of displacement (\mathbf{u}) and traction ($\boldsymbol{\sigma}_x = \boldsymbol{\sigma} \cdot \mathbf{e}_x$) expressed in the Cartesian coordinates (x, z) with the basis $\{\mathbf{e}_x, \mathbf{e}_z\}$:

$$\begin{aligned} \mathbf{u}(x, z; t) &= \mathbf{U}(x) \exp i(k_z z - \omega t), \\ \boldsymbol{\sigma}_x(x, z; t) &= \mathbf{T}(x) \exp i(k_z z - \omega t); \end{aligned} \quad (4)$$

with k_z the axial wavenumber. The modes propagating in such a structure are called Lamb modes. We distinguish two types of Lamb modes: symmetrical (S-modes) and anti-symmetrical branches (A-modes) (Lamb 1917).

• For the tube

We seek to solve the wave equation for displacement vector (\mathbf{u}) and radial traction vector ($\boldsymbol{\sigma}_r = \boldsymbol{\sigma} \cdot \mathbf{e}_r$) expressed in the cylindrical coordinates (r, θ, z) with the basis $\{\mathbf{e}_r, \mathbf{e}_\theta, \mathbf{e}_z\}$:

$$\begin{aligned} \mathbf{u}(r, \theta, z; t) &= \mathbf{U}^{(n)}(r) \exp i(n\theta + k_z z - \omega t), \\ \boldsymbol{\sigma}_r(r, \theta, z; t) &= \mathbf{T}^{(n)}(r) \exp i(n\theta + k_z z - \omega t); \end{aligned} \quad (5)$$

with k_z the axial wavenumber and n the circumferential wavenumber.

We distinguish two types of waves propagating in a cylindrical waveguide: *circumferential waves* and *axial waves*. *Circumferential waves* are waves traveling in planes perpendicular to the axis direction. They correspond to $u_z(r) = 0$ (∇r), $k_z = 0$ and $n = k_\theta a_q$. *Axial waves* are waves traveling along the axis direction, the circumferential wavenumber is an integer $n = 0, 1, 2, \dots$. Among the *axial waves*, we distinguish three types of modes numbered with two parameters (n, m) representing the circumferential wavenumber and the order of the branches: longitudinal (L), flexural (F) and torsional (T) modes. The longitudinal and torsional modes are axially symmetric ($n = 0$) and denoted $L(0, m)$ and $T(0, m)$. The flexural modes are non-axially symmetric ($n \geq 1$) and are denoted $F(n, m)$ (Gazis 1959). In this article, we focus on longitudinal and first flexural modes ($n = 1$).

A closed-form solution: the matricant

Introducing the expression (4) for the plate or (5) for the tube into the equation (3), we obtain the wave equation in the form of a second-order differential equation with nonconstant coefficients. In the general case, there is no analytical solution to the problem thus formulated. Most current methods of solving the wave equation in unidirectionally heterogeneous media are derived from the Thomson-Haskell method (Thomson 1950; Haskell 1953). These methods are appropriate for multilayered structures (Kenneth 1982; Lévesque and Piché 1992; Wang and Rokhlin 2001; Hosten and Castaings 2003). However, for continuously varying media, these techniques replace the continuous profiles of properties by step-wise functions, thereby making

the problem approximate, even before the resolution step. The accuracy of the solution, like its validity domain, are thus hard to evaluate. Moreover, a multilayered model of functionally graded waveguides creates “virtual” interfaces likely to induce artifacts. Lastly, for generally anisotropic cylinders, the solutions cannot be expressed analytically, even for homogeneous layers (Mirsky 1964; Nelson et al. 1971; Soldatos and Jianqiao 1994).

To solve the exact problem, that is, to maintain the continuity of the variation in properties, and to take into account the anisotropy of cylindrical waveguides, we write the wave equation under the sextic Stroh formalism (Stroh 1962) in the form of an ordinary differential equations system with nonconstant coefficients for which an analytical solution exists: the matricant (Pease 1965; Baron 2005).

Hamiltonian form of the wave equation. In the Fourier domain, the wave equation can be written as:

- For the plate

$$\frac{d}{dx}\boldsymbol{\eta}(x) = \mathbf{Q}(x)\boldsymbol{\eta}(x); \quad (6)$$

- For the tube

$$\frac{d}{dr}\boldsymbol{\eta}(r) = \frac{1}{r}\mathbf{Q}(r)\boldsymbol{\eta}(r). \quad (7)$$

The components of the state-vector $\boldsymbol{\eta}(\xi)$ are the components of the displacement vector \mathbf{u} and the components of the traction vector $\boldsymbol{\sigma}_\xi$. As for the matrix $\mathbf{Q}(\xi)$, it contains all the information about heterogeneity: it is expressed from the stiffness coefficients of the waveguide in the appropriate system of coordinates (Cartesian for the plate and cylindrical for the tube) and from two acoustical parameters (wavenumbers, angular frequency, horizontal slowness). Detailed expressions of $\mathbf{Q}(\xi)$ are given in Appendix A for the case of a material with hexagonal crystallographic symmetry; but it can be expressed for any type of anisotropy (Shuvalov 2003).

Explicit solution: the Peano expansion of the matricant. The wave equation, thus, formulated has an analytical solution expressed between a reference point ξ_0 and some point along the cortical thickness direction ξ . This solution is called the matricant and is explicitly written in the form of the Peano series expansion:

$$\mathbf{M}(\xi, \xi_0) = \mathbf{I} + \int_{\xi_0}^{\xi} \mathbf{Q}(\varsigma)d\varsigma + \int_{\xi_0}^{\xi} \mathbf{Q}(\varsigma) \int_{\xi_0}^{\varsigma} \mathbf{Q}(\varsigma_1)d\varsigma_1d\varsigma + \dots, \quad (8)$$

Fig. 3. Variation in porosity across the cortical thickness: linear regression for each age range ($R^2 \geq 0.9$).

where \mathbf{I} is the identity matrix of dimension (6, 6). If the matrix $\mathbf{Q}(\xi)$ is bounded in the study interval, these series are always convergent (Baron 2005). The components of the matrix \mathbf{Q} are continuous in ξ and the study interval is bounded (thickness of the waveguide), consequently the hypothesis is always borne out. The matricant verifies the propagator property (Baron 2005):

$$\boldsymbol{\eta}(\xi) = \mathbf{M}(\xi, \xi_0)\boldsymbol{\eta}(\xi_0). \quad (9)$$

Free boundary conditions. The waveguide is considered to be in vacuum, so the traction vector $\boldsymbol{\sigma}_\xi$ defined in (4 and 5) is null at both interfaces. Using the propagator property of the matricant through the thickness of the structure, eqn (7) is written as $\boldsymbol{\eta}(\xi_0 + t) = \mathbf{M}(\xi_0 + t, \xi_0)\boldsymbol{\eta}(\xi_0)$ with $\xi_0 = 0$ for the plate and $\xi_0 = a_0$ for the tube. Factorizing the matricant $\mathbf{M}(\xi_0 + t, \xi_0)$ under four block matrices of dimension (3, 3), eqn (7) becomes:

$$\begin{pmatrix} \mathbf{u}(\xi = \xi_0 + t) \\ 0 \end{pmatrix} = \begin{pmatrix} \mathbf{M}_1 & \mathbf{M}_2 \\ \mathbf{M}_3 & \mathbf{M}_4 \end{pmatrix} \begin{pmatrix} \mathbf{u}(\xi = \xi_0) \\ 0 \end{pmatrix}. \quad (10)$$

Equation (10) has non-trivial solutions for $\det \mathbf{M}_3 = 0$. As detailed in Appendix A for a transversely isotropic material and from eqn (8), the components of \mathbf{M}_3 are bivariate polynomials in (s_z, ω) or (k_z, ω) . Consequently, seeking the zeros of $\det \mathbf{M}_3$ amounts to seeking the pairs of values (s_z, ω) or (k_z, ω) , which describe the dispersion curves of guided waves propagating in a plate or a tube respectively.

RESULTS

Gradient of porosity

The variation in porosity across the cortical thickness and its age-related evolution are presented in Table 2. Figure 3 shows that a linear profile is a good

Fig. 4. Age-related evolution of the porosity gradient: exponential regression ($R^2 = 0.93$).

approximation to model porosity changes. For every age range, $p\% = a\xi + b$, where ξ is the spatial variable along the cortical thickness, $(a, b) \in \mathbb{R}^2$.

The porosity gradient (%/mm) is deduced from an estimation of the slope a for each age class (Table 2).

Figure 3 clearly shows that porosity sharply increases with age in the endosteal region, whereas it remains fairly stable in the periosteal region. Moreover, cortical thickness greatly decreases with age, from adulthood to old age. These two processes identified by Bousson (Bousson et al. 2000, 2001) are linked under the name trabecularization of the endosteal region.

The age-related evolution of the porosity gradient represented on Figure 4 reveals an inverse trend compared with the evolution of BMD (Melton III et al. 2000): it remains almost constant up to the 4th decade and then it increases with advancing age. The regression is exponential, similar to the evolution of the risk of fracture with age reported in the literature (Hui et al. 1988; De Laet et al. 1997; Kanis et al. 2008).

Sensitivity of guided waves to the gradient of material properties

The effect of a realistic intracortical porosity gradient on guided wave propagation was investigated to determine how sensitive the guided waves are to the age-related evolution of long bone strength; in particular,

Table 3. Geometry of the waveguides for three age ranges

	Thickness (plate or tube)	Tube dimensions		
	t (mm)	a_0 (mm)	a_q (mm)	t/a_q
[30–39]	4.368	7.64	12	0.36
[60–69]	3.104	8.9	12	0.26
[80–99]	2.502	9.5	12	0.21

Fig. 5. Dispersion curves of Lamb modes propagating in a transversely isotropic plate, for three age ranges: [30–39] straight line, [60–69] dots and [80–99] dotted line.

whether they are sensitive both to thinning of the cortex and to increased endosteal porosity during aging. We compared the ultrasonic guided waves' interaction with three planar waveguides and three tubular waveguides modeling the diaphysis of the femur at three different age ranges: [30–39], [60–69] and [80–99] (Bousson et al. 2001). Waveguides dimensions are reported in Table 3. The dispersion curves are plotted as functions of the frequency-thickness product in the usual range for the study of ultrasonic waves in long bones (Bossy et al. 2004; Muller et al. 2005; Tatarinov et al. 2005; Protopappas et al. 2006). For guided waves in long bones, the typical frequency range is between 50 kHz to 350 MHz (Moilanen et al. 2008) to generate wavelengths greater than the cortical thickness (Bossy et al. 2004). Consequently, the frequency-thickness product to be considered is roughly [0.2, 1.5] MHz.mm for [30–39], [0.15, 1.1] MHz.mm for [60–69] and [0.125, 0.875] MHz.mm for [80–99].

The dispersion curves of Lamb modes propagating in plates show measurable differences throughout aging (Fig. 5). The discrepancy between the dispersion spectra obtained for each age range grows with the frequency-thickness product. For example, at 1 MHz.mm, the phase velocity of the S_0 mode for the [80–99] age group is 6% lower than for the [30–39] age group, the phase velocity of the A_2 mode for the [60–69] age group is 5% higher than for the [80–99] age group and 10% lower than for the [30–39] age group. All these differences correspond to several thousand meters per second, which are experimentally measurable quantities.

The same trends can be seen from the dispersion curves of the longitudinal and flexural modes propagating in the tubes (Fig. 6). The cut-off frequencies of all the modes are distinct for the three age ranges considered (Table 4).

Fig. 6. Dispersion curves of the eight first longitudinal modes (in black) and the ten first flexural (in grey) modes propagating in a transversely isotropic tube, for three age ranges: [30–39] straight line, [60–69] dots and [80–99] dotted line.

The phase velocities are also significantly different: for instance, the discrepancy between the $F(1, 3)$ -mode phase velocity for [80–99] and the $F(1, 3)$ -mode phase velocity for [30–39] is about 420 m/s.

One of the critical parameters of long bone strength is cortical thickness. To evaluate cortical thickness, Moilanen and his team showed the relevance of considering the $F(1, 1)$ mode instead of the A_0 mode (Moilanen et al. 2007). This is confirmed by our results on the group velocity of these two modes calculated for the three age ranges (Fig. 7).

It is clearly shown that around the frequency of 200 kHz used by Moilanen and colleagues, the group velocity of A_0 mode is consistently different from the

Fig. 7. Group velocity of A_0 mode (in black) and $F(1, 1)$ mode (in grey) propagating in a transversely isotropic plate and tube respectively, for three age ranges: [30–39] straight line, [60–69] dots and [80–99] dotted line.

group velocity of the $F(1, 1)$ mode and it appears that the group velocity of the $F(1, 1)$ mode is very sensitive to the porosity gradient in the frequency range considered.

DISCUSSION

The Stroh formalism used in this study has several advantages. First, it allows ultrasound propagation to be investigated in a continuously varying medium (FGM) instead of approximating it by a multilayered medium, thus, avoiding potential round-off errors and artifacts that cannot be estimated. It provides an exact solution to the exact problem and the degree of round-off error is manageable (Baron 2005). Furthermore, this formalism is numerically stable and is applicable to planar and tubular geometries whatever the degree of anisotropy of the material. The conventional methods used to solve the wave equation are unable to deal with cylindrical coordinates coupled with general anisotropy. The Stroh formalism is one of the only ways to provide an analytical solution (Peano expansion of the matricant) to the wave equation in a cylindrical structure whatever the anisotropy of the material (Shuvalov 2003). Moreover, fluid-loading of the waveguide here can be treated as in the case of the plate (Baron and Naili 2010). The advantages of this formalism in the context of bone characterization are clear, since long bone can be realistically modeled as an FGM orthotropic tube surrounded by blood and full of marrow. In addition, because this method takes into account actual variations in material properties of long bones, it could prove useful as a reference to validate models which do not allow for the gradient of material properties, confirming the range of validity (frequency domain, thickness range, order of the modes) of the results yielded by such simplified models.

Bone fragility has long been known to be related to the quantity of material (bone density), its quality

Table 4. Variations in cut-off frequencies for longitudinal and flexural modes with aging

	L(0,2)	L(0,3)	F(1,2)	F(1,3)	F(1,4)	F(1,5)
$\Delta f_{30/60}$ (kHz)	4.9	88.3	2.9	4.5	87.2	80.8
$\Delta f_{60/80}$ (kHz)	3.4	60.3	2.2	4	60.1	59.7
$\Delta f_{30/80}$ (kHz)	8.3	148.6	5.1	8.4	147.3	140.5

(stiffness) and its organization (geometry and micro-architecture). An accurate evaluation of fracture risk has to assess these three parameters together. As cortical bone ages, endosteal trabecularization induces thinning of the cortex. Thus, the spatial variation in porosity across the cortical thickness revealed during aging can be taken as the “missing” parameter to represent bone quality. This is confirmed by Figure 4, which illustrates an evolution in porosity gradient with age similar to the evolution in risk of fracture reported in the literature for the vertebra (Cooper et al. 1992) and for the hip (De Laet et al. 1997). As previously pointed out, the gradient of material properties (density and stiffness coefficients) reflects the spatial distribution of the quantity and quality of bone across the cortical thickness. Looking at the dispersion curves obtained here for the plate and for the tube, this discrepancy between the different age ranges appears to be experimentally measurable. Thus, this study indicates that the gradient of homogenized material properties can be evaluated from measured ultrasound velocities.

Solving the inverse problem, however, will be tricky, and further work will be required before this can be achieved. An accurate evaluation of the various factors influencing bone strength would require a wider range of measurements (other ultrasound frequencies, other imaging modalities).

Our work demonstrates the sensitivity of guided waves to realistic variations in the intrinsic properties of human cortical bone: porosity, density, stiffness, as revealed by the gradient in material properties. Nevertheless, it remains difficult to establish a reliable criterion to apply in a clinical protocol. Careful consideration needs to be given to choosing appropriate anatomical sites for ultrasonic evaluation. To avoid too much ultrasound absorption, the most suitable sites are the phalanx, the radius and the tibia (Njeh et al. 2001). These sites are long bones for which the question of the influence of the curvature on wave propagation needs to be addressed (Baron 2011). The choice of geometric model (plate or tube) is particularly important in pediatrics since the thickness over outer radius ratio (t/a_q) of growing bone is greater than 0.5. Thus, ultrasound evaluation is a promising alternative technique in pediatrics.

Our model could usefully be extended. Several realistic characteristics can easily be added to the formalism we use. First, how soft tissue affects wave propagation can be modeled by fluid-loading, as examined in a recent paper (Baron and Naili 2010). Second, the gradual variation in the intrinsic properties of the bone matrix described in Lakshmanan et al. (2007) can be included in the homogenization step and would contribute to the mesoscopic gradient of bone properties.

Furthermore, it would be relevant to consider not only the variation in “global” intracortical porosity (the

ratio of the volume of pores over the total volume) but also the distribution of pore sizes and of the number of pores across the cortical thickness. In Bousson et al. (2001), it was noted that increased endosteal porosity arises from an increase in the size of pores rather than from an increase in the number of pores; this difference in the organization of the microstructure may affect the mechanical behavior of the bone.

CONCLUSION

The gradient of material properties appears here to be relevant to evaluating age-related changes in cortical bone, particularly in the context of osteoporosis and therapeutic follow-up. This article describes an original method applied to bone characterization able to take into account the heterogeneity (porosity gradient) and the anisotropy (orthotropy) of the material as well as the tubular geometry of the structure, even under *in vivo* conditions (soft tissue).

Ultrasound evaluation appears to be a good candidate to characterize long bone (structure, geometry and material); however, the potential of *in vivo* techniques that take into account the influence of soft tissue and marrow needs to be further explored.

The results we obtained are promising but the method should be extended, in particular, with a view to solving the inverse problem. An *in vitro* experimental program would validate the feasibility of the ultrasound measurements on bone samples of different ages. It could also evaluate the relevance of using an *in vivo* characterization of the gradient of properties across the cortical thickness to determine bone strength and the risk of fracture.

Anisotropy

ABSTRACT

Child cortical bone tissue is rarely studied because of the difficulty of obtaining samples. Yet the preparation and ultrasonic characterization of the small samples available, while challenging, is one of the most promising ways of obtaining information on the mechanical behavior of non-pathological children's bone. We investigated children's cortical bone obtained from surgical waste. 22 fibula or femur samples from 21 children (1–18 years old, mean age: 9.7 ± 5.8 years old) were compared to 16 fibula samples from 16 elderly patients (50–95 years old, mean age: 76.2 ± 13.5 years old). Stiffness coefficients were evaluated via an ultrasonic method and anisotropy ratios were calculated as the ratio of C_{33}/C_{11} , C_{33}/C_{22} and C_{11}/C_{22} . Stiffness coefficients were highly correlated with age in children ($R > 0.56$, $p < 0.01$). No significant difference was found between C_{11} and C_{22} for either adult or child bone ($p > 0.5$), nor between C_{44} and C_{55} ($p > 0.5$). We observe a transverse isotropy with $C_{33} > C_{22} = C_{11} > C_{44} = C_{55} > C_{66}$. For both groups, we found no correlation between age and anisotropy ratios. This study offers the first complete analysis of stiffness coefficients in the three orthogonal bone axes in children, giving some indication of how bone anisotropy is related to age. Future perspectives include studying the effect of the structure and composition of bone on its mechanical behavior.

1. Introduction

Bone is a hierarchical and organized structure with properties varying by successive stages from juvenile to mature state.

Numerous studies have aimed to determine the mechanical properties of cortical bone tissue collected from adult human subjects (Bensamoun et al., 2004; Choi et al., 1990; Cuppone et al., 2004; Grimal et al., 2009; Ho Ba Tho et al., 1991; Keller

*Corresponding author at: Aix-Marseille Université, CNRS, ISM UMR 7287, 13288 Marseille cedex 09, France.

¹equal contribution.

et al., 1990; Lotz et al., 1991; Reilly et al., 1974; Reilly and Burstein, 1975; Smith and Smith, 1976; Zioupos and Currey, 1998). Ultrasonic waves have frequently been used in the measurement of the elastic properties of adult bone *in vitro* (Ashman et al., 1984; Yoon and Katz, 1976; Rho, 1996; Espinoza Orías et al., 2009; Rudy et al., 2011; Baumann et al., 2012; Bernard et al., 2013). A method based on the measurement of both longitudinal and shear ultrasonic bulk wave velocities (BWV) allows the determination of numerous stiffness coefficients of the elasticity tensor C_{ijkl} , on a single specimen (Ashman et al., 1984; Rho, 1996; Espinoza Orías et al., 2009; Rudy et al., 2011; Baumann et al., 2012; Lang, 1969). Cortical bone is an anisotropic medium due to its highly oriented, mineralized collagen fibril structure, and the literature on adults contains different assumptions regarding the type of anisotropy of the cortical bone structure. Some authors (Haïat et al., 2009; Neil Dong and Edward Guo, 2004; Rho, 1996; Yoon and Katz, 1976) assume that human cortical bone can be considered as transverse isotropic (five independent elastic coefficients), meaning that bone elastic properties are similar in the transverse directions (radial and tangential) but are different in the axial direction. Others have made the more general assumption of orthotropy (Ashman et al., 1984; Hoffmeister et al., 2000; Rho, 1996) (with three perpendicular planes of symmetry), where nine elastic coefficients are needed to fully characterize the medium.

Little reference data is available on young bone mechanical behavior, especially on children's cortical bone. Several papers study mechanical properties of children's bone by uniaxial bending (Currey and Butler, 1975; Jans et al., 1998; Davis et al., 2012; Agnew et al., 2013; Berteau et al., 2013; Albert et al., 2013a, 2013b, 2014), compression (McPherson et al., 2007; Ohman et al., 2011) or ultrasonic characterization (Berteau et al., 2012, 2013). Some even study mechanical properties at the tissue level by nanoindentation (Fan et al., 2006; Weber et al., 2006; Albert et al., 2013a, 2013b; Imbert et al., 2014). However, most of these studies were conducted on only a few samples, because of the scarcity of specimens for laboratory testing. Moreover, the representativeness of these samples is questionable, since they are largely associated with child pathologies. Due to the limited number of samples available, papers have up to now focused on mechanical properties in only one axis, generally the axial direction. The notion of anisotropy, particularly transverse isotropy or orthotropy, has rarely been investigated. Only one study on this subject reports orthotropy in children's bone before ossification (McPherson and Kriewall, 1980). In our study, children's bone samples were recovered from small surgical waste, with exclusion criteria; the only way to obtain non-pathologic bone samples from children. Yet this adds a difficulty: the specimens have been cut into very small cubes (~ 2 mm), smaller than those used in a previous study which tested 5 mm samples on Resonant Ultrasound Spectroscopy (RUS) and obtained promising results (Bernard et al., 2013).

Here, we report measurements of ultrasonic wave velocities (compressional and shear) in the three orthogonal bone axes (axial, radial and tangential) to obtain the diagonal elements of the stiffness matrix (C_{11} , C_{22} , etc.). To our knowledge, this study is the first to provide numerous stiffness coefficients on non-pathologic pediatric cortical bone. The

major aim of the study was to obtain stiffness coefficients of children's cortical bone samples, and to analyze the anisotropic Hooke's law enabling us to explore the anisotropic behavior of child cortical bone. Values from children were compared with those from elderly adult cortical bone samples to evaluate how stiffness evolves with age. To achieve this objective, we required an experimental protocol specifically for measuring ultrasonic parameters with very small samples, both compressional and shear; the protocol needed to be reproducible and robust.

2. Methods

2.1. Sample preparation

15 fibula and 7 femur samples from 21 children (1–18 years old, mean age: 9.7 ± 5.8 years old) were extracted from surgical waste during lower limb lengthening surgery performed in Marseille, France. Samples were extracted from the lower 1/3 of the bone. The selected population was composed of walking children not on drugs disturbing their bone metabolism.

16 fibula samples from 16 elderly patients (50–95 years old, mean age: 76.2 ± 13.5 years old) were extracted from the same anatomic location, but from cadavers at Inserm U1033 and UMR-T 9406 Ifsttar/UCBL (Lyon, France) bone bank.

The fresh material was frozen and stored, the child bone at -80°C (to lessen the impact of collagen degradation, which will be analyzed in a future study) and the adult bone at -20°C . The samples were slowly thawed and then cut with a water-cooled low-speed diamond saw (Buehler Isomet 4000, Buehler, Lake Bluff, IL, USA) into cubic parallelepipeds (dimensions: $2 \times 2 \times 2 \text{ mm}^3$; mean = 1.96 ± 0.56 mm). The faces of the specimens were oriented according to the radial (axis 1), tangential (axis 2) and axial (axis 3) directions defined by the anatomic shape of the bone diaphysis (Fig. 1).

The greatest challenge here was the very small size of the surgical waste bone (less than 1 cm in the axial axis), the radial thickness of the sample being imposed by the cortical thickness taken. The second difficulty was cutting samples this

Fig. 1 – Sketch showing orientation of cortical bone samples prepared to study bone anisotropy. Figure adapted from (Reilly et al., 1974).

small with parallel faces. This necessitated an enhanced mounting protocol for the cutting. The mass density (ρ g/cm³) was measured with a micrometric balance equipped with a density kit (Voyager 610, Ohaus Corporation, FlorhamPark, NJ, USA, measurement uncertainty of 0.001 g/cm³) and the dimensions were measured with a digital caliper (Absolute digimatik solar, Mitutoyo, Kanagawa, Japan, measurement error of 0.03 mm).

2.2. Theoretical approach

In this study, we considered cortical human bone as an elastic unlimited medium (the wavelength is smaller than the transverse dimension of the sample). Human bones are generally considered to be orthotropic (Ashman et al., 1984; Yoon and Katz, 1976).

For generally anisotropic media, Hooke's law is written as follows:

$$\sigma_{ij} = C_{ijkl} \varepsilon_{kl} \text{ where } i, j, k, l \in \{1, 2, 3\} \quad (1)$$

In Eq. (1), σ_{ij} denotes the ij component of the stress tensor, ε_{kl} represents the components of the strain infinitesimal tensor and C_{ijkl} is the stiffness tensor. Assuming orthotropic behavior of the bone requires nine independent elastic coefficients of the stiffness tensor which can be expressed in Voigt notation as follows:

$$C_{ij} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{21} & C_{22} & C_{23} & 0 & 0 & 0 \\ C_{31} & C_{32} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{66} \end{bmatrix} \quad (2)$$

We calculated the velocities of pure compressional and shear waves propagating along the three principal axes, which gave us the diagonal elements of the stiffness matrix. The relationships between the velocities and elastic coefficients of the material are:

$$\begin{aligned} C_{11} &= \rho V_{11}^2 \\ C_{22} &= \rho V_{22}^2 \\ C_{33} &= \rho V_{33}^2 \\ C_{44} &= \rho V_{23}^2 = \rho V_{32}^2 \\ C_{55} &= \rho V_{13}^2 = \rho V_{31}^2 \\ C_{66} &= \rho V_{12}^2 = \rho V_{21}^2 \end{aligned} \quad (3)$$

V_{ii} : velocity of a compressional wave propagating in the i direction, with particle motion in the i direction;

V_{ij} : velocity of a shear wave propagating in the i direction, with particle motion in the j direction;

Anisotropy was measured as the ratio of elastic constants in the axial/radial (C_{33}/C_{11}), in the axial/tangential (C_{33}/C_{22}) and in the radial/tangential (C_{11}/C_{22}) anatomic specimen axes (Rudy et al., 2011; Baumann et al., 2012).

2.3. Ultrasonic measurements

To find the diagonal elements of the stiffness matrix, the velocities of compressional and shear waves need to be determined. Two mountings, one for compressional waves and the other for shear waves, were used. For both compressional and shear waves, we assumed a non-dispersive

medium and we determined the wave velocity propagating in the x_i direction using a comparison method:

$$V_{ij} = \frac{l_{\text{sample}_i}}{-\Delta t + \frac{l_{\text{ref}}}{V_{\text{ref}}}}$$

- V_{ij} : compressional ($i=j$) or shear ($i \neq j$) wave velocity;
- l_{sample_i} : thickness of the sample in direction x_i ;
- Δt : time delay between the first arriving signal traveling in the reference medium and the first arriving signal propagating through the bone sample;
- l_{ref} : distance between the two transducers in the reference medium;
- V_{ref} : ultrasonic wave velocity in the reference medium.

2.3.1. Compressional wave velocity measurement

The ultrasonic bench consisted of two transducers (VP1093, center frequency 5 MHz, CTS Valpey Corporation, Hopkinton, MA) facing each other with their axes aligned and operating in transmission mode. The whole device was immersed in water. First, a reference measurement was made in water without samples (V_{ref}). The bone sample to be tested was then placed over a gelatin block (agar) to keep it aligned between the transducers (Fig. 2).

Fig. 2 – Picture of the experimental set-up (left), and example of a reference signal (water) and ultrasonic wave through the bone sample.

The entire protocol was validated on bovine bone samples. We obtained $V_{11} = 3375 \pm 65$ m/s, $V_{22} = 3637 \pm 91$ m/s and $V_{33} = 3999 \pm 31$ m/s, in agreement with the literature (Lees et al., 1979; Lipson and Katz, 1984; Lasaygues and Pithioux, 2002).

2.3.2. Shear wave velocity measurement

Measurements were made with two transverse wave transducers (Panametrics V156, 5 MHz, Inc., Waltham, MA) facing each other with their axes aligned and operating in transmission mode. First, a reference measurement was made in a 5 mm thick aluminum sample. The bone samples to be tested were then placed in contact between the transducers (Fig. 3).

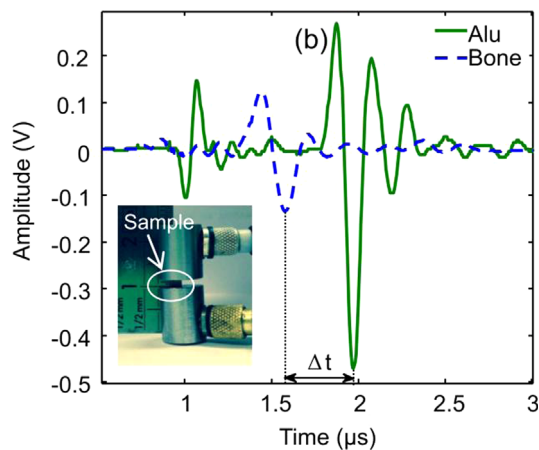

Fig. 3 – Picture of the experimental set-up (left), and example of a reference signal (aluminum sample) and ultrasonic wave through the bone sample.

2.4. Statistical analysis

Statistical analysis was performed using the SPSS program (SPSS Statistics 22, IBM, USA). The Shapiro–Wilk test was used to evaluate the normality of the distribution. A Pearson correlation was performed for normal distribution and a Spearman correlation was performed for non-normal distribution. The significance level is $p < 0.05$. The Wilcoxon rank-sum test was used to determine the difference between coefficients.

3. Results

Raw data are presented. All the values of ultrasonic wave velocities are presented in Table 1, with mean and standard deviation for each group. The relationships established above between the velocities and the stiffness coefficients of the material gave the C_{ij} coefficients summarized in Table 2. The mean values of elastic coefficients from our study are also compared with values from the literature (Table 2).

The elastic coefficients for adult fibulae are quite similar to those from the literature for femur and tibiae evaluated with ultrasonic methods (Ashman et al., 1984; Hoffmeister et al., 2000). Values from the children's bone, especially the femur, are lower than those from the adults. Due to the mean age gap of the two groups (resp. 12.9 ± 3.3 years.o for fibula and 3.6 ± 5.3 y.o for femur), we cannot compare fibula and femur values in these children. A significant correlation was found in the children's bone between all the stiffness coefficients and age ($R > 0.56$, $p < 0.01$). Moreover, the stiffness coefficients are all correlated ($R > 0.55$, $p < 0.01$). In the elderly adult bone, we only found a negative correlation between C_{33} and age ($R = -0.63$, $p < 0.01$).

No significant difference was found between C_{11} and C_{22} and between C_{44} and C_{55} , for either adult or child bone ($p > 0.5$), which confirms transverse isotropy with $C_{33} > C_{22} = C_{11} > C_{44} = C_{55} > C_{66}$. In both groups, we found no correlation between age and anisotropy ratios.

Fig. 4 shows the evolution of stiffness coefficients with age, revealing that stiffness coefficients increase in growing bone. Moreover, the effect of main direction is observed, with

the axial stiffness coefficient (C_{33}) 1/3 above radial and tangential values (respectively C_{11} and C_{22}).

Fig. 5 illustrates the evolution of the axial stiffness coefficient (C_{33}) with age. Depending on age range, the linear interpolation slope changes from positive to negative. A Spearman correlation was found between age and C_{33} ; in the children's bone, we obtained a positive value ($R = 0.694$, $p < 0.01$) whereas in the elderly adult bone, we obtained a negative value ($R = -0.634$, $p = 0.08$).

Fig. 6 represents the evolution of anisotropy ratios with age. In both groups, we found no correlation between age and anisotropy ratios.

4. Discussion

The first aim of the study was to determine and to compare stiffness coefficients in children's and elderly adults' cortical bone samples. The method we used is based on measuring both compressional and shear ultrasonic bulk wave velocities (BWV) propagating along various directions of a bone specimen (Lang, 1969). While this method is widely used, it has major drawbacks related to specimen size and geometry. With a range frequency of 1–2.5 MHz, the specimen must typically be larger than a few millimeters (~ 5 mm). This is because measured wave velocities must be linked to bulk waves, which propagate when the wavelength is smaller than the dimension of the specimen (Ashman et al., 1984). In this study, samples were machined from fibulae whose cortical thickness was below 3 mm. By improving the cutting process so as to avoid any lack of parallelism, we finally obtained specimens of approximately $2 \times 2 \times 2$ mm³. For both compressional and shear wave velocity measurements, we used a frequency of 5 MHz to achieve a wavelength greater than the typical size of bone tissue heterogeneities ($< a$ few hundred microns) and smaller than the specimen dimensions. Another limitation of this study was that only elastic constants for the main diagonal of the stiffness tensor could be evaluated. It takes one or several 45° oblique cuts to retrieve all non-diagonal terms of the stiffness tensor, which was not technically possible with our specimen size. This prevented conversion of the elastic stiffness coefficients into engineering coefficients (Young's moduli, shear moduli and Poisson's ratios).

The longitudinal stiffness coefficients (C_{11} , C_{22} and C_{33}) generally found for adult cortical bone with the ultrasonic method range between 16.8 GPa and 31.7 GPa (Ashman et al., 1984; Bernard et al., 2013; Espinoza Orías et al., 2009; Hoffmeister et al., 2000). However, these values were for femur or tibia bone; to our knowledge, no value for the fibula is available. These results on adult fibulae therefore contribute a new batch of data and allow us to compare adults' and children's values for the same bone from the same anatomic location. The results on children's bone enrich the literature concerning the mechanical properties of children's bone. Our findings show that stiffness coefficients increase with age up to puberty, when they appear to reach adult values (Fig. 4). The evolution of C_{33} with age shows a linear regression by age group, positive in the children and negative in the adults (Fig. 5). This trend is similar to the evolution of the bone

Table 1 – Ultrasonic wave velocities (compressional and shear) for all directions.

mineral density with age (Bonjour, 1998; Boot et al., 2010). An *in vivo* study by Drozdowska and Pluskiewicz (2003) assessed the speed of sound (SOS) at the hand phalanx in a population of people aged from 7 to 80. The authors conclude that the SOS increases linearly to a maximum reached at around 25–30 years old, after which values decrease more slowly up to the age of 80. These data differ from ours because the *in vivo* approach introduces the effect of soft tissue and bone geometry. Moreover, the study was performed on the hand phalanx, which is not mechanically stressed. Nevertheless, even with the gap in age coverage between our studies (our population being children of 1–18 and adults of 50–95), our *in vitro* results exhibit the same trend as their *in vivo* study.

The second aim of this study was to analyze the anisotropic behavior of our samples. The results for all specimens show transverse isotropy for both adult and child bone, and both fibula and femur, at the location tested. Several studies point to the fact that ultrasonic wave velocity measurement relies on anatomical location. It has been suggested that ultrasonic wave velocity depends on the circumferential location (Bensamoun et al., 2004; Rho, 1996). Rudy et al. (2011) showed that anisotropy depends on the location along the bone: their tissue specimens, pooled from multiple donors, exhibited orthotropy at all locations along the femoral diaphysis and transverse isotropy at mid-diaphysis. In this study, samples were extracted from the lower 1/3 of the bone, which does not explain the transverse isotropy.

Anisotropy in cortical bone can be explained by multiple factors. Bone material properties depend on microscopic-scale components such as hydroxyapatite crystals and collagen (Hasegawa et al., 1994; Burr, 2002; Currey, 2003; Follet, 2004; Boivin et al., 2008), and their layout, as confirmed experimentally in a study showing that ultrasonic velocity is influenced by changes in organic matrix (Mehta et al., 1998). Katz et al. (1984) argued that orthotropic versus transversely isotropic symmetry was dependent on whether the tissue exhibited a predominately laminar or Haversian microstructure, respectively. According to Baumann et al. (2012), transverse isotropy is governed primarily by apatite crystal orientations while orthotropy is governed primarily by intracortical porosity. While our study did not investigate any of these factors, further exploration would enrich our knowledge of the anisotropy of bone.

In conclusion, this study contributes a new set of ultrasonic wave velocities and elasticity values for children's cortical bone, providing insights into the evolution of stiffness coefficients with age. Moreover, it offers the first complete analysis of stiffness coefficients in the three orthogonal bone axes in children, giving some indication of how bone anisotropy is related to age. Future perspectives include studying the effect of the structure and composition of bone on its mechanical behavior.

Acknowledgments

This research is supported by the French National Research Agency (ANR MALICE Program, under Grant no. BS09-032). We thank the Timone Hospital surgery team and the donors or their legal guardians who gave informed written consent to

providing their tissues for investigation, in accordance with the French Code of Public Health (Code de la Santé Publique Française) and approved by the Committee for the Protection of Persons. This work has benefited from the help of Marine LOUBET for the setting up of experiments. We thank Marjorie SWEETKO for English language revision.

Cortical porosity

Growth

ABSTRACT

Cortical porosity is a major determinant of bone strength. Haversian and Volkmann's canals are 'seen' as pores in 2D cross-section but fashion a dynamic network of interconnected channels in 3D, a quantifiable footprint of intracortical remodeling. Given the changes in bone remodeling across life, we hypothesized that the 3D microarchitecture of the cortical pore network influences its stiffness during growth and ageing.

Cubes of cortical bone of 2 mm side-length were harvested in the distal 1/3 of the fibula in 13 growing children (mean age \pm SD: 13 ± 4 yrs) and 16 adults (age: 75 ± 13 yrs). The cubes were imaged using desktop micro-CT ($8.14 \mu\text{m}$ isotropic voxel size). Pores were segmented as a solid to assess pore volume fraction, number, diameter, separation, connectivity and structure model index. Elastic coefficients were derived from measurements of ultrasonic bulk compression and shear wave velocities and apparent mass density.

The pore volume fraction did not significantly differ between children and adults but originates from different microarchitectural patterns. Compared to children, adults had 42% ($p=0.033$) higher pore number that were more connected (Connective Density: +205%, $p=0.001$) with a 18% ($p=0.007$) lower pore separation. After accounting for the contribution of pore volume fraction, axial elasticity in traction-compression mode was significantly correlated with better connectivity in growing children and with pore separation among adults.

The changes in intracortical remodeling across life alter the distribution, size and connectedness of the channels from which cortical void fraction originates. These alterations in pore network microarchitecture participate in changes in compressive and shear mechanical behavior, partly in a porosity-independent manner. The assessment of pore volume fraction (i.e., porosity) provides only a limited understanding of the role of cortical void volume fraction in its mechanical properties.

1. Introduction

Human cortical bone displays a multiscale porous architecture originating from optimization to contradictory needs. Bone has to be stiff and strong to resist loading but light to allow mobility (Bala et al., 2015; Seeman and Delmas, 2006). During last decade, cortical porosity has emerged as a major predictor of bone strength (Baron et al., 2007; McCalden et al., 1993) and fragility fracture (Bala et al., 2014b, 2015; Bjornerem et al., 2013). The cortical void volume fraction contributes to bone mechanical behavior because the apparent density (inverse of porosity) is inversely proportional to the 7th power of its stiffness (Schaffler and Burr, 1988).

Cortical bone void volume originates from Haversian and Volkmann's canals that contain bone vasculature and innervation. While these canals are 'seen' as pores in cross-section images (Chappard et al., 2013; Thomas et al., 2006), they form a three dimensional network of interconnected canals (Chappard et al., 2013; Cooper et al., 2007). The structure of this porous network is not static; the number of canals, their diameter, and their connectedness are the quantifiable footprints of the bone remodeling activity and balance (Cooper et al., 2007).

During growth, the skeleton adapts its size, shape and material properties to be of sufficient strength to support the evolving physical activity (Currey and Butler, 1975; Jee and Frost, 1992; Loro et al., 2000; Palacio-Mancheno et al., 2014; Parfitt et al., 2000). Histomorphometric studies highlighted that this adaptation was made possible through changes in modeling and remodeling activity and its balance at both the tissue and the Bone Multicellular Unit (BMU) level (Parfitt et al., 2000; Rauch et al., 2007). For instance, from 2 to 20 years, the thickening of the cortex is determined by a net positive balance at the tissue level between endocortical resorption and periosteal formation (Rauch et al., 2007). In this age range, intracortical remodeling activation frequency decreases and displays a $\sim 5\%$ positive balance at BMU level reducing intracortical porosity and participating to bone consolidation (Parfitt, 1994b, Parfitt et al., 2000).

During young adulthood, remodeling is slow and in steady-state at the tissue-level - the number of Bone Multicellular Units (BMU) resorbing bone equals the number of BMU refilling cavities excavated earlier at other locations. At the level of the BMU, remodeling is balanced - each BMU resorbs and deposits similar volumes of bone matrix. At this stage there is little or no bone loss or structural decay in cortical bone (Bala et al., 2014a; Compston, 2011). After midlife in women and later in men, a rapid extent of remodeling surfaces at the tissue level coupled to a $\sim 5\%$ negative balance at the BMU level, increases pore number and diameter resulting in an overall higher cortical void volume fraction and permanent bone loss (Bjornerem et al., 2011; Lips et al., 1978; Qiu et al., 2010; Recker et al., 2004; Vedi et al., 1983). This has been repeatedly observed using 2D histomorphometry (Lips et al., 1978; Rauch et al., 2007; Schnitzler, 2015; Schnitzler and Mesquita, 2013; Schnitzler et al., 2009; Zebaze et al., 2010). However, the structural changes in pore network 3D microarchitecture beyond these alterations in the void volume fraction are not known.

Recent studies suggest that porosity achieved during growth may influence intracortical remodeling and structural decay later in life (Bala et al., 2014b; Bjornerem et al., 2013; Bui et al., 2013; Loro et al., 2000; Seeman, 2008). Haversian and Volkmann's canal density, size and connectivity in young adult defines indeed the extent of surfaces available for unbalanced remodeling to be initiated upon at the onset of age-related perturbation at the BMU level (Bui et al., 2013). However, porosity is only regarded as a single value describing void volume fraction and may not be sufficient to predict entirely the influence of microstructure on cortical bone fragility (Chappard et al., 2013; Yeni et al., 1997; Yeni and Norman, 2000). There is most likely a contribution of age-related structural changes in pore network microarchitecture but these parameters, especially in growing bone, are rarely investigated.

Given the age related-changes in bone remodeling activity and balance across life, we hypothesized that cortical bone void volume fraction originates from canals networks with different microarchitectures in growing children and adults. This study also aimed to evaluate comprehensively the impact of the canal network microarchitecture on cortical bone elasticity. We tested these hypotheses in human cortical bone samples collected in the distal fibula of growing children and ageing adults. Pore number, diameter, connectivity and other morphological parameters of the cortical void volume were quantified using micro-CT. These variables were compared to the elasticity assessed in the same samples using ultrasonic bulk wave velocities in the three principal directions of bone. Understanding the contribution of pore volume fraction and pore network microarchitecture to bone mechanical properties during growth and ageing may help in finding early predictors of bone fragility.

2. Material and methods

2.1. Specimens

Bone samples were collected in the distal 1/3 of the fibula in 13 children (9 males and 4 females, mean age \pm SD: 13.2 \pm 3.5 years, range: 6–18 years) during corrective surgery after a fracture at the growth plate or equinovarus of the foot ($n=2$). Equinovarus of the foot is apparently not associated with alterations in bone remodeling parameters (Rauch et al., 2007). Surgeries were performed at the Timone Hospital (Marseille, France). All children were ambulatory prior to surgery and none received medications known to affect bone remodeling. In accordance with the French code of public health and after approbation of the study by the committee for the protection of persons, informed consents were obtained from children's legal guardians. In addition, bone samples were harvested in the distal 1/3 of the fibula from 16 human donors (7 males and 9 females, mean age \pm SD: 75.0 \pm 12.9 years, range: 50–91 years). Autopsies were performed between 2010 and 2012 under the guidance of the INSERM UMR-S 1033 (Lyon, France) and the IFSTTAR UMR-T 9406 (Bron, France) in order to build a bone sample bank. Samples were maintained frozen at -20°C wrapped in Phosphate Buffer Saline soaked gauze. Twenty-nine 2x2x2

Fig. 1 – From left to right, bone cubical samples were cored from the distal fibula and oriented according to the radial (1), circumferential (2) and axial (3) axes for assessment of the elastic coefficients by ultrasound and pore network architecture using micro-CT.

mm cubic samples were extracted from the cortex using a water-cooled low speed diamond saw (Buehler Isomet 4000, Buehler, Lake Bluff, IL, USA). All cubes included the periosteal region and the 2 mm thickness permitted to avoid the highly ‘trabecularized’ endosteal region in samples from elderly. The regions of coring were matched by the quadrant and the fraction of bone length between children and adults. Cubes faces were identified according to the radial (axis 1), tangential (axis 2) and axial (axis 3) orientations in the fibula (Fig. 1).

2.2. Image acquisitions

The cubic samples were imaged using a desktop micro-CT system (Skyscan 1174, Bruker, Kontich, Belgium). Scanning was done with the bone specimen immersed in distilled water in a 6 mm inner diameter plastic tube and held in place thanks to gauze. Sample axial axis (i.e., Haversian canals' principal orientation) was aligned to the rotation axis of the sample holder. Scans were performed with a field of view of 1024×1024 pixels a source voltage 50 kV, current 800 μ A, rotation step 0.6° over a 360° rotation and a 0.5 mm-thick aluminium filter for beam hardening reduction. An isotropic voxel size of $8.14 \mu\text{m}$ was used with an exposure time of 4 seconds, 2 frames averaging leading to a total scan time of 82 minutes for each sample. The images were reconstructed using a filtered back-projection algorithm (NRecon software, V 1.6.9, Skyscan NV, Kontich, Belgium). For each cube, a stack of 210 sections was reconstructed.

2.3. Morphometric analysis

From the stack of contiguous reconstructed images, the volumes of interest were selected for morphometric analysis using a semi-automated method (CTAnalyser Software V 1.14.4, Skyscan NV, Kontich, Belgium). For each specimen,

the external borders were contoured by the operator and then automatically interpolated over the axial axis defining the volume of interest (VOI). Within the tissue volume (TV, mm^3), the porosity (void volumes) was segmented as a solid and the mineralized bone as a background by using global thresholding. Calibration was performed using a phantom of hydroxyapatite rods, a cut-off of 0.79 g/cm^3 was chosen after observation of several reconstructed images from samples spreading the whole age-range. The following morphometric variables were calculated: the pore volume fraction (Po.V/TV, %), the pore surface to pore volume ratio (Po.S/Po.V, $1/\text{mm}$). Pore diameter (Po.Dm, μm) corresponding to the average diameter of the pores and pore separation (Po.Sp, μm) corresponding to the average separation between pores were both calculated using a sphere-fitting algorithm (Hildebrand and Ruegsegger, 1997; Ulrich et al., 1999). As an index of heterogeneity in the intra-individual distribution of pore size and separation, the standard deviation of Po.Dm and Po.Sp are reported as Po.Dm.SD and Po.Sp.SD both expressed in μm . The pore number (Po.N, $1/\text{mm}$) was calculated as: $\text{Po.N} = 1/(\text{Po.Sp} + \text{Po.Dm})$. Connectivity (ConnD, $1/\text{mm}^3$) was evaluated by the Euler characteristic according to the method detailed by Odgaard (1997) and normalized by the TV. We also assessed the pore pattern factor (Po.Pf in analogy with the trabecular pattern factor, $1/\text{mm}$) calculated as the ratio of volumes and surfaces before and after dilation. Lower Po.Pf indicates higher concavity i.e., better-connected pore network.

2.4. Ultrasound based measurement of bone elasticity

Bone elasticity was determined using a well-established method based on the measurements of ultrasonic bulk compression and shear wave velocities and sample apparent mass density (Espinoza Orias et al., 2009; Granke et al., 2011). This method provides measurements of the elastic properties in the

Table 1 – Values of microstructural parameters of the pore network and elastic coefficients. P-values for group comparison were obtained using Man-Whitney's U test. Bold font denotes p -values ≤ 0.05 .

	Children (5–18 yrs) Mean (SD)	Adults (50–91 yrs) Mean (SD)	P-Value
Po.V/TV (%)	10.3 (6.5)	15.9 (10.3)	0.151
Po.S/Po.V (1/mm)	40.5 (15.9)	37.7 (13.4)	0.628

C66	3.0 (0.4)	3.6 (1.0)	0.017

three principal directions of a same bone material volume. The apparent mass density (ρ , g/cm³) was measured with a micro-metric balance equipped with a density kit (Voyager 610, Ohaus Corporation, FlorhamPark, NJ, USA, measurement uncertainty of 0.001 g/cm³) and the dimensions were measured with a digital caliper (Absolute digimatik solar, Mitutoyo, Kanagawa, Japan, measurement error of 0.03 mm). Taking into account average values of mass densities, determined during the experiments, equal to 1700 kg/m³, we obtain a relative error of 0.06%. For Time-Of-Flight measurements, uncertainties are of around 0.02 μs , given by the laboratory test apparatus/electroacoustic device (Eurosonic, Vitrolles, France). Given the apparent density ρ , the diagonal terms C_{ij} ($1 \leq i \leq 6$) of the elastic tensor are calculated from:

$$C_{ii} = \rho \cdot v_{ii}^2 (i = 1, 2, 3)$$

$$C_{44} = \rho \cdot v_{23}^2 = \rho \cdot v_{32}^2$$

$$C_{55} = \rho \cdot v_{13}^2 = \rho \cdot v_{31}^2$$

$$C_{66} = \rho \cdot v_{12}^2 = \rho \cdot v_{21}^2$$

where the longitudinal elastic coefficients C_{11} , C_{22} , and C_{33} represent the stiffness in traction-compression mode, C_{44} , C_{55} , C_{66} represent the shear stiffness coefficients (Fig. 1). Velocity v_{ij} denotes velocity of a wave propagating in the i direction, with particle motion in the j direction. For compressional waves, $i=j$, and for shear waves, $i \neq j$. Compressional and shear waves velocities were measured using a pulse transmission method with a pair of 5 MHz transducers (VP1093, CTS Valpey Corporation, Hopkinton, MA, USA for compressional waves and Panametrics V156, Inc., Waltham, MA, USA for shear waves). The received signal was post-processed with a custom MatLab program (The Mathworks Inc., Natick, MA, USA) (Lefevre

et al., 2015). Repeated measurements on a set of same samples revealed a good reproducibility for the stiffness with coefficient of variation ranging between 0.8% and 2.5% depending on the coefficients.

2.5. Statistics

Data are reported as mean \pm SD unless otherwise stated. As our population is composed of growing children and ageing adults, all analyses were performed separately in the two groups and not on the pooled population. Statistical analyses were performed using SPSS 20.0 (IBM, Amonk, NY, USA). Normality was tested using Shapiro-Wilk procedure. Most of the variables were not normally distributed, non-parametric test were consequently used. Differences between groups were tested using Mann-Whitney U test. Bivariates correlations between morphometric variables and age were tested by the Spearman's rank correlation test (r'). Correlations between morphometric variables and elastic coefficients were calculated with or without accounting for the contribution of the pore volume fraction. A two-tailed significance level of 0.05 was used.

3. Results

3.1. Pore volume fraction originates from different microarchitectures in children and adults

The pore volume fraction (Po.V/TV) did not significantly differ between growing children and adults but originated from different microarchitectural pattern (Table 1). Relative to children, adults had a higher pore number (Po.N: +42%) and connectivity density (ConnD: +205%), a lower pore separation (Po.Sp: -18%) and intra-individual distribution of separation (Po.Sp.SD: -20%). In accordance with a higher ConnD in adults, Pore pattern factor tended to be lower in adults compared to children but the difference did not reach significance level (Po.Pf: -19%, $p=0.076$) (Table 1).

Table 2 presents the correlation coefficients obtained between the age and the parameters of the pore network microarchitecture. Among growing children, increasing age was negatively correlated with Po.V/TV. This decrease in the pore volume fraction was associated with a decrease in Po.N, Po.Dm and an increase in Po.Sp. Between 5 and 18 years old there was also a positive correlation between age and the specific surface of the pore (Po.S/Po.V). As expected, among adults, increasing age between 50 and 91 years old was correlated with higher Po.V/TV. This increase in pore volume fraction was associated with an increasing Po.N and a decreasing Po.Sp (Fig. 2).

3.2. Pore network microarchitecture contributes to cortical bone elasticity

Despite the differences in pore network microarchitecture, cortical bone from both children and adults were both transversely isotropic (with $C_{33} > C_{11} = C_{22}$ and $C_{44} = C_{55} > C_{66}$). However, relative to children all elastic coefficients were higher in adults (+11%, +17% and +22% for C_{11} , C_{22} and C_{33} , respectively,

and +17%, +23% and +20% for C_{44} , C_{55} and C_{66} , respectively) (Table 1).

Among growing children, increasing age was associated with increasing elastic coefficients in traction-compression. In adult group, increasing age was associated with lower elastic coefficients in traction-compression mode. Correlation between age and shear elastic coefficients did not reach statistical significance in both groups (except for C_{44} in adult group, $r' = -0.70$) (Table 2).

Table 3 reports the correlation coefficients obtained between the elastic coefficients and the parameters of the pore network microarchitecture. Among the children samples, the C_{33} elastic coefficient (i.e., axial traction-compression) was negatively correlated with Po.V/TV, Po.N and Po.Dm (r' from -0.46 to -0.82) and positively Po.S/Po.V, Po.Sp and Po.Pf (r' from 0.48 to 0.88). Similar results were obtained with

C_{66} (transverse shear). The positive correlation between C_{33} and Po.Pf remained significant after adjustment for Po.V/TV (r' -adjusted=0.52, $p=0.020$). In the adult group, C_{33} was negatively correlated with Po.V/TV ($r' = -0.63$) and Po.N ($r' = -0.59$) and positively with Po.Sp ($r' = 0.71$) and Po.Sp.SD ($r' = 0.72$). No correlation was observed between C_{66} and pore network microarchitecture. When accounting for the contribution of Po.V/TV, the correlation between C_{33} and Po.Sp and Po.Sp.SD remained significant (r' -adjusted=0.56, $p=0.007$ and r' -adjusted=0.70, $p=0.001$, respectively).

4. Discussion

To our knowledge, the present study is the first to evaluate the 3D-microarchitecture of the pore network in both children and adults in appendicular skeleton. In site- and size-matched samples of compact-appearing cortex, we report that cortical porosity originates from different canal network microarchitectures in growing children and adults. Growth was associated with a decrease in cortical void volume fraction due to a decrease in pore diameter, pore number and pore connectivity. On the opposite, in adults, ageing was associated with an increase in void volume fraction related to an increase in pore number and pore connectivity, not in pore size. Within the limitations of a small sample size that may result in low statistical power to detect statistical significance for some differences, our data support that elastic properties are influenced by pore network microarchitecture even after accounting for void volume fraction contribution, suggesting an independent contribution.

4.1. Pore network microarchitecture during growth

During growth, long bones increase in width by periosteal apposition (modeling formation) and endocortical resorption (modeling resorption) and in length by endochondral ossification (Cadet et al., 2003; Enlow, 1962; Rauch, 2012). At the same time, bone also undergoes Haversian remodeling to adapt to the mechanical environment and to face the increasing need in calcium (Parfitt, 1994b; Parfitt et al., 2000). Our knowledge of growth-related changes in cortical

porosity has been nurtured by histomorphometric studies performed in iliac crest samples limiting comparison with present results. Most of these studies reported a high porosity in children principally originating from large asymmetrical drifting osteons (Schnitzler and Mesquita, 2013). In this set up, bone resorption not only progresses in the cutting cone forming a round and narrow canal in the matrix, but also toward the endosteal surface. In these units, the onset of bone formation appears to be delayed forming canals up to 30 times larger than common cutting cones (Robling and Stout, 1999; Schnitzler and Mesquita, 2013). Later when growth slowdowns, these asymmetrical osteons are replaced through remodeling by smaller symmetrical concentric osteons (Parfitt, 1994a; Schnitzler, 2015; Schnitzler and Mesquita, 2013).

We propose that the age-related decrease in void volume fraction we observed might also be due to the replacement of large drifting osteons by smaller symmetrical osteons. Our bone samples were not evaluated by histomorphometry. However, in the context of this study, we collected fibula samples from a 6 years old and 16 years old boys and imaged them using microradiography (Montagner et al., 2015). The resulting images supported our statement and suggested a transition from large asymmetric drifting osteons to smaller symmetric osteons during growth at the fibula (Fig. 3). Growth has been associated with an age-dependent decrease in remodeling frequency. Rauch et al. indeed highlighted a fall in the percentage of active osteons from ~70% at 5 years old to ~20% at 20 years old (Rauch et al., 2007). These mechanisms contract the remodeling space consolidating bones (Parfitt et al., 2000; Schnitzler et al., 2009).

In the present study, the consolidation of the cortical bone (i.e., suggested by an increase in C₃₃) was not only associated with the decrease in porosity but also with an increase in the pore pattern factor. This suggests that in growing children, the age-related decrease in pore network connectivity also increases stiffness in axial direction. However, as observed for most of the variables describing pore network

microarchitecture, correlations were stronger with the elastic coefficients corresponding to the tension-compression mode than in shear. This may indicate that shear elasticity is more sensitive to different parameters of cortical structure other than porosity or material properties. Indeed, several *ex vivo* studies show alterations of bone tissue structure and composition at the micro- and nano-scale during growth. Akkus et al. suggested that the remaining fraction of primary lamellar bone continues to mature as they observed an increase in mineral particles size and an improvement in its crystallinity between 17 and 25 years (Akkus et al., 2003). Saito et al., described also age-related changes in average collagen enzymatic cross-linking profile with a transition from the immature forms to mature ones (Saito and Marumo, 2010). All these parameters of bone quality are known determinants of bone mechanical behavior in human adults and in animal models (see (Bala and Seeman, 2015; Ural and Vashishth, 2014) for reviews). Finally, it has been shown in rats cortical bone that Young's and shear moduli derived from ultrasounds were not determined by the same physicochemical properties. For instance, shearing was influenced by crystal size while elasticity was principally determined by apparent density (Kohles and Martinez, 2000). Taken together, these results suggest that cortical shear and tensile-compressive stiffness may not be similarly sensitive to growth-related changes in microstructure and material composition.

4.2. Pore network microarchitecture during aging

We observed an increasing void volume fraction with age. In our experimental set up, higher pore number, not higher pore diameter, accounted for the most of the higher void volume fraction in older subjects. While this is consistent with some earlier works by Kerley (1965) for instance, this seems in contradiction with the repeated observation that most of the age-related increase in porosity can be explained by an increase in pore area, not in pore number (Cooper et al.,

Fig. 3 – Microradiographs of fibula cortical bone cored in the same quadrant from a 6 years old (left panel) and a 16 years old (right panel) boy. White arrows highlight large asymmetric drifting osteons, dark grey arrows highlight smaller symmetric osteons.

2007; Perilli et al., 2015; Thomas et al., 2006). This apparent discrepancy may be explained by the variability in the localization of the VOIs analyzed among the studies. Indeed, the age-related changes in void volume fraction are highly heterogeneous in the bone cross-section and through the thickness of the cortex (Keshawarz and Recker, 1984; Perilli et al., 2015; Zebaze et al., 2010). A recent study by Perilli et al. reported in human subtrochanteric cortical bone that both higher pore number and size accounted for higher void volume fraction in older subject in medial and lateral regions. In the anterior region, the pore diameter, not the pore number, was higher in older subjects compared to the younger ones (Perilli et al., 2015). Across the cortical thickness, with increasing age, bone remodeling becomes particularly vigorous in the inner part of the cortex, the closest to the medullary cavity (Zebaze et al., 2013; Zebaze et al., 2010). In this region, pores not only enlarge focally because of the negative balance, but also coalesce resulting in giant pores and most likely in a local decrease in pore number. This creates a gradient in pore size from the periosteum to the endosteum (Bell et al., 1999; Bell et al., 2001; Chappard et al., 2013; Zebaze et al., 2010).

In the current study, we extruded small cubical samples of compact-appearing cortex excluding the cortico-trabecular junction with its giant pores. In our VOIs, we propose that age related increase in porosity principally originates from an increase in pore number, modestly from an increase in pore size. Indeed, the negative bone balance at the BMU level responsible for canals enlargement is only ~5%; 95% of the bone removed by osteoclasts is refilled representing a deficit of a few microns in regard of the osteonal wall width - a difference unlikely to be detectable using an 8.14 μm voxel size (Qiu et al., 2010). An increase in the number of canals in these confined VOIs suggests an excavation of new canals. This increase in pore number perhaps originates from

remodeling initiated upon surfaces of existing BMUs and their branching (Maggiano et al., 2016) or within osteocyte lacunae (Perilli et al., 2015). Indeed, many studies suggest that osteocytes are key regulators of osteoclasts and osteoblasts activities but also may be able to locally remodel the perilacunar bone matrix (Atkins and Findlay, 2012; Bonewald, 2011; Qing et al., 2012; Teti and Zallone, 2009). However, knowing whether new canals can emerge from, or under the control of osteocytes activity needs further research. In addition to increasing the cortical void volume fraction, the excavation of new canals incidentally decreased the average separation between them and that correlated with a lower axial elasticity in traction-compression mode.

It is well documented that the age-related increase in porosity originating from alterations in intracortical remodeling is detrimental for bone strength (Bala et al., 2015; Granke et al., 2011; McCalden et al., 1993). At the tissue level (i.e., mesoscale), variations in cortical porosity explained from 62 to 98% of the variation in compression-tension and shear elastic coefficients (Dong and Guo, 2004; Granke et al., 2011). At the organ level (i.e., macroscale), variations in porosity, explained the majority of the variation in long bones mechanical properties in several human and animal models (Baron et al., 2007; Bousson et al., 2006; Granke et al., 2011; Yeni et al., 1997). However, in these studies, porosity was only regarded as a fraction of void volume and therefore did not provide information about the role of pore network micro-architecture in bone mechanical behavior.

In our population, we noticed that in elderly men and women, changes in pore separation and pore separation intra-individual distribution were correlated with axial tensile-compressive elasticity after accounting for void volume fraction. This new result suggests that for a given porosity, the way this void is fashioned in the bone volume affects significantly bone elasticity. In addition, our results

also displayed that shear elastic coefficients C_{55} and C_{66} were less sensitive to porosity and pore network microarchitecture among adults than observed among growing children. As bone anisotropy is influenced by material properties and structural properties (including osteonal morphology), this could reflect that bone anisotropy may emerge from relatively different structural and compositional variables across life.

Indeed, during growth and ageing the changes in cortical remodeling activity, balance and their consequences on pore network architecture are very distinct. However, with bone tissue age as well as individual's age, matrix properties also vary affecting tissue stiffness. During the last decade, the study of the so-called bone quality or we should say bone qualities has revealed that bone matrix stiffness was also a function of bone mineralization, bone mineral characteristics (crystallinity, maturity, carbonation), arrangement, maturity and cross-linking profile of bone collagen fibrils, all these properties varying with age of both the tissue and the individual (Bala and Seeman, 2015; Malo et al., 2013). The fact that the age-related changes in elastic coefficients are likely multifactorial, with changing in both cortical structure and matrix properties are likely to be the reason why the relationships between some pore network architecture and elastic coefficients were opposite in the present study (e.g., for Po.Sp.SD). Consequently, our understanding of the bio-mechanical impacts of changes in void volume fraction during pathology or treatments is only a partial improvement in the prediction of bone elasticity using bone imaging and computational modeling of the cortex may need to further consider pore network microarchitecture and regional heterogeneity (Granke et al., 2011; Hellmich et al., 2004). Studying the relative contributions of structural and material properties in age-related changes in mechanical properties will be the very objective of our future studies.

4.3. Strengths and limitations

A strength of the study was the use of a high-resolution imaging modality combined with relevant image processing in assessing bone microstructure *in vitro*. In addition, assessments were performed in site-matched samples of a long bone in growing children and adults. This study is the first to offer an analysis of the 3D microarchitecture of the pore network in growing children in a long bone. Indeed, our knowledge of growth-related changes in cortical porosity comes from histologic studies in iliac crest samples, an irregular and non-load-bearing bone site that rarely fractures (Rauch et al., 2007; Schnitzler, 2015; Schnitzler and Mesquita, 2013; Schnitzler et al., 2009). In addition, elasticity has been evaluated based on the assessment of ultrasonic bulk wave velocities. While this method has been largely used for investigation of bone mechanical properties, it is non-ionizing, non-destructive and provides both axial and one of the few with Resonant Ultrasound Spectroscopy to allow the assessment of shear elastic properties in the three principal directions of bone (Ashman et al., 1984; Espinoza Orias et al., 2009; Granke et al., 2011; Bernard et al., 2013; Remilleux et al., 2015). In addition for such small dimensions, direct mechanical testing are complicated to realize and interpret.

The first limitation of our study was the sample size that precluded the analysis of the sex- and pubertal stage-related differences in the trends we reported with age in both children and adults groups. Bone microarchitecture is known to vary with age with different chronologies in male and female during bone growth or aging (Chen et al., 2010; Khosla et al., 2006; Wang et al., 2010). The trends described in the current paper are coherent with the known age-related changes in bone remodeling and its balance at the BMU level, though. Second, our analyses were performed on VOIs of relatively small size (cubes of 2mm-sides) and consequently were blind to the porosity gradient along the cortical thickness that appears due to the trabecularization of the cortex with ageing. Therefore, it may remain complicated to generalize those results to what happen in different ROIs. However, despite limited to the compact-appearing cortex, our results are relevant in regard of bone strength because the VOIs were the farthest from the neutral axis, i.e., where the effect of bone porosity on strength is at maximum in a bone submitted to bending (Burr, 2010). Third, we used a polychromatic cone-beam micro-CT device, incidentally submitted to beam-hardening. However due to the small size of our specimens and the use of an aluminum filter that reduces beam hardening artefact, no correction was necessary. Fourth, it has been observed that most of the architectural parameters are inter-correlated (Chappard et al., 2013) and may result in multicollinearity. Unfortunately, using non parametric statistics it was not possible to statistically evaluate for potential collinearity among variables. Finally, while pediatric samples were included in our study based on the literature's definition of 'reference' for this very population (Rauch et al., 2007), we acknowledge that they were cored following orthopedic issues and results need to be interpreted with cautious.

5. Conclusion

In conclusion, within the limitation of a small sample size, we infer that during both growth and ageing, changes in pore network microarchitecture, that reflects activity and balance of remodeling upon canals surfaces, contributes to cortical bone stiffness. Alterations in this microarchitecture may impact cortical bone mechanical properties independently of the changes in the void volume fraction. While cortical porosity is a strong determinant of bone elasticity, further considering how this void volume fraction is fashioned will improve our ability to predict the changes in strength associated with pathologies and treatments.
